In other cases it happens that, when rupture of the sac takes place, the effused blood, instead of being limited by the surrounding cellular tissue, becomes suddenly and widely extravasated into the substance of the limb. When this untoward accident happens, the shock and local disturbance are very great, and the patient is suddenly seized with a very severe lancinating and numbing pain in the part. This pain is most severe in those cases in which the rupture takes place under the deep fascia, by which the effused blood is tightly bound down; and it may be so severe as to occasion syncope. In other instances, faintness occurs from the sudden loss of blood out of the current of the circulation into the substance of the part, the swelling being greatest in those instances in which the blood is suddenly and largely effused into the cellular tissue. If the extravasation happen in a limb, this will become greatly swollen, hard, brawny, and cold. The superficial veins are congested, and the circulation in the lower parts of the member is soon completely arrested by the pressure of the extravasated and semi-coagulated blood upon its vessels, more particularly the large venous trunks. In some

sequence of this, gangrene of a moist kind usually makes its appearance, and speedily destroys the patient's life.

DIAGNOSIS.—The diagnosis of aneurism may in many cases be effected with the greatest possible ease by a student in surgery; in other instances it requires a vast amount of care, and the most experienced judgment, to come to a correct conclusion as to the nature of the tumour. This is easily done when the aneurism is superficial, recent, and circumscribed, the blood in it being fluid, and all the signs of the disease well marked. The diagnosis is often replete with difficulty when the aneurism is deeply seated, or, if external, when it is old and filled with coagula; also if suppurative action have taken place about it, or if it have become diffused.

In effecting the diagnosis of aneurism we have, in the first place, to ascertain the existence or absence of a tumour; and, after this has been done, to ascertain whether it be aneurismal or of some other character. Both points, the latter especially, are difficult to determine in internal aneurisms; in the external, the doubt is not as to the presence of a tumour, but as to its nature. The tumours with which aneurisms may be confounded may conveniently be divided into two classes—those that do and those that do not pulsate.

Every pulsating tumour is not an aneurism. Thus there may be pulsation in various kinds of *encephaloid tumour*, or in *growths composed of erectile tissue*. In such cases as these, many of the signs of aneurism are present; thus the size of the tumour may be diminished by compression, and the distinct influx of blood into it may be felt on the removal of the pressure, the tumour returning to its original size with a soft swelling pulsation. There may also be a bruit, often of a loud and distinct character. But these tumours may generally be distinguished from aneurisms in not being quite so distinctly circumscribed—in being soft, spongy, and elastic, without the sensation of fluid that is met with in some forms of aneurism, or of solid coagula that occurs in others. Again, the bruit is either of a soft, blowing, and more prolonged character, or else sharp and superficial; the pulsation, also, is not so distinct, and is more of the nature of a general swelling and heaving of the tumour than of a distinct thump. Much light is also occasionally thrown upon these affections by their being met with in situations where aneurism cannot occur from the absence of any arteries of sufficient size to give rise to it, as, for instance, on the head of the tibia or the side of the pelvis; but if a tumour of this kind be situated upon or under a large artery in the usual site of an aneurism, then the diagnosis is certainly replete with difficulty, and cannot indeed in many cases be made. Several instances have of late years occurred, in which surgeons of the greatest skill and experience (as Guthrie and Stanley) have ligatured arteries, on the supposition that they had to do with aneurism, when in reality it was one of the pulsating tumours just described that closely simulated it.

Pulsation may be communicated to a tumour of a fluid character seated upon an artery; here the diagnosis, though often difficult, is more readily made than in the last case. Attention to the history of the case, to the impossibility of diminishing the tumour by pressure, either directly upon it or on the artery leading to it, its fluctuation, and want of circumscription, will usually point out its nature. Especial attention should likewise be paid to the facts that the pulsation is a distinct heaving up and down of the tumour, and neither excentric nor distensible, and that the swelling may often be wholly or partly separated, by raising it up, from the artery lying beneath it. By attention to these points, abscesses in the axilla, under the pectorals, at the root of the neck, and in other situations where pulsation

may readily be communicated to the fluid mass, can be distinguished from aneurism; yet errors in diagnosis have happened, and will continue to do so, from the intrinsic difficulty of these cases, and from no want of skill or care on the part of the surgeon: and those will be most charitable to the critics on the mistakes of others, who have most frequently had occasion to experience these difficulties in their own practice.

Tumours that do not pulsate, either by their own vessels or by those that lie beneath them, are not so readily confounded with aneurism as the class of affections that has just been described. Yet it must be borne in mind, that in some instances even aneurisms do not pulsate, or but very indistinctly so, having become filled with a dense and firm coagulum. The non-pulsating tumours that chiefly require attention are *glandular*, *arterial*, or *ganglionic swellings*, seated over the carotid artery, at the root of the neck, or in the popliteal space. If these be of a fluid character, the fluctuation, unvarying size, and the want of pulsation in them, sufficiently indicate that they are not connected with the artery, from which they may also frequently be separated, and upon which they may be distinctly marked. If solid, they are usually irregular and nodulated on the surface, and can frequently be detached by the fingers being passed underneath them and raising them from the subjacent vessel. I believe there is more danger of mistaking a consolidated aneurism which is undergoing or has undergone spontaneous cure, and in which there is consequently no pulsation, for a solid (perhaps a malignant) tumour of some kind, than the reverse. I have known one instance in which the thigh was amputated for a very painful solid tumour of the popliteal space, which proved on dissection to be a consolidated aneurism pressing upon the posterior tibial nerve (Fig. 19th).

Aneurisms, more particularly those that are diffused, have not infrequently been mistaken for *abscesses*; and it is no very uncommon thing for a surgeon to be called to an aneurism which, under this supposition, has been diligently poulticed, or painted with iodine ointment. Occasionally, the more fatal error has been committed of puncturing the tumour with the view of letting out pus, when none appears, and, either immediately or after a lapse of a few hours, proper arterial hemorrhage ensues. That this accident may arise from the intrinsic difficulties of the diagnosis, is evident from the fact that it has happened to such surgeons as Desault, Pelletan, Dupuytren, Pirogoff, and others of less note. I have once actually seen this accident occur to a surgeon of considerable experience, who, mistaking a diffused popliteal aneurism for an abscess, opened it with a bistoury, but finding no pus, applied a poultice; alarming hemorrhage ensued in about forty hours, and I amputated the thigh on the second day after this untoward occurrence.

The difficulty in diagnosis is especially apt to occur in those aneurisms which, having become diffused, have ceased to pulsate, have no bruit, are elastic, softened, and diffident to the feel, and in which the skin has become reddened and inflamed by pressure from within. It is only by careful attention to the history of the case, and by skilful manipulation, that the true nature of the tumour can be made out. But an aneurism may actually become associated with an abscess in one of two ways. Thus it may suppurate, inflammation of a suppurative character taking place in the cellular tissue around it, with swelling, redness, œdema, and heat of the integumental structures, increase of size in the tumour, and probably diffuse solidification of it. If this abscess be opened or allowed to burst, dark grumous pus will escape, followed by coagula and masses of broken down decolorised fibrine, and sometimes accompanied, but more usually followed after a lapse of some hours, by a free and perhaps fatal discharge of florid blood.

Another form of combination between abscess and aneurism consists in the opening of an artery by ulceration into the cavity of an abscess, so that the blood is projected directly into this from the opened vessel. In cases of this kind—of which the instance that occurred to Mr. Liston is a good example—we have the ordinary signs of abscess, usually of a chronic character, to which those of an aneurism are generally suddenly superadded, with great increase in the bulk of the tumour. This accident has chiefly been observed in abscess of the neck, opening up a communication with the carotid artery.

With *rheumatism* and *neuralgia* it would at first appear to be difficult to confound an aneurism, but in practice it is not so. I have known several cases in which the lancinating pains of aneurism, more especially when the tumour was internal, have been mistaken and treated for rheumatic or neuralgic affections; and I have even known the pain occasioned by the presence of a large aneurism of the thigh treated for several weeks as rheumatism. In such cases as these, it is of course obvious that a little care and proper examination will usually serve to establish the diagnosis. The aneurismal may be distinguished from the rheumatic pain by its having a twofold character—being both lancinating and intermittent, as well as continuous, aching, and burning. When this kind of pain is persistent, especially about the back, the side of the head and neck, or arm, it ought always to cause the surgeon's attention to be directed to the condition of the neighbouring large vessels.

TERMINATIONS.—*Spontaneous Cure* of an aneurism is of very rare occurrence. The manner in which it happens has been especially and ably studied by Mr. Hodgson, and more recently by Dr. Bellingham; and the pathology of this process is of considerable interest, from its bearing upon the cure of the disease by surgical operation. The spontaneous cure may accidentally, though very rarely, occur by inflammation of the aneurism and consequent obliteration of the artery; but most frequently it is by the gradual deposition of laminated fibrine in the interior of the sac that it is filled up completely. This process can only take place in arteries of the second or third magnitude, and never in aneurisms of the aorta; and it can only happen in the sacculated aneurisms, the fusiform not admitting of it, it being necessary that the blood flowing through the sac be somewhat retarded in its passage, so as to give time for the deposit of its fibrine upon the interior of the tumour. This process, which is a very different one from the coagulation of the blood, is the increase of a natural condition always going on in the sac. In all cases of sacculated aneurism, there is a tendency to the production of a spontaneous cure, though this is so rarely accomplished. The tendency to it takes place by a contraction and partial occlusion of the artery below the sac, and the consequent diminished force of the circulation through it, by which the deposition of fibrine is greatly increased, at the same time that the collateral vessels given off above the sac often enlarge to a considerable extent, and thus divert from it blood which would otherwise have passed through it. This condition of the vessel below the sac may be looked upon as the first and most important step towards the consolidation of the tumour. The process is also materially assisted by the mouth of the sac being small, and so situated that the blood cannot be directly driven into it.

For spontaneous cure to take place, however, it is necessary that the current of blood should continue to circulate through the sac. If it be suddenly arrested, coagulation of the blood which happens to be in the sac may there take place, filling it with a large dark soft clot; the sudden formation of which is indeed, like a foreign body, apt to induce suppuration

and sloughing of the sac and neighbouring tissues, and hence is rather pathological than otherwise. But, though the blood continue to circulate through the sac, the deposit of fibrine will not take place unless the impetus with which that fluid is sent into and through the tumour be considerably diminished. This may happen from the occurrence, in the distal portion of the artery or the mouth of the sac, of some or other of those conditions that have already been described. So, also, it has been found that, in these cases in which two aneurisms are situated upon one artery, the second or distal one is very apt to undergo partial or even complete consolidation, the blood losing its impetus in its passage through the first sac. Any constitutional cause or condition also, by which the impulse of the heart is lessened, and the force of the flow of blood through the sac diminished (as the occurrence of phthisis), will favour greatly the deposit of laminated fibrine, and the consolidation of the tumour.

As the aneurism undergoes spontaneous cure, the pulsation in it gradually becomes more and more feeble, until it ceases entirely; the bruit proportionately lessens, the tumour becomes harder, and at last completely consolidated; at the same time, the anastomosing circulation is sometimes found to be established in some of the collateral vessels of the limb. Eventually, the solidified tumour shrinks in size, undergoing a species of drying and absorption, with ultimate conversion into a small mass of fibro-cellular tissue.

Causes of Death from Aneurism.—An aneurism may prove fatal in various ways. It does so when internal, most frequently by pressure on parts of importance in its vicinity, the patient being destroyed by the exhaustion induced by interference with their functions; this is usually the way in which aneurisms of the aorta occasion death. Then, again, death may result by the occurrence of *syncope*, more especially if the aneurism be of large size, and situated near the root of the aorta. External aneurisms most commonly prove fatal by *rupture of the sac*; this may either take place into the interior of a limb, giving rise to one or other of the diffused forms of aneurism, and terminate fatally by the induction of syncope or gangrene; or they may kill by rupture occurring externally, on one of the surfaces of the body.

Suppuration with sloughing of an aneurismal sac is not of very frequent occurrence, but is especially apt to happen in those cases in which the disease has increased rapidly, or suddenly become diffused, with much heat and tension of neighbouring parts. It is peculiarly likely to happen in tumours of a large size that have become partly diffused, that are filled with masses of decolorised fibrine, and that are situated in places where the cellular tissue is loose and lax, as in the axilla. The symptoms of this condition impending are swelling, tension with heat, throbbing, and redness of the parts around the tumour; the integuments covering which put on pressure, and are evidently deeply inflamed, at the same time that there is a good deal of fever and general constitutional irritation. As the suppuration advances, the ordinary signs of congestive abscess occur: the skin covering the tumour becomes red and livid at one part, where pointing takes place; and if the surgeon make an incision into it, or if the tumour burst (as assuredly it will if left to itself), a quantity of sanious pus mixed with large masses of broken down coagula and fibrine will be let out. The discharge of the contents of the aneurismal sac, disintegrated by and mixed up with the results of suppurative action, may be followed by so profuse a gush of arterial blood that the patient is suddenly exhausted.

The rupture of an aneurism is not always immediately fatal, the aperture

in the sac being plugged up by a mass of coagulum, as happened in case Fig. 192; on the gradual detachment of the deeper portions of which the

Fig. 192 - Aperture in Oesophagus produced by Pressure of an Aortic Aneurism.

Fig. 193 - Stellate Rupture of an Aortic Aneurism into Pericardium

bleeding may recur in small quantities at intervals, and more or less speedily carry off the patient. On the mucous surfaces, as of the oesophagus or trachea, rupture occurs in a similar manner (Fig. 192). On the serous surfaces, as into the pleura or pericardium, the aneurism may burst by a fissure or stellate opening (Fig. 193) forming in the membrane. An aneurism has been known to give way and discharge blood for some weeks before it proved fatal; and it may even happen that, after the rupture has occurred, no hemorrhage may take place, but death may result from the pressure of the tumour. Thus, in the case of the late Mr. Liston, the sac of the aneurism which caused the death of that great surgeon had actually given way, a mass of coagulum projecting from it into the trachea; yet death resulted from the irritation induced by pressure upon the inferior laryngeal nerve, and not from hemorrhage.

TREATMENT.—The treatment of aneurism is of two kinds—constitutional and local. In many cases, as in the various forms of internal aneurism, for instance, the constitutional treatment can alone be employed; and in all cases of external aneurism it should be had recourse to as an important adjunct to any local measures that are adopted.

In the *Constitutional or Medical Treatment* of aneurism, the great object is to bring about the same condition as that by which the spontaneous cure of the disease is affected, and, indeed, to put the patient and the part in the most favourable state for nature to consolidate the tumour; and, though it may not be possible in the great majority of cases to effect a cure in this way, at all events the disease may be palliated, and its progress retarded. The sacculated is, however, the only form of aneurism that can ever be cured by constitutional means; in the fusiform variety, all that can be done is to retard the progress of the disease.

The principal objects to be held in view are, in the first place, to lessen the force of the heart's impulse, so as to diminish the excentric pressure upon the arterial coats; and, secondly, so to modify the condition of the blood as to dispose it to the deposition of its fibrine. In carrying out these indications, it should be borne in mind that there are two opposite conditions of the system in which aneurism occurs; in one there is a plethoric, and in

the other an anemic tendency. The plethoric and irritable state of system chiefly occurs in young subjects, in whom the progress of the disease is acute and rapid, attended by much impulse and excitability of the heart, and throbbing of the arteries generally. The other condition of the system principally occurs in elderly people, in whom there is a feeble pulse, a weak heart, a cachectic state of health, and a tendency to anæmia; in such a habit of body the disease makes slow progress. In these opposite conditions it is perfectly clear that the same plan of treatment cannot succeed; and that the constitutional means must accordingly be modified according to the state in which the patient is.

In the acute or hypereemic state, the plan of treatment originally introduced by Valsalva, and hence called by his name, by which plethora is removed, the irritability of the heart and the force of its action lessened, and the blood brought into a healthy condition, may be advantageously employed, in the modified manner that has been recommended and adopted by some modern surgeons. Pelletan and Hodgson especially report very favourable results of this treatment, and I have seen several instances in which it has proved decidedly beneficial. As recommended by Valsalva, this method of treatment was intended to carry out two important points: 1, by a process of gradual starvation and depletion to reduce the quantity of blood in the system, the power of the heart's action, and consequently the pressure exercised upon the walls of the aneurism; and, 2, after the patient had in this way been reduced, the plasticity of the blood was to be improved by feeding him up in a gradual and careful manner, so that the tendency to the deposit of laminated fibrine might be increased. Valsalva endeavoured to carry out the first of these objects by subjecting the patient to small and repeated bleedings, and by gradually reducing the quantity of food that was daily taken, until it was lowered to half a pound of pudding in the morning, and a quarter of a pound in the evening. In this way the patient's strength was reduced until he could scarcely be raised up in bed without fainting; the quantity of food was then gradually augmented, so that the plasticity of the blood might be restored. It is seldom that surgeons carry out Valsalva's plan of treatment in the precise manner indicated by him; it is most commonly found to be more convenient to modify it somewhat according to the circumstances of the case, though the principles on which it is conducted are essentially the same.

In adopting any constitutional treatment in cases of aneurism, the first and most essential point to be attended to is, to keep the patient perfectly quiet in bed and free from all mental, emotional, or conversational excitement. The diet should at the same time be very carefully regulated, being gradually reduced in quantity, and being made to consist principally of farinaceous food, with but a very small quantity of meat, but little liquor, and a total absence of all stimulants. Perhaps the best regimen is that recommended by Bellingham, consisting of two ounces of bread and butter for breakfast, two ounces of bread and the same quantity of meat for dinner, and two ounces of bread for supper, with a little milk and water, occasionally sipped in small quantities. At the same time purgatives should be administered, especially such as give rise to watery stools, and remove obstructions of the portal and renal systems; with this view a scruple of the compound jalap powder may be given twice a week. In some cases, if the heart's action be particularly strong, recourse may advantageously be had to small bleedings from time to time.

By judiciously carrying out this plan of treatment and modifying it according to the circumstances of the case, consolidation of the aneurismal

tumour may occasionally be produced; or, if this be not attained, the progress of the disease will be very materially retarded.

When aneurism, however, occurs in feeble, cachectic, and anemic patients, this plan of treatment is altogether inadmissible: here, the blood being deficient in fibrine, and the system in an irritable state from debility, the best results follow such a course of treatment as will improve the plasticity of the blood, and regulate the action of the heart. With this view, complete rest, the administration of the preparations of iron, a dry but nourishing meat diet, and the occasional employment of opiates to relieve pain and to quiet the system, will be attended by the best results. In aneurism occurring in elderly people, and amongst the poorer classes, this plan of treatment is perhaps more successful than any other.

In the *Local Treatment* of aneurism but little can be done with the view of checking its progress, except by the employment of direct surgical means. The application of ice to the surface of the tumour is said to have acted beneficially in some cases; but it is a painful remedy, and may occasionally be attended by sloughing of the skin to which it is applied. When the pain attending the increase of the tumour is considerable, much relief may be obtained from the application of belladonna plasters, or the use of an embrocation composed of equal parts of oil and of the strong tincture of aconite. These means comprise the only local measures that can be adopted in those cases of internal aneurism, which are beyond the reach of surgical interference.

SURGICAL TREATMENT OF ANEURISM.

In all those cases in which it is possible to delay with safety, no surgical proceeding should be undertaken for the cure of aneurism until the patient has been subjected to proper constitutional treatment for some time; the success of the more direct surgical means depending greatly, in the hyperemic forms of aneurism, on the heart's impulse being lessened, and in the blood being got into as healthy a state as possible; whilst, in the anemic form of the disease, an increase in the plasticity of the blood is essential for the cure of the case; for, as the occlusion and consolidation of the sac, after surgical procedure, depend on the same conditions being induced that are successful after medical treatment, the same constitutional means should be adopted in one case as in the other. Before proceeding to the employment of any direct surgical means for the cure of an external aneurism, it is necessary to ascertain that there is no internal aneurism present, and that the heart is free from disease. From want of this precaution, it has happened that patients have died on the operating table at the moment when the artery was being ligatured, or that they have expired shortly afterwards, from the disturbance of circulation consequent upon the necessary surgical procedures.

Surgeons are in possession of several modes of treating external aneurisms: viz., Ligature, Compression by Instruments, Flexion, Digital Compression, Manipulation, Galvano-puncture, and Injection.

LIGATURE.—The employment of the ligature was the only means adopted by surgeons, for the cure of aneurism, up to a very recent date; the use of compression in the treatment of the disease, as at present employed, being one of the most modern, as well as one of the greatest improvements, in surgical practice. The manner in which the ligature should be applied, and the various cautions respecting its use, have been sufficiently discussed (page 168 *et seq.*). The question as to the part of the vessel to which it should be applied in aneurism, remains for consideration; and this involves some important points.

Situation.—There are three situations in which the ligature may be applied: 1, above and below the sac, by the old operation; 2, on the cardiac side of the sac, by Anel's (Fig. 194) or Hunter's (Fig. 195) operation; 3, on the distal side of the sac, by Brasdor's or Wardrop's operation (Fig. 196).

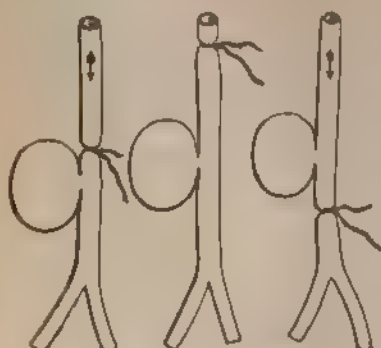

Fig. 194 —Anel's Operation. Fig. 195 —Hunter's Operation. Fig. 196 —Distal Operation.

1. The application of the ligature on both sides of the aneurisma is seldom practised at the present day, when the aneurism arises from disease of the coats of the vessel, but in those cases in which it comes from traumatic causes, it may frequently be adopted as the best means of cure, even in aneurisms of the largest size, as has been mentioned in the chapter on Traumatic Aneurism. The older surgeons, however, were acquainted with this mode only of treating aneurisms. The mode of applying the ligature to both sides of the sac is as follows. After having arrested the circulation through the aneurism, by compressing the artery leading to it, either by means of a tourniquet, or, where that is not applicable, by the pressure of an assistant's fingers, the surgeon slits up the sac, turns out the contained coagula and masses of fibrine, and then, passing a probe upwards and downwards into the artery, through the mouth of the sac, ties the vessel on each side, immediately above and below the aperture. This operation, as performed by the older surgeons on any of the larger arteries, as the popliteal, was not only so difficult in itself that surgeons were seldom willing to undertake it, but was so fatal in its results, being commonly attended by secondary hemorrhage in consequence of the artery being ligatured in a diseased part, or by diffuse inflammation, suppuration, and gangrene in the deeper tissues of the limb operated upon, that recovery after its performance was considered a miracle, and most surgeons preferred submitting the patient to amputation at once, to the risks of so hazardous a procedure.

2. The ligature of the artery on the cardiac side of the aneurism, without opening the sac, was first done by Anel, in the year 1710, in a case of brachial aneurism. This operation, though attended with the risk of wounding or inflaming the sac, which was in close proximity to the seat of ligature, constituted a considerable advance in the treatment of the disease, inasmuch as it did not necessarily lead to the opening up of the aneurismal tumour, and to the dangers that were inseparable from that mode of procedure. As Anel, however, performed his operation as a mere matter of convenience in a particular case, and without the recognition of any new principle of treatment being involved in it, it attracted but little attention at the time, and does not appear to have been repeated by any of the surgeons of his day.

It was reserved for John Hunter to make the great improvement in operative surgery of ligaturing the artery at a distance from the sac, where its coats were healthy, and where there was no danger of interference with the aneurism itself. In this way the objections to Anel's operation were avoided, for though, like Anel, Hunter tied the artery on the cardiac side only of the sac, yet he differed from him in doing so in a healthy part of its course, and at a considerable distance above the tumour, where the application of the

ligature would be attended with less risk of hemorrhage, and with no danger of opening, irritating, or inflaming the sac, which are inseparable from Anol's operation. The following are the reasons, given in Sir Everard Home's own words, that induced John Hunter to adopt the operation that is now generally known in surgery as the *Hunterian*. "Mr. Hunter proposed, in performing this operation, that the artery should be taken up at some distance from the diseased part, so as to diminish the risk of hemorrhage, and admit of the artery being more readily secured should any such accident happen. The force of the circulation being thus taken off from the aneurismal sac, the cause of the disease would, in Mr. Hunter's opinion, be removed; and he thought it highly probable that, if the parts were left to themselves, the sac, with the conglobated blood contained in it, might be absorbed, and the whole of the tumour removed by the actions of the animal economy, which would consequently render any opening into the sac unnecessary."

Hunter's first operation was performed in December, 1785, in a case of popliteal aneurism, in which the femoral artery was ligatured rather below the middle of the thigh, underneath the sartorius muscle; and since that time it has been universally employed by surgeons as almost the only mode of treating aneurism, until the introduction of compression in 1842.

The *Effects produced upon the aneurismal tumour by the ligature of the vessel according to the Hunterian method*, deserve careful attention. The immediate effects, on drawing tight the ligature, consists in a cessation of pulsation and bruit in the tumour, which at the same time subsides, becoming partially emptied of its blood. The supply of blood to the limb being in a great measure cut off, it becomes numb and cold, with a diminution of muscular power. The more remote effects consist in an increase of the activity of the collateral circulation, by which the vitality of the limb is maintained. At the same time, and, indeed, in consequence of this, the temperature of the limb often rises, until it becomes higher than that of its fellow.

The consolidation of the aneurismal tumour begins as soon as the ligature is applied, and is usually completed in a few days, by changes taking place within it similar to those that occur in the spontaneous cure of the disease. This important change is effected by the gradual deposit of stratified and decolorised fibrine in concentric layers within the sac, and not by the sudden coagulation of its contents. For this deposition to take place, it is necessary that, though the direct flow of blood through the tumour be arrested by the ligature of the main trunk, some should yet be carried in by collateral channels. This is a necessary condition for the success of the ligature; for, if it happen that all the flow of blood through the tumour be arrested, coagulation of that which happens to be contained in it will ensue, followed by gangrene, supuration of the sac, and other unfavourable results; the coagulum appearing to act as a foreign body, and to be insusceptible of those changes that are necessary for the consolidation of the tumour. It is of importance to observe, that the proper consolidation of the aneurismal tumour, by the deposit of laminated fibrine, will occur even though a very considerable quantity of blood continue to flow through it. In the Museum of University College there is an exceedingly interesting preparation that illustrates this point; it is one in which Sir Charles Bell ligatured the femoral artery for popliteal aneurism. The patient died a week after the operation, from erysipelas; on examination, it was found, and is shown by the preparation, that the femoral artery was double, and that, though only one portion of the vessel had been ligatured, the tumour, which continued to be supplied by the other, was completely consolidated. Hence, it would appear that, if one half of the

influx of blood only be arrested, obliteration of the sac by deposition of laminated fibrine may be expected to occur. After the aneurismal sac has been thus occluded, it progressively diminishes in size, and is at last converted into a small fibro-cellular mass. The artery that has been ligatured becomes closed at two points—at the part deligated (Fig. 197, a), and where it communicates with the sac (Fig. 197, b). In both these situations, it will be found to be converted into fibro-cellular tissue; whilst between them there is an open space, through the medium of which the collateral circulation is freely carried on.

Fig. 197. — Portion of Artery ligatured for Popliteal Aneurism, after removal of the site of the Ligature, and at b, where the Tumour has become consolidated and absorbed between these points the Artery is open.

3. *Distal Ligature.*—In some cases in which the ligature cannot, for anatomical reasons, be applied on the proximal side of the aneurism, as in the arteries about the root of the neck, it was recommended by Brasdor that an endeavour should be made to obliterate the aneurism by ligaturing the vessel on its distal side. This operation was first practised by Deschamps, and has been especially commented upon by Wardrop. In principle, it resembles the Hunterian operation, the object being to arrest so much of the flow of blood through the sac that the consolidation of this may take place in the usual way, by the deposit of laminated fibrine. In the Hunterian operation, this is effected by deposit from the lessened quantity of blood that flows through the sac; in the distal operation, it is sought to be accomplished in the same way, and the success of the operation must necessarily depend, in a great measure, upon the extent to which the flow of blood through the sac is interfered with. This operation, however, is rarely successful; for, independently of the ordinary dangers resulting from the application of the ligature to a large vessel, the sac will continue to be distended with, and to receive the direct impulse of, the blood that is driven into it, though it be not transmitted through it; and hence, though the progress of the aneurism may be arrested for a time, it will often speedily increase again, and may perhaps eventually destroy the patient by suppuration and sloughing. I have collected the details of 27 cases, in which this operation has been practised, and of these I find that in 20 instances a fatal result speedily followed the operation; whilst in the remaining 7 cases the patient survived the effects of the ligature of the artery, though he was not at all cured of the disease for which the operation was practised. This operation, however, we shall consider more in detail in speaking of the particular cases in which it has been practised.

Indications and Contraindications of Ligature.—Ligature of an artery for aneurism, by the Hunterian method, succeeds best in those cases in which the tumour is circumscribed, of moderate size, slow in its growth, having a tendency to consolidation, and unaccompanied by much oedema of the limb. When the aneurism is undergoing spontaneous cure, no surgical interference should be employed, but the case left to nature. In this way it occasionally happens, during the preparatory treatment of the disease, that the aneurism becomes consolidated.

All operations should be avoided when there is any serious disease in the

heart, and in cases of multiple aneurism where the second tumour is situated internally; but it has happened that two aneurisms in one limb, as of the popliteal and femoral arteries, have been cured by one ligature applied to the external iliac. Two aneurisms seated in corresponding parts of opposite limbs, affecting, for instance, the two popliteal arteries, may be successfully operated upon. But, if two aneurisms be seated on different parts of the body, as the axilla and groin for instance, at the same time, the aneurismal diathesis would be indicated, and it would certainly not be expedient to operate.

In certain cases, the Hungarian operation seldom succeeds; and these, therefore, may be considered as unpromising to it. This happens in those instances in which it is necessary to apply the ligature very close to the sac, so as indeed rather to perform Auel's operation, as here there is the double danger of inflaming or wounding the sac, and of interfering with the collateral circulation of the limb. Those cases, also, in which the aneurism is very acute in its progress, increasing rapidly with forcible pulsation, having very fluid contents, and a large mouth to the sac, into which the blood is consequently driven by a full wave at each pulsation of the heart, are rarely favourable for the use of the ligature, inasmuch as stratification seldom occurs. When the aneurism is situated in the midst of loose and very yielding tissues, as in the axilla, where it readily expands to a large size, not being bound down by the surrounding parts, suppuration and sloughing of the sac are especially apt to occur after ligature. When it is diffused widely through the limb, with coldness and a tendency to incipient gangrene, the circulation of blood through the part is so much choked that the deligation of the vessel will in all probability arrest it entirely, and thus produce mortification. When arteries can be felt to be ossified, it is a question whether they can be safely ligatured, as in all probability they will be cut or broken through by the noose, and the changes necessary for their occlusion will not take place. Porter, however, recommends that the ligature should be applied in such case, though I cannot but doubt the propriety of this advice. When inflammation has been set up in the sac, with a tendency to suppuration of the tumour, it is a debateable question whether the ligature should be applied or not. In these cases I agree with Hodgson, that the artery should be tied; for even if the sac eventually suppurate, there will be less risk to the patient if this event occur after the application of the ligature, than if it happen while the artery leading into the tumour is pervious. If suppuration have already taken place in or around the sac, the application of the ligature above the inflamed tumour on the point of bursting would be worse than useless. In such cases, the line of practice must be determined by the seat of the aneurism. If this be in the axilla, groin, or neck, it should be laid freely open, the coagula scooped out, and the artery tied above and below the mouth of the sac—a most formidable and doubtful operation, but the only one that holds out a chance of success. If the aneurism be in the ham or calf, amputation would probably be the best course to pursue.

In some instances, there is no resource left to the surgeon, but to amputate. 1. Amputation must be performed when the aneurism is associated with carious bone, or diseased joint, as when popliteal aneurism has produced destruction of the knee. 2. If the aneurism have attained so great a magnitude that it has already interfered seriously with the circulation through the limb, as indicated by considerable œdema, lividity, and coldness of the part, with distension of the superficial veins, it is a question whether the application of the ligature may not immediately induce gangrene, and

whether the patient would not have the best chance of recovery by submitting to amputation at once; this is more particularly the case when the aneurism has become diffused with impending gangrene, when removal of the limb must not be delayed. 3. If gangrene have actually supervened and the patient's strength be sufficient to bear the operation, amputation should be done without delay. 4. If a diffused aneurism, whether suppurating or not, on the lower extremity, have been opened by mistake for an abscess, there is no resource left but immediate amputation.

The ligature fails from various causes in a very considerable number of the cases in which it is employed for the cure of aneurism. Thus, in the 116 cases of ligature of the larger arteries for aneurism, that have been collected and tabulated by Dr. Crisp, it would appear that the mortality amounted to about 22 per cent. And Porta finds that, among 600 cases of ligature of arteries for diseases and injuries of all kinds, the mortality amounted to 25 per cent. It must be borne in mind, that these are collections of previously reported cases, and that, if the unrecorded cases could be got at, the rate of death would, in all probability, be found to be much higher even than that above stated.

ACCIDENTS AFTER LIGATURE FOR ANEURISM.—The accidents that may follow the application of the ligature in a case of aneurism, are: 1, Secondary Hemorrhage from the seat of ligature; 2, the Continuance or the Return of Pulsation in the Sac; 3, the occurrence of Suppuration and Sloughing of the Tumour, with or without Hemorrhage from it; and 4, Gangrene of the Limb.

1. *Secondary Hemorrhage from the seat of ligature presents nothing peculiar, and has already been discussed at p. 178.*

2. *The Continuance or Return of Pulsation in an Aneurismal Sac after the ligation of the artery leading to it, is an interesting phenomenon, and one that deserves some attention.* When the Hunterian operation is successfully performed, though the pulsation in the sac be entirely arrested, a certain quantity of blood continues to be conveyed into and through it by the anastomosing channels, and it is from this that is deposited the laminated fibrine by which the consolidation of the tumour is ultimately effected. The stream of blood furnished by regurgitation, or by transmission through the smaller collateral channels, is continuous, and not pulsatory; occasionally, however, it is transmitted in sufficient quantity by some more than usually direct and open anastomosing or feeding branch, and thus gives rise to a continuance or to a return of the pulsation. It is interesting to observe that, in some of the cases in which this has happened, there has been a return of the bruit, but that in the majority no sound appears to have been emitted.

The *period* of the return of the pulsation in the sac after the ligation of the artery varies greatly. In by far the majority of cases, at least two-thirds of those in which it has happened, a certain degree of thrill or of indistinct pulsation has been found in the sac shortly after the application of the ligature; at all events within the last twenty-four hours. This may be looked upon as being rather a favourable sign than otherwise, as it is indicative of a free state of the collateral circulation, and generally soon disappears spontaneously, the sac undergoing consolidation. Next in order of frequency are those cases in which the pulsation returns in about a month or six weeks after the ligation of the artery, when the collateral circulation has been fully established, and, after continuing for some length of time, gradually ceases. It more rarely happens that the pulsation returns between these two periods; that is to say, about ten days or a fortnight after the application of the

ligature; though in some instances the slight vibratory thrill, scarcely amounting to a pulsation, which perhaps is perceptible a few hours after an artery has been tied, gradually strengthens at the end of a week or ten days into as distinct and forcible a beat as had been noticed before the operation. In some rare instances the pulsation has re-appeared after the lapse of some months, the aneurismal tumour having in the meanwhile undergone absorption, then indeed it may with justice be looked upon as constituting a *secondary aneurism*, and as indicating a recurrence of the complaint.

The cause of the continuance or of the return of the pulsation in an aneurismal sac, must be looked for in too great a freedom of the collateral circulation. Indeed, I consider it an essential requisite for the manifestation of this phenomenon, that there should be so free and direct a communication between the artery on the proximal side of the ligature, and that portion of the vessel situated between the ligature and the sac, or the sac itself, as to enable the impulse of the heart to be transmitted in a pulsatory manner into the tumour. No regurgitant blood coming upwards from that portion of the artery which is distal to the sac, however free it may be, can communicate an impulse, as it never flows *per saltum* except in the special case of a continuous circle of large anastomoses, such as are met with between the arteries within the skull, or in the palmar and plantar arches. If any of the direct collateral or feeding vessels happen to be sufficiently large at the time of the operation to transmit the wave of blood, the pulsation in the sac will be continuous, or will return almost immediately after the application of the ligature. If they be at first too small for this, they may become enlarged as part of the anastomosing circulation, and then the pulsation will return as soon as their calibre is sufficient to transmit the heart's impulse. Besides these conditions in the size and distribution of the vessels of the part, it is not improbable, as has been supposed by Porter, that certain states of the blood in some individuals may, from causes with which we are unacquainted, render it less liable to coagulate than usual, and thus dispose to a return of the pulsation in the sac, which remains filled with fluid blood.

The phenomenon under consideration has been noticed in all parts of the body after the performance of the Hunterian operation, though it occurs with different degrees of frequency after the ligature of different arteries, and is certainly of more common occurrence after operations for carotid aneurism than for any other form of the disease. Thus, of 31 cases in which the carotid artery has been tied for aneurism, I find that pulsation in the tumour continued or returned in 9 instances; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, the pulsation occurred in 6 cases only; and in several of these it is interesting to note that there were two aneurismal sacs in the same limb—one in the groin, the other in the ham; and that the pulsation, though permanently arrested in the popliteal, occurred in the inguinal aneurism. In the ham and axilla, pulsation occasionally though very rarely recurs. The cause of this difference in the frequency of the recurrence of pulsation in different aneurisms, is evidently owing to the different degrees of freedom of communication that exist between the sac and the collateral branches in various forms of the disease; thus, in a carotid aneurism, the impulse of the heart may at once be brought to bear upon the contents of the sac, through the medium of the circle of Willis. But, in the case of inguinal, femoral, or popliteal aneurism, the anastomoses, consisting rather of the inoculations of terminal branches than of open communications between large trunks, are less liable to transmit the blood in a pulsatory stream. For the same reason—the great freedom of the communication between the vessels of opposite sides—the pulsation has more fre-

quently been found to continue uninterruptedly and distinctly, though reduced in force, after the ligature of the artery, in carotid aneurisms, and in those in any other situation. The cases in which it returns after the cessation of a few hours only are perhaps as frequent in the groin and ham as in the neck. In those instances in which the pulsation returns within the first twenty-four hours after the ligature, it usually ceases again in a few days, though it sometimes continues a week or two. When it recurs at a later period, it is apt to last somewhat longer.

The prognosis of these cases is on the whole favourable, but few of them having eventually proved fatal. Of 26 patients in whom pulsation recurred, I find that 3 died; and in all of these the fatal result was occasioned by inflammation and sloughing of the sac. In all of the 3 instances, the pulsation recurred within the first twenty-four hours. When it returns at a more advanced period, there is little risk to the patient, as it is usually readily amenable to proper treatment.

A *Secondary Aneurism* is of extremely rare occurrence; indeed I believe there are only two unequivocal instances of this affection upon record, one of which took place in the ham; the original tumour having disappeared entirely after operation, the secondary disease made its appearance after a lapse of six months in one case, and in the other after four years. It is of importance to distinguish between a secondary aneurism and secondary or recurrent pulsation in an aneurismal sac. The term "*secondary aneurism*" should be restricted to those cases only in which an aneurismal tumour appears in the site of a former one, which has undergone consolidation and absorption after operation. The question may be raised, whether aneurisms of this kind are in reality secondary, or whether they may not originate in the dilatation of a portion of the artery contiguous to the seat of the former disease. It is certainly not very easy to understand how an aneurismal sac that has once undergone consolidation and absorption, can again become dilated into a pulsating tumour; and I think it most probable that, although the consecutive aneurism may be found in the same surgical region as the primary one, it in reality takes its origin from a slightly higher part of the artery, where the same structural changes may have been in progress that determined to the disease in the first instance at a lower point. Inside aneurism thus arising is, indeed, occasionally met with in the ham as a primary disease. I have seen a case in which an aneurismal tumour was situated in the ham, and another at or immediately above the aperture in the adductor muscle: if the artery in such a case as this had been tied before the second tumour had attained any magnitude, we can easily understand how, when this became dilated, it might have been considered to be a new enlargement of the original sac, whereas, in reality, it was nothing more than a new aneurism forming in the close vicinity of the old one.

The enlargement of an aneurismal sac without pulsation, after the ligature of the artery leading to it, is an interesting phenomenon, and one that might cause the true nature of the tumour to be misunderstood, as it closely resembles in its slow and gradual increase the growth of a malignant tumour. It is occasioned by the distension of the sac by the dark regurgitant blood brought into it through the distal end of the vessel, without sufficient force to cause pulsation, though with sufficient pressure to occasion a gradual increase in the size of the swelling.

Treatment of Recurrent Pulsation.—In by far the majority of cases of secondary pulsation, this phenomenon ceases of itself in the course of a few days or weeks by the consolidation of the sac, in the same way as after ligature of the artery, from the deposition of lamellated fibrine. This tendency

to consolidation of the tumour may be much assisted by means calculated to lessen the force of the impulse of the blood into the sac, such as rest, the elevated position, and the cautious application of cold to the part; cold, however, must be carefully applied, lest, as the vitality of the limb is diminished, gangrene be induced. At the same time, direct pressure may be exercised upon the sac, so as to moderate the flow of blood into it; this has in many cases succeeded in procuring consolidation of the tumour, and may most conveniently be applied by means of a compress and narrow roller. This plan is especially adapted to popliteal and inguinal aneurisms, but cannot so well be exercised upon those situated in the neck. Care must be taken that the pressure be not at first too powerful, lest gangrene result; the object is not so much to force out the contents of the tumour or to efface it, as simply to restrain and moderate somewhat the flow of blood into it.

In the event of the pulsation not disappearing under the influence of pressure, conjoined with rest, dietetic means, and the local application of cold, we must either perform the old operation of opening the sac, or amputate the limb. Of these measures, I should certainly advise amputation, as offering the most favourable chance to the patient. The operation of opening the sac, turning out its contents, and ligaturing the vessel supplying it, is under any circumstances a procedure fraught with the greatest danger to the patient, and full of difficulty to the surgeon, even when he knows in what situation to seek the feeding vessel. How much greater then must the difficulty be, when he is in uncertainty as to the point at which the artery enters the sac, and cannot know whether there be more than one arterial branch leading into it. In the event, therefore, of all other means failing, and of the pulsation in the tumour continuing, amputation is the only resource left to the surgeon.

3. *Suppuration and Sloughing of the Sac.*—When, after the ligature of its supplying artery, an aneurism is about to suppurate, instead of diminishing in size it increases, with heat, pain, pulsation, and some inflammatory discoloration of the skin covering it. This gradually becomes thinned, and at last gives way; the contents of the tumour, softened and broken down by the inflammatory action and the admixture of pus, are discharged through the aperture in its wall, in the form of a dark purplish-brown or plum-coloured and often fetid fluid, intermixed with masses of soft dark coagula, or of the drier laminated fibrine, which may not inaptly be compared in appearance to portions of raisins or dates. The escape of these matters, variously altered, may be accompanied or followed by the escape of florid arterial blood. This hemorrhage, which is the great source of danger in the suppuration of an aneurismal sac, may occur in a sudden or violent gush at the time of the rupture of the tumour, by which the patient may at once be destroyed; or it may continue in small quantities, which, after ceasing, recur from time to time, thus gradually exhausting the patient. It is this occurrence of secondary hemorrhage that constitutes the principal danger after suppuration of an aneurism, which otherwise is not a source of any very serious risk to the patient; about one-fourth only of the cases in which the sac has suppurated having had a fatal termination, and almost all those in which death resulted, having proved fatal by hemorrhage. The patients in the few remaining instances have been carried off by some special accidents, such as the pressure of the sac on the pharynx or œsophagus, or the discharge of the contents of the tumour into the pleura or bronchial tubes. Hemorrhage is more liable to occur when the suppuration takes place a few weeks after the ligature of the artery, than when a longer interval has elapsed. That

hemorrhage does not happen more frequently after suppuration of the sac, is very remarkable, and must be owing either to the sealing by adhesion or plugging by conglulum of the mouth of the aneurism, where it communicates with the interior of the artery. It is owing to this plugging also, that in many cases the fatal bleeding does not occur at the moment of rupture, but only after a lapse of some days ; or even weeks, and then most usually under the influence of some incautious movement of the patient, by which the conglulum or adhesion is suddenly disturbed. Those cases are most dangerous in which pulsation has returned in the sac after the ligature of the vessel, but before the supervention of suppuration ; as in these the tumour is so freely supplied with blood that, if it burst, fatal hemorrhage will with certainty supervene.

This accident is much more frequent in some situations than in others, and is more liable to occur in aneurisms of the axilla or groin, than in those of the ham or of the neck. The greater frequency of suppuration in axillary and inguinal aneurisms, is owing to the large size that these tumours rapidly attain, in consequence of the laxity of their cellular connections, and to the difficulty of their removal by the absorbents of the part. This accident is also greatly predisposed to, by the blood contained within the aneurismal tumour undergoing simple coagulation instead of fibrinous consolidation. The mass of conglulum, instead of being absorbed, and thus gradually disposed of, as happens in a properly stratified aneurismal sac, is very apt to break up and undergo decomposition, being converted into an unhealthy grumous fluid, which excites inflammation in the parts with which it is in contact. This state of things is especially liable to happen in those aneurisms that are of very large size, with thin parietes, and which contain, previously to the operation, much fluid blood and comparatively little laminated fibrine. In other cases it would appear that the fibrine, though properly deposited, acts as a foreign body, and gives rise to inflammation and suppurative action in the wall of the sac and the surrounding cellular tissue. Besides this, it has been very justly remarked by Porter, that the excessive handling and frequent examination to which an aneurismal tumour occurring in a hospital patient is usually subjected, may induce inflammatory action and give rise to suppuration.

The period at which suppuration of the sac may occur after the ligature, varies from a few days to as many months. In the majority of instances, it would appear to take place between the third and eighth weeks ; later than this it seldom happens, though it may do so after the lapse of several months, as in a case recorded by Sir A. Cooper, in which a carotid aneurism suppurred at the eighth month.

Treatment.—When an aneurism is suppurating, and is on the point of giving way, it will be better to make an incision into it, so as to let out at once the broken down and semi-putrefied contents. Its cavity must then be dressed like an ordinary abscess, with a view to its filling up by granulation ; which, however, will necessarily be a slow process, in consequence of the great size and depth of the opening. During the whole of this time a tourniquet should be kept loosely applied upon the artery above the sac, so as to be tightened at any moment that bleeding takes place. If hemorrhage have already supervened, the case is attended with immediate danger. In such a case as this, the first indication is clearly to arrest the immediate flow of blood, so as to prevent the patient from dying at once. This can best be accomplished by turning out the coagula and plugging the sac with lint or compressed sponge, retained *in situ* by a firm graduated compress, and well applied roller. The hemorrhage having thus been arrested for a time, the

surgeon should take into consideration what steps should be adopted permanently to restrain it. In some cases indeed, though these are exceptional, the plug and compress may be sufficient to prevent a recurrence of the bleeding; but in general it will not do to trust to these means, unless the anatomical relations of the part be such as to preclude the possibility of adopting any more active measures.

Various plans suggest themselves to the surgeon for the permanent suppression of the bleeding. The sac may be laid open, and an attempt made to ligature that portion of the artery from which the blood issues. But this can scarcely be expected to succeed, as, in the majority of the cases, the coats of the vessel being softened and pulpy, there would be little prospect of its holding a ligature, even if it were possible to expose it before the patient perished of hemorrhage. Indeed, though this plan has been several times tried, I am not aware that by it the surgeon has ever succeeded in arresting the bleeding from a suppurating aneurismal sac.

The application of the actual cautery to the bleeding orifice would, I think, hold out a better chance, more particularly if the blood were poured out from a collateral vessel of a small size. In this way Morrison, of Monte Video, succeeded in arresting the bleeding of an aneurism in the groin that had suppurated. Should this means, however, not suffice (and it is the only means that can be applied in many situations, as in the groin and axilla), there is no course left but, in those situations in which it can be done, either to ligature the artery higher up or to amputate. The application of a ligature nearer the centre of the circulation, even though practicable, appears to me to be of very doubtful utility; for the probability is, that the circulation through the limb, embarrassed as it must have been by the first ligature, and by the subsequent distension and suppuration of the sac, will be so much interfered with when the artery is tied a second time, that gangrene will result; or else that the collateral circulation, if sufficiently active to maintain the vitality of the limb, will also keep up the hemorrhage from the opening in the artery communicating with the sac. Under these circumstances, the only course left to the surgeon is amputation of the limb, when the aneurism is so situated that it can in this way be removed.

4. *Gangrene of the Limb.*—The general subject of gangrene of a limb, following injury and ligature of the main artery, has already been described (p. 183); and we have, at present, only to consider those cases in which it occurs after the operation for aneurism.

Cause.—If the aneurismal sac have attained a large size with great rapidity, it may, by its pressure on the anastomosing vessels, or on the veins in its vicinity (Fig. 198), produce such an amount of disturbance in the circulation of the limb, preventing the influx of arterial or obstructing the efflux of venous blood, as to occasion a great liability to the occurrence of gangrene. But perhaps the principal source of danger consists in the aneurism becoming evidently and widely diffused, more particularly in those cases in which the anatomical relation of the anastomosing vessels is such, as in the

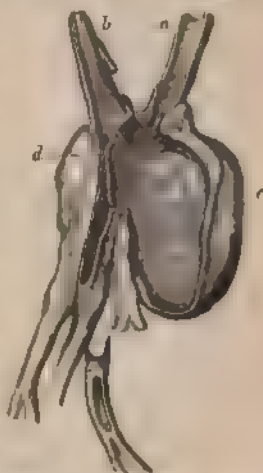

Fig. 198.—Popliteal Aneurism compressing the Veins and the Artery, causing Gangrene of the Limb. *a*, Artery. *b*, Vein, compressed at *d*. *c*, Aneurism.

ham, that they may readily and uniformly become compressed by the effused blood. In these cases, the additional embarrassment induced in the circulation of the limb by the ligature of its main artery will readily induce gangrene; and hence it is that, in diffuse aneurism of the lower extremity, ligature of the artery is so commonly followed by mortification.

The loss of blood, either in consequence of secondary hemorrhage, or in any other way before or after the application of the ligature, is very apt to be followed by gangrene; the more so, if the state of things have rendered it necessary to apply a ligature to a higher point on the trunk of the vessel than had previously been tied. This secondary ligature of a large artery in cases of aneurism has, I believe, been invariably followed by gangrene of the limb when done in the lower extremity; the interference with the collateral circulation by the second ligature being so great, that the vitality of the part cannot be maintained.

Besides these causes, the occurrence of *erysipelas*, exposure of the limb to cold or to an undue degree of heat, or subjecting it to the compression of a bandage, may be attended by consequences fatal to its vitality.

The period of *supervention* of gangrene of the limb is usually from the third to the tenth day; it seldom occurs before this period, unless incipient mortification have already set in before the artery is tied. Gangrene usually follows the ligature of the external iliac at an earlier period than that of any other artery. In cases of aneurism, the gangrene is always of the dark and moist variety, owing to its being commonly dependent on pressure upon the large venous trunks by the aneurismal tumour.

Treatment.—The general preventive treatment of gangrene dependent on the ligature of the artery for aneurism must be conducted on the same principles as when it arises after the ligature of arteries generally. But some special modifications of it are required, so far as the aneurism is concerned. When the gangrene occurs from the pressure of the sac upon the accompanying vein, it has been proposed to lay the tumour open, and to turn out its contents, thus removing the compression exercised by it. The danger of such a proceeding consists in the probability of the occurrence of hemorrhage from the opening made into the sac, and in the risk attending suppuration set up in this; yet it would appear that, in two cases in which this practice has been adopted, no bad results followed. Thus, Lawrence has related a case of diffused aneurism of the popliteal artery, in which this plan was had recourse to with the best results; and Benza (*Medical and Physical Journal*, vol. lv.) has recorded a case of popliteal aneurism in which the same practice was adopted in consequence of great oedema and incipient gangrene of the foot; after the extraction of a quantity of flesh-like fibrine from the sac, the patient made an excellent recovery. These cases would certainly justify the surgeon in adopting such a course when the danger of gangrene is imminent, and dependent on the size and pressure of the tumour. Should, however, the gangrene show any disposition to extend, or should there be hemorrhage from the sac after it has thus been laid open, the surgeon must hold himself in readiness to amputate without delay. When gangrene has once fairly set in, there is no reasonable prospect of saving the limb; and the sooner amputation is done, the better. The limb must always be removed high up above the sac, and, if possible, not only at some distance from the parts that have mortified, but above the limit to which the serous infiltration that precedes this condition has extended. The upper extremity must generally be removed at the shoulder-joint; the lower, above the middle of the thigh. In these cases there will generally

be a considerable amount of hemorrhage, and many vessels will require to be tied in the stump, in consequence of the enlargement of the collateral circulation.

COMPRESSION BY INSTRUMENTS—In consequence of the dangers and difficulties attendant upon the use of the ligature, surgeons have for many years past endeavoured to treat aneurism by compression. The employment of direct pressure on the aneurism was almost naturally suggested as a means to counteract the extension of the disease by the pressure of the blood from within, and has consequently been applied from a very early period in the treatment of the affection. This plan of treatment was first employed by Boudolot at the close of the seventeenth century; afterwards by Genga, Heister, Guattani, and others. These surgeons made the pressure directly upon the sac; and Guattani and Flajani relate several cures that they effected in this way; but the method was so uncertain in its results, and so dangerous, from irritating and inflaming the sac, that it fell into disuse. The French surgeons introduced a modification of the pressure plan, by laying open the sac, clearing out its contents, and applying the pressure directly over the ends of the vessel. Deschamps exposed the artery leading to the sac, and compressed this with an instrument he termed the "*prosse-artere*." These barbarous modes of treatment, however, were entirely set aside by the facility and comparative success of the Hunterian operation; and compression in aneurism was rarely practised by surgeons after the great step made by John Hunter in the treatment of this disease. Yet we find that John Hunter himself, Blizard, and Freer attempted, though with but little success, to cure this disease by pressure on the artery leading to the sac. Pelletan and Dubou appear to have been the first who employed the pressure upon the artery above the sac, instead of upon the aneurism itself; this was in 1810. Since this period various attempts were made methodically to treat aneurisms in this way; but the merit of having introduced the practice of compression in the treatment of aneurism into modern surgery, of having given it a definite place in our art, and of having established the true principles on which it acts, incontestably belongs to the Dublin surgeons; amongst whom the names of Hutton, Bellingham, Tufnell, and Carte deserve especial mention.

Principle.—In the early trials of the cure of aneurism by compressing the artery on the cardiac side of the tumour, the surgeons who employed this method acted on an erroneous theory; and, the principle not being understood, the practice was bad. It was supposed that it was necessary, in order that the cure might take place, that the *whole* flow of blood through the artery should be entirely arrested; that inflammation of the vessel at the point compressed should be set up; and that the consolidation of the aneurism depended upon the obstruction of the vessel consequent upon this inflammation. This led to compression being exercised so forcibly, with the view of exciting inflammation in the artery, that the patient could seldom bear it for a sufficient length of time to effect a cure; sloughing of the skin commonly resulting as a necessary consequence of the severe pressure to which it was subjected. To the Dublin surgeons belongs the very great merit not only of having pointed out the error of this doctrine, but of having distinctly laid down as the principle of the practice, that the aneurism was cured, when the artery leading to it was compressed, in precisely the same way as when a spontaneous cure takes place, or when the Hunterian operation is performed—viz., by the deposit of stratified fibrine in the sac, and by the consequent consolidation of this (Fig. 199), aided by the contraction of the walls of the sac; and that, as in the case of ligature of the vessel, it

was not necessary for the whole of the circulation through the artery to be entirely and permanently arrested, but merely for it to be lessened in quan-

Fig. 190.—Sac of Aneurism cured by Compression. Deposit of Laminated Fibrine.

tity and force to such an extent as to be compatible with the deposition of laminated fibrine in the sac; and it was clearly shown by examination after death that, if the pressure were properly conducted, the artery was in no way injured or occluded at the part compressed. This recognition of the true principles on which compression of the artery leading to the sac cures the aneurism, has led to important results; for, as the severe pressure that was formerly considered necessary is now known not only to be useless, but to be absolutely injurious, no amount of compression is exercised beyond what is requisite to restrain and moderate the flow of blood into the sac; no attempt being ever made to compress the artery so severely as to lead to its obliteration by inflammation.

Though I have stated generally that aneurisms, when treated by compression, are cured by the deposit of laminated fibrine, I think this remark ought to be confined to the common sacculated form of the disease. In the tubular variety, which is certainly of far less frequent occurrence in the extremities, the cure of the aneurism takes place by contraction of the sac, and by its becoming filled by fibrine in a somewhat irregular manner. Illustrative of this mode of cure, there is a preparation in the Museum of University College (Fig. 200).

Fig. 200.—Sac of Tubular Aneurism cured by contraction. Deposit of Fibrine.

Circumstances influencing Success.—The success of the treatment by compression depends greatly upon a scrupulous attention to a number of minor circumstances, which, though each be trivial in itself, become of importance when taken as a whole. During the whole of the treatment, also, the patient's general health should be attended to in accordance with those dietetic and medical principles that have already been laid down in speaking of the constitutional treatment of the disease, having for their object the increase of the fibrination of the blood. The irritability of the heart and arteries must also be subdued, and the irritation of the system lessened, by the use of opiates; and the patient should be put into a comfortable bed, with firm and well-secured pillows and mattresses, so that his position may not be changed. As it is principally in aneurism of the lower extremity that compression can be employed, we shall proceed to describe the method of its application here.

Application of the Compressor.—The limb having been bandaged smoothly, with a soft cotton or air-pad upon the tumour, and laid comfortably on pillows, the thigh should be shaved, and dusted with hair-powder. The apparatus must next be applied; and much of the success of the treatment will depend upon the kind of instrument used. The ordinary horse-shoe, or Sigoroni's tourniquet, was the one first employed, and this will, in many cases, answer the purpose perfectly well; but, as it is somewhat difficult to regulate the pressure with this instrument, and as it is not unfrequently exercised too powerfully, it has generally given place at the present day to the very ingenious apparatus of Dr. Carte, which, as it substitutes an elastic force derived from vulcanised India-rubber bands for the unyielding pressure of the screw, accommodates itself better to the limb, and is less likely to

produce injurious compression. This instrument, as well as the other contrivances which have at various times been invented for the treatment of aneurism by compression, are described by Dr. Bellingham and Mr. Tufnell, in their works on this subject, to which I must refer for a fuller account than I can here give. In some cases the circulation through the artery may conveniently be controlled by the pressure of a weight laid over it in the groin as it passes over the pubes; usually from a four to a seven pound weight is sufficient for this purpose. In this way, when only one compressor is applied on the limb, the flow of blood may be checked during the time that the screw is loosened. Care must of course be taken that the weight do not slip off. It is best made of lead, cast in a conical shape, and may be retained *in situ* by having a wide leather socket made to fit it, shaped somewhat like the hopper of a mill; its broad end should be upwards, and the narrow end should press on the vessel.

In applying the compressor, especial care must be taken that it is well padded in every part, so as not to gall the skin. In some of the early cases in which I saw compression employed in London by means of the horse-shoe tourniquet, much inconvenience resulted from want of attention to this particular. The tendency to fretting of the skin is much lessened by powdering the limb; and the removal of the cuticular hairs by shaving, diminishes materially the irritation produced by the instrument. In order to keep up continuous pressure, and at the same time to prevent any one part of the skin from being injuriously galled, it is of very great consequence that two instruments should be used at the same time, so that when one is screwed up the other may be loose; these instruments need not be placed closely together. If the aneurism be in the ham, it will be sufficient for one (Fig. 201) to be applied to the groin, whilst the other (Fig. 202) is put

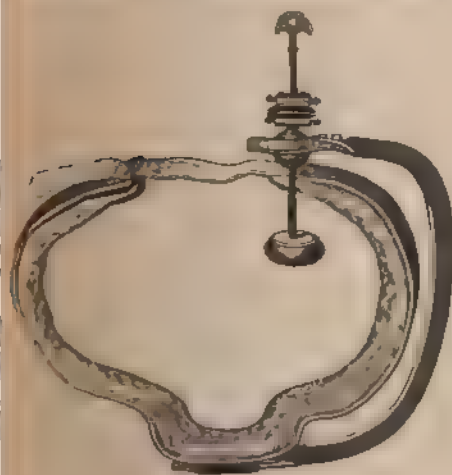

Fig. 201.—Compressor for the Groin.

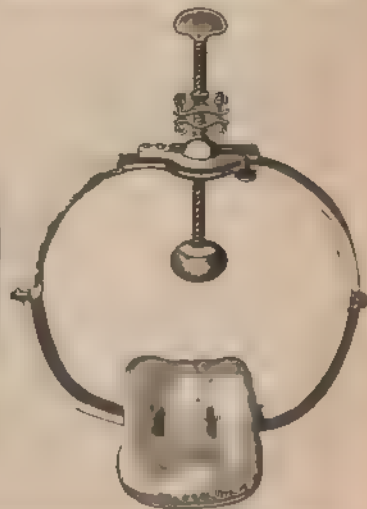

Fig. 202.—Compressor for the Middle of the Thigh

upon the middle of the thigh. In using the instrument, the great point, as Tufnell most properly remarks, is to control the circulation with the minimum of pressure. In order to do this, the first instrument should be screwed up so that all pulsation ceases in the tumour, but still not so tightly as completely to arrest all the flow of blood through it. As the pressure

exercised by this becomes painful, the second one must be screwed tight, and then the first compressor may be slackened. In this way an alternation of pressure can be kept up without much pain or inconvenience. If possible, the patient should be taught how to manage the instrument himself, and will often find occupation and amusement in doing so. If, however, it excite much pain or irritation, as it does in some subjects, it may be necessary to give opiates. The pressure should, if possible, be continued during sleep; but, if it prevent the patient from taking his natural rest, the suggestion made by Tufnell, of unscrewing the instrument slightly, and, when the patient is asleep, gently tightening it again without awakening him, may advantageously be adopted; it is indeed surprising how very little unscrewing will relieve the pain of the compression. A large cradle should be placed over the patient's body, so that the weight of the bed-clothes may be taken off the apparatus, and that the patient may manage it without risk of disturbance. Should there still be much uneasiness, the instrument might be taken off for a few hours, and compression kept up in an intermittent manner. Even under such circumstances as these, consolidation of the sac may ensue.

The *Effects* upon the tumour vary considerably. In some cases it rapidly and suddenly solidifies; more commonly, however, this is a gradual process, the aneurism becoming more painful and solid, with less pulsation and bruit. As the solidification takes place, there is usually a good deal of restlessness, a feeling of general uneasiness, and of constitutional disturbance, which is best quieted by opiates. As the pressure is continued, and the tumour begins to harden, the anastomosing vessels enlarge, with a good deal of burning pain in the limb generally, and arterial pulsations in situations where usually none are felt. The abnormal pulsation, in these cases, is always found to occur in much the same situations, the same vessels appearing to undergo dilatation. Thus Tufnell has made a remark, which I have had more than one opportunity of verifying, that in the treatment of popliteal aneurism by compression, three arteries will be found to be enlarged, one of which passes over the centre of the tumour, another over the head of the fibula, and the third along the inner edge of the patella; he also states that the severe burning pain which is felt in these cases is owing to the artery accompanying the communicans peronei nerve being enlarged. After complete solidification of the tumour has taken place, the compression ought to be continued for at least forty-eight hours, so as to secure against the occurrence of a relapse.

The *Duration* of the treatment varies very greatly. In some cases the tumour has become solidified in a few hours or days. The shortest period in my own practice in which the aneurism has been cured, has been six days. In other instances, the treatment has required to be protracted for more than three months before a cure resulted. Of 26 cases of femoral or popliteal aneurism cured by compression in the London hospitals, the average time, according to Mr. Hutchinson, was nineteen days. Much of course will depend, in this respect, on the constitution of the patient, and on the condition of the tumour; those circumstances which are most favourable to the spontaneous cure of the aneurism will also influence the rapidity of the cure by compression.

Applicability.—Of the great value of compression in the treatment of aneurism there can be no doubt; yet it cannot be looked upon as taking the place of the ligature in the cure of this disease, except in those cases in which the tumour is situated in the arteries of the lower extremity below the middle of the thigh. In aneurisms occurring in the vicinity of the

trunk, as in the iliac, the carotid, subclavian, and axillary aneurisms, is quite inapplicable. Spontaneous aneurism is extremely rare in the lower extremity, and, as the traumatic forms of the disease which are generally required that the sac should be destroyed, it is seldom necessary to have recourse to it in this part of the body, though it has been successfully applied to the brachial artery.

The great question with regard to compression arises in the selection, to be whether it possesses any special advantages over the ligature in the treatment of femoral and popliteal aneurisms, to which its employment is commonly chiefly confined. The principal objections that have been urged against compression are, that its employment is more painful and tedious than the use of the ligature; and that those cases that are amenable to the ligature or that require amputation rather than it, are equally amenable to compression, and cannot be saved by the latter method.

To these objections I think it only with justice to answer, that the pain attendant on the employment of compression depends very much on the skill and care with which the operation is applied, and on the management, as well as upon the kind of instrument used, being certainly much diminished when Cartes's elastic compression is employed. With regard to the relative tediousness of the treatment under the two plans, I would appear that in reality there is but little difference: for although some cases, in which compression is used, are protracted over a considerable space of time, yet they do not occupy more than is often consumed when aneurisms of various kinds follow the use of the ligature, and in yet more many happens in compression, but can never occur after the employment of the ligature, that the patient is cured of his disease in a few days or two. Taking, however, the averages, we find that in the London cases the treatment lasted twenty-five days, and in the recent London cases one and nineteen, and this is not very different from what happens with the ligature, for, of 54 cases recorded by Crisp, in which the femoral artery was tied, the average time for the separation of the ligature was eighteen days, and if to this a week more be added for the closure of the wound, and for the treatment of the various accidents so often accompanying, and following, ligature, we should probably be within the mark, and yet only bring the duration of the treatment of the two methods to the same level.

After all, surgeons will eventually be guided in their estimate of the value of these two plans, not so much by the question of submitting their patients to a slightly more painful or tedious treatment, as to the comparative risk of life attendant upon one or other method. Upon this point the statistics have yet to be made; partly because cases of the treatment of aneurism by compression have not yet been sufficiently numerous, and partly because the unsuccessful cases of ligature have not been so commonly published as the successful ones. If, however, we compare the 32 cases of femoral and popliteal aneurism treated in Dublin up to February, 1851, as given by Dr. Bellingham (*Med.-chirurg. Transactions*, vol. 34), with the results of 188 cases of femoral and popliteal aneurism, recorded by Verreaux, in which the artery was ligatured, we shall find that of the 32 compression cases 26 were cured; in 1, the ligature was applied after pressure had failed, in 2, amputation was performed, in 1, death occurred from erysipelas, in 1, from chest-disease; and in 1 case the pressure was discontinued. Thus it would appear that 6 out of the 32 failed, being in the proportion of 1 to 5.3 cases, and 2 died, being in the ratio of 1 to 16. Of the 188 cases in which the artery was ligatured, 142 were cured, 46 died, 7 were amputated, in 10 the sac suppurated, and in 2 gangrene of the foot

occurred. Thus the deaths after ligature were in the proportion of 1 to 4, and the failures or serious accidents in that of 1 to 3, showing clearly a very considerable preponderance in favour of the treatment by compression. Besides this, in many patients who recovered after the ligature, various accidents, such as gangrene, erysipelas, secondary hemorrhage, &c., resulted as the direct consequences of the treatment; and these do not happen when pressure is employed.

If compression fail, ligature may often be advantageously applied; and, as has been shown by the known cases, with a better success than if compression had not previously been tried, that treatment having caused the collateral circulation to enlarge, and thus lessened the tendency to gangrene.

It should also not be forgotten that in some cases, such as when aneurism is complicated with heart-disease, or occurs in a very broken and unhealthy constitution, in which the operation necessary for the application of the ligature would scarcely or not at all be admissible, compression may be safely employed.

After carefully considering the relative merits of the two plans of treatment, I think we may conclude that, though in some few cases neither ligature nor compression can be adopted, and amputation is the sole resource, yet in others compression can be employed when it would not be safe to have recourse to the use of the ligature; and that in all ordinary cases of femoral and popliteal aneurism especially, compression should be preferred to the ligature, inasmuch as it is not a more tedious, and an infinitely safer method of cure. At the same time, it must not be forgotten that its success depends very greatly on the continuous care bestowed upon the case during the progress of the treatment.

FLEXION.—The treatment of aneurism by compression has of late been much simplified, and all apparatus dispensed with, by two methods; in one of which the artery and aneurism are compressed by the *flexion* of the contiguous joint, while in the other the artery is compressed by the finger alone.

The treatment of aneurism by the flexion of the contiguous joint is, of course, applicable in those cases only in which the disease is situated opposite to and inside the flexure of a joint, as in the popliteal cavity, at the bend of the arm, and possibly in the axilla. It is in cases of popliteal aneurism that this method of treatment is specially applicable; and the merit of first successfully employing it in this disease is undoubtedly due to Mr. Hart.

Nothing can be simpler than this plan. It consists in flexing the leg upon the thigh, so that the heel is brought up towards the buttock, where it is retained by a strap or bandage. The patient is at the same time confined to bed, and put under proper constitutional treatment. By this means, the popliteal artery being bent at an acute angle, the circulation through it is nearly, if not completely arrested; and the obstacle to the flow of blood is still further increased by the compression of the tumour between the posterior flat surface of the femur and the upper part of the calf. In this way the aneurism is most favourably situated for the consolidation of its contents, which, in the cases recorded, has taken place at an early period.

In order that this plan may be successfully carried out the limb should be bandaged, and then at first gently flexed, the bending being gradually increased as the patient can bear it. Great care should be taken not to make the flexion too forcible at first, and not to place the limb in a position that would be irksome or painful to the patient. The principle on which

the cure is effected in these cases appears to be, that by flexion the artery leading to and from the sac, and the aneurism itself, are so compressed that retardation of the circulation ensues, and deposition of laminated fibrine takes place in the usual way.

The compression by flexion, like every other method of treating aneurisms, occasionally fails. It is most likely to be attended by success in those cases in which the aneurism is small, situated low in the popliteal space, and in a young or middle-aged subject, who can bear the continued flexion without much inconvenience.

The good effects of flexion would probably be much increased by the simultaneous employment of digital compression. Should this method of treatment fail, compression by instruments or the ligature can be had recourse to as readily as they might have been in the first instance.

DIGITAL COMPRESSION.—The treatment by *digital compression* was first employed by Dr. Vanzetti of Padua. In this plan of treating aneurisms no apparatus of any kind is used; but the circulation through the artery leading to the tumour is controlled by the pressure of the finger. In order to carry it out efficiently there must be relays of assistants, each one of whom compresses the vessel for about ten minutes at a time. So soon as his fingers become fatigued, but before he relaxes the pressure, another assistant compresses the vessel; and thus the circulation through it may be uninterruptedly controlled. In this way aneurisms of the popliteal artery, in the orbit, at the bend of the arm, and even, it is said, in the groin, have been successfully treated—the tumour having in some instances become consolidated in a few hours. The effect of the treatment, and the rapidity of cure, would be increased by the application of direct pressure to the tumour, or by manipulation and by the previous employment of proper constitutional means. It might be very advantageously conjoined with the treatment by flexion; but its great advantage seems to be, that it is applicable to arteries at the root of the neck, to which it would not be possible to apply any kind of compressor, or when the surgeon is so placed as not to be able to obtain such an apparatus.

MANIPULATION.—Mr Fergusson has proposed to treat some aneurisms by a procedure which he terms *manipulation*. This consists in squeezing the aneurismal tumour in such a way as to detach a portion of the coagulum within it, which, being carried on with the current of blood into the distal end of the artery, obstructs this; and thus, by impeding the circulation through the sac, may lead to the gradual consolidation of the tumour. This procedure has as yet been employed to too limited an extent to enable us to form an estimate of its value, and can scarcely be considered, nor is it intended to be, of very general application. To aneurisms, however, that are not amenable to ordinary surgical treatment, and that must necessarily prove fatal if left, as those situated at the root of the neck, more particularly of the subclavian artery, it might possibly be advantageously applied. It is scarcely necessary, however, to point out the obvious danger of rupture of the sac, or of the diffusion of the aneurism on the separation of the coagulum, to make surgeons adopt due caution in carrying out this method of treatment. There is another danger also especially attendant on this procedure, when applied to aneurisms about the neck; viz., that the detached coagulum may be carried by the circulation into the cerebral arteries, and by obstructing them occasion the same kind of cerebral disturbance that occurs when these vessels become occluded by fibrous plugs—embolia. That this danger is a real and a great one, is evident from the fact that, in several cases in which manipulation of subclavian and carotid aneurisms has been tried, the patient

has been suddenly seized with syncope and hemiplegia. Mr. Trevis has successfully conjoined manipulation with compression in a case of popliteal aneurism, in which the pressure on the artery was slow in consolidating the tumour; the detachment of a portion of the coagulum almost at once led to the consolidation of the tumour.

GALVANO-PUNCTURE.—The attempt to procure consolidation of an aneurismal sac by the employment of electricity or galvanism is of comparatively recent date. It appears to have been first practised by Mr. B. Adams about the year 1832. Little attention, however, was given to this method of treatment until a few years back, when it was revived by some of the French and Italian surgeons, especially by Pétrequin and Burel. The principle on which this operation is conducted consists in endeavouring to procure coagulation in the aneurismal sac, by decomposing the blood contained in it by means of the galvanic current. In some instances the attempt to do so has induced inflammation of the sac and of the surrounding structures, and in all it must occasion the liability to this, as the change that it brings to be effected in the contained blood, consists not in the deposition of a fibrine, but in the coagulation of it *en masse*. It has of late been recommended to conjoin the employment of compression of the artery, either above or below the sac, with the transmission of the galvanic current through it, there being in this way less liability for the coagulum that is deposited to be broken down and washed away, than would happen if the contained blood were allowed to pass through the sac whilst it is in the act of forming.

The coagulation of the blood is effected by introducing two acupuncture needles into the sac in opposite directions, and keeping them in contact with one another, after connecting them with a galvanic battery of moderate tension; coagulum becomes deposited around one of the needles. The operation should be continued for periods varying from ten minutes to a quarter of an hour, and requires to be repeated several times. Pétrequin recommends that the direction of the current be changed from time to time, so that a number of clots may be formed in the sac. In this way a solid mass of coagulum may occasionally be formed in the tumour, so as to fill it up more or less completely, and to prevent the passage of blood through it. Occasionally it happens, however, that the blood has continued fluid, and the sac pervious, no coagulation having been effected; and in other instances, the amount of inflammation that has been set up in the sac has been so great as to give rise to its sloughing, to the occurrence of secondary hæmorrhage from it, and to the loss of the patient's limb or life. This inflammation may, in some cases, doubtless, have been the result of the injury inflicted upon the sac by the introduction of the needles, and by the charring of the tissues by them; but, in other cases, I think it probable that it may have taken place from the rapid coagulation of the contained blood, as occurrence which, as we have already seen, tends especially to inflammation, suppuration, and sloughing of the aneurismal sac. The pain of the operation is always very considerable; so much so, that patients who have been subjected to it once have refused to submit to a repetition of it.

Up to July, 1851, M. Bonnet had collected 23 cases of aneurism treated in this way; of these, 8 were of the brachial artery, 7 of the popliteal, 2 of the subclavian, and 1 of each of the following: the ophthalmic, the temporal, the carotid, the thoracic aorta, the ulnar, and one unknown. Of these the proceeding failed in 13 instances; 9 cases were reported as successful, but in 7 of these M. Bonnet states that doubts must be entertained both as to the results and as to the treatment, for the cure took place not by galvanism.

puncture alone, but in some by the conjoined influence of compression and the application of ice; and in others as the result of inflammation and supuration of the sac. There are consequently only two cases in which the cure can clearly be attributable to this means alone, and without the occurrence of any serious accident.

When we compare galvano-puncture with ligature or compression, in the treatment of external aneurism, it is, I think, impossible to hesitate for a moment in giving a decided preference to the latter modes of treatment. Not only is the principle on which it is attempted to procure obliteration of the sac in galvano-puncture a vicious and peculiarly dangerous one, viz., the coagulation of the blood, and the inflammation of the wall of the sac; but the results that have hitherto been obtained by this method are not such as would justify a prudent surgeon in submitting his patient to experiments of this kind, when he possesses so certain and comparatively safe modes of cure as those by deligation or compression. In internal aneurisms, or in those cases in which the disease is so situated at the root of the neck, that the artery can neither be ligatured with safety or compressed, galvano-puncture may perhaps be employed with some advantage, in conjunction with proper medical treatment.

INJECTION WITH PERCHLORIDE OF IRON.—The injection of aneurismal sacs with a solution of the perchloride of iron has also been practised, with the view of coagulating their contents; such treatment, however, is not only coarse and unscientific, but dangerous, and, when compared with the ligature or compression of the artery leading to the sac, must be looked upon as a retrograde step in surgery.

ARTERIO-VEINOS ANEURISM.

Preternatural communications between arteries and veins, though usually the result of wounds, occasionally happen from disease; ulceration taking place between the vessels, and thus causing an aperture to lead from one into the other. When such communications are of a traumatic character, they may, as has already been stated, constitute either an *Aneurismal Varix* or a *Varicose Aneurism*. As the result of disease, aneurismal varix only can occur, varicose aneurism never happening except as a consequence of wound. These spontaneous communications have been met with between the aorta and the vena cava, and between the iliac, femoral, carotid, and subclavian arteries and their accompanying veins. In nature, symptoms, course, and treatment, they so closely resemble traumatic aneurismal varix, described at page 189, that their consideration need not detain us here.

SPECIAL ANEURISMS.

CHAPTER XLII.

ANEURISMS OF THE THORAX, HEAD AND NECK, AND UPPER EXTREMITY.

ANEURISM OF THE THORACIC AORTA.

SYMPTOMS.—The symptoms of Intrathoracic Aortic Aneurism are of two kinds : *auscultatory* and *rational*.

The *Auscultatory Signs* vary greatly in distinctness, and even in presence. In some cases, more especially in fusiform aneurisms, they are almost from the first of a very marked and obvious character ; in others, especially in sacculated aneurisms, they are absent throughout, the aneurism terminating fatally without its existence having been determined by the stethoscope. They consist in murmurs of various kinds and degrees of intensity, bellows, rasping or whizzing ; in the second sound of the heart being audible over a greater space than normal ; and in the existence of dullness on percussion. These various signs may often be heard more distinctly upon or to the left side of the spine, than at the anterior part of the chest ; when occurring anteriorly, they are chiefly met with on the right side.

The value of the auscultatory signs in the diagnosis of aneurism within the chest is not perhaps so great as in many other thoracic diseases, in the early stages of the affection, and in those cases in which the aneurism continues small and sacculated throughout, or is so deeply seated as not to approach the parietes of the chest. This need not be a matter of surprise, when we reflect how deeply the ascending portion of the aorta and the arch are situated ; how they are covered in front by the lungs and loose cellular tissue, through which sound is with difficulty transmitted ; and how they are covered in behind by the spine and its muscles. When, in addition to this, it is borne in mind that aneurisms of the arch often prove fatal by bursting into contiguous cavities and canals before they have attained a greater size than a walnut or a pigeon's egg, and thus are incapable of furnishing a murmur of any very marked kind, it can be easily understood that the value of auscultation is but small in many cases of thoracic aneurism.

The *Rational Signs* of intrathoracic aortic aneurism are of three kinds .— Pressure Effects ; Pulsation ; and Tumour.

Pressure-Effects may be exercised on any of the contiguous structures ; and a glance at the anatomical relations of the thoracic aorta, more particularly the arch, will enable the surgeon to judge of their complexity and importance. They will necessarily vary according to the size of the aneurism and the portion of the aorta affected by it ; more according to the latter than the former condition. When the aneurism arises from the *root of the aorta*, and more especially when it is intrapericardial, it is usually of small size, and its pressure-effects will be little obvious. When the aneurism arises from the *termination of the arch*, or the *descending aorta*, it may often attain a considerable amount of development without any very obvious

pressure-effects being induced. Aneurisms that are situated *within the concavity of the arch* necessarily give rise to very severe effects, by the compression they must exercise upon some one or other of the very important structures that are spanned by and included within the aortic arch. When the *anterior part of the aorta* is affected, the aneurism may attain a very considerable bulk, even coming forward so as to project and pulsate between the intercostal spaces, without any very noticeable pressure-effects being induced. But when the *posterior wall of the artery* is the seat of the disease, then severe symptoms are early set up by the compression of the structures lying contiguous to the artery and along the spine. When the *upper part of the aortic arch* is the seat of aneurism, a peculiar train of cerebral symptoms, such as vertigo, insensibility, or defective vision, may be induced by its interference with the circulation through the carotids.

The pressure-effects that need chiefly engage our attention, are:—1, Pain; 2, Dyspnoea; 3, Dysphagia; and 4, Edema.

1. *Pain* is usually one of the earliest symptoms of intrathoracic aneurism, and is often of great value in a diagnostic point of view, as it is often most marked when the other symptoms are the least developed. It is generally more severe in sacculated than in fusiform aneurisms, and when the posterior rather than the anterior aspect of the vessel is the seat of disease. The pain, as has been pointed out by Dr. Law, is of two distinct kinds. The first kind is lancinating, intermittent, and neuralgic in its character, evidently dependent upon pressure on the spinal or sympathetic nerves. This pain is chiefly seated on the left side, and shoots up the side of the head and face, along the upper arm to the elbow, along the intercosto-humoral nerve, through the chest, or between the scapulae. The second form of pain usually occurs at a later stage of the disease, is continuous, and of a boring, hot, or burning character. It seems to depend upon the perforation of the tissues, more especially the bones, by the aneurismal tumour, and chiefly occurs on the right side of the chest.

2. *Dyspnoea* is of very frequent occurrence in intrathoracic aneurism; in all probability it is more uniformly met with than any other single symptom. It may arise from five distinct conditions, and its characters vary with its cause.

a. *From direct pressure on the trachea.* In these cases the dyspnoea is attended by much and constant wheezing, cough, often by whistling sounds in the chest, and by slow expansion of that cavity. There is usually expectoration of thick tenacious or ropy mucus.

b. *From direct pressure on a bronchus.* In these cases there are wheezing, cough, and some degree of expectoration, with perhaps diminished respiratory murmur in the side affected, and puerile respiration in the opposite lung, as has been pointed out by Dr. Stokes.

γ. *From pressure upon the lung.* In these cases the respiration is comparatively little interfered with, the spongy tissue of the lung accommodating itself and yielding to the pressure of the tumour. After a time, the pulmonary tissue will become incorporated with the wall of the sac; and then more serious difficulty in breathing, with hemoptysis, will supervene.

δ. *Dyspnoea* may be, and very commonly is, induced by *irritation, compression, flattening out, or stretching of the left pneumogastric and recurrent laryngeal nerves*, by the pressure of the tumour. In these cases the larynx becomes the seat of the difficult respiration, its muscles being driven into a state of spasm, so as to occasion paroxysmal attacks of intense difficulty of breathing.

The voice becomes hoarse, croupy, or croaking; the cough has a loud *crepitant* or metallic sound, and is attended by the expectoration of thin frothy mucus. The laryngeal spasm and stridor often do not occur in ordinary respiratory disease, but are produced under exertion, or in making the patient inspire fully and deeply. The laryngeal symptoms are sometimes so much more prominent than any of the other signs of intrathoracic aneurism, and so closely resemble chronic or even acute laryngitis, with impending asphyxia, that there are in a few cases in which surgeons have performed tracheotomy, on the supposition that they had to do with cases of pure and uncomplicated laryngeal disease, and in other instances this operation has been performed with the view of prolonging life, even when the dependence of the laryngeal spasm on aneurism of the aorta has been recognised.

4. Dyspnoea may be dependent on the compression of the pulmonary vessels by the aneurismal tumour. In cases of this kind there would be considerable lividity of surface, and signs of pulmonary congestion.

The dyspnoea of aneurism will often be sufficiently intense to occasion death. It may be mistaken for ordinary asthma; but the diagnosis is usually effected by observing that in aneurism the paroxysms of dyspnoea often come on in the day as well as at night, and are greatly increased by change of position, as by placing the patient either upright or recumbent, the tumour thus shifting its point of pressure. It is not, as Dr. Beilingham has pointed out, influenced by atmospheric changes, and is generally associated with laryngeal stridor. When such symptoms as these are associated with pain and dysphagia, they point very strongly, even in the absence of auscultatory signs, to the presence of an aneurismal tumour.

Aneurisms situated within the concavity of the aortic arch are those which, either directly by their pressure on the air-tubes or the pulmonary veins, or indirectly by the influence they exercise on the recurrent laryngeal nerve, are chiefly associated with dyspnoea.

3. *Dysphagia* is a symptom of sufficiently frequent occurrence in aortic aneurisms, Dr. Eaton having determined its existence in nine out of twelve cases. It seldom occurs, however, in the earlier stages of the disease, or when the aneurism is small, and hence is of much less diagnostic value than dyspnoea. When, however, it is associated with that symptom, the combination becomes important; as the co-existence of the two conditions clearly points to the compression of the œsophagus and the air-tubes by a tumour, which other diagnostic signs may prove to be aneurismal.

It is of importance to bear in mind that in some aneurisms, especially of the descending thoracic aorta, dysphagia may be one of the most marked signs. In such cases as these, stricture of the œsophagus has erroneously been supposed to exist, and the patient has even been treated by the introduction of bougies on this supposition,—an error of practice that has terminated fatally by the perforation of the aneurismal sac, where it projected against the œsophagus, by the point of the instrument.

The difficulty in deglutition in cases of compression of the œsophagus by aortic aneurism, is almost invariably referred to the episternal notch. The dysphagia is commonly associated with pain, or with the sensation of a cord drawn tightly around the body.

4. *Edema*, with more or less lividity of the upper extremities and head and neck, occasionally but rarely occurs. It is generally most marked on the left side, and arises from the compression of the superior vena cava or the innominate veins by aneurisms springing from the fore or upper part of the arch.

Pulsation and Tumour, in intrathoracic aortic aneurism, so far as they

are observable externally, are always absent in the early stages of the disease, and very frequently continue so throughout the progress of the affection; indeed, in aneurisms springing from the intrapericardial aorta or the concavity of the arch, death usually takes place, either by rupture into one of the serous cavities or the air-tube, or by the exhaustion induced by dyspnoea, long before the aneurism has attained a sufficient size to be cognisable externally. There are, however, three portions of the thoracic aorta which, when affected by aneurism, yield external evidence by the existence of pulsation or tumour of the true nature of the disease. These are—1, the anterior aspect of the ascending aorta; 2, the summit of the arch; and 3, the posterior aspect of the descending aorta.

1. When the aneurism is situated in the *anterior aspect of the ascending aorta and commencement of the arch*, pulsation may be detected by pressure between the intercostal spaces on the right side of the sternum, and a thrill, as well as distinct impulse, may often be felt over that side of the chest, before any external tumour becomes visible; thus simulating the beat of the heart, in addition and opposite to the seat of the true cardiac impulse. As the aneurism increases in magnitude, an external tumour appears, the wall of the chest becoming absorbed and perforated opposite the point of greatest impulse.

2. When an aneurism springs from the *summit of the arch*, a pulsating tumour appears at the root of the neck, behind or even above the margin of the sternum, most commonly towards the right side, and occasionally rises so high out of the thorax, and is so distinctly felt in the neck, as to run the risk of being confounded with aneurism of the brachio-cephalic or carotid arteries (Fig 207, p. 628). This error may be avoided by the impossibility of tracing with the finger the lower boundary of the tumour, and the existence of distinct dullness on percussion, possibly of impulse or of auscultatory evidence of aneurism, below the level of the upper margin of the sternum or clavicle.

3. When aneurism springs from the *posterior wall of the descending aorta*, a pulsating tumour may gradually develop itself to one side of the spine or under the scapula, commonly on the left side; and it may attain an excessive development, fully as large as the head, before the patient is destroyed by the rupture of the tumour externally.

TREATMENT.—The treatment of intrathoracic aneurism must be conducted on those principles that have been laid down at pp. 593—595.

ANEURISM OF THE INNOMINATE ARTERY.

Aneurisms of this artery may be either of the tubular or the sacculated kind, and usually give rise to a train of serious and dangerous symptoms, from their pressure upon important parts in their neighbourhood. Indeed, a glance at the relations of this artery will show the important effects that must be produced by the pressure of a tumour springing from it. Before it lie the left innominate vein and the superficial cardiac nerve; to its left is found the trachea, and more posteriorly the oesophagus; on its right are the innominate vein of that side, and the summit of the costal pleura; externally and posteriorly it is in relation with the pneumogastric, and more posteriorly and internally it lies before the right recurrent laryngeal nerve.

SYMPTOMS.—The general symptoms of an aneurism of this artery are the existence of a pulsating tumour of a globular shape behind the right sterno-clavicular articulation, attended with pain, and perhaps oedema of the right side of the face and arm, with some difficulty in respiration, laryngeal cough, and dysphagia. The tumour is usually soft and compressible, filling up

more or less completely the hollow about the sternum, and even rising as high in the neck as the lower margin of the cricoid cartilage; it pushes forwards, first the sternal, and afterwards the clavicular portion of the sterno-mastoid muscle, and has occasionally been seen to extend into the posterior inferior triangle of the neck; and, in deed, is generally more distinctly defined towards its brachial aspect. In some cases it is limited into the neck, but the sternum, clavicle, and costal cartilage of the first rib are found to be considerably pushed forwards beyond their natural position. In the space around the right sterno-clavicular articulation, and above the upper part of the sternum, there will be dulness on percussion. In very many instances there is no bruit, but merely a strong impulse with the heart's sounds, as distinct or even more so than in the cardiac region, and in other cases there is every variety of bruit.

Pressure-Effects.—The most important symptoms are occasioned perhaps by the pressure-effects of the tumour upon the neighbouring parts, affecting the pulse, the venous circulation, the nerves, respiration, and deglutition.

The *pulse* is usually influenced, being much smaller and feebler in the radial artery of the affected than of the sound side, and in some instances being completely arrested; owing, doubtless, to the occlusion of the sub-clavian. The pulsation in the right carotid and its branches is also frequently much less powerful than in the opposite vessel. These signs commonly occur before any external tumour is seen or can be felt, and hence constitute an important element in the early diagnosis of the disease.

Enlargement of the superficial veins of the neck and right upper extremity is of frequent occurrence, the external jugular being the vessel that is usually first dilated; at a more advanced period the superficial subcutaneous veins of the upper part of the right side of the chest often become tortuous, and form a dense plexus in this situation, while many anastomose with the cephalic and thoracic veins above, and the superficial epigastric below. As the pressure increases, oedema commences in the right eyelids and face, and may speedily extend to the whole of the head, face, and arm, which become hard and brawny in consequence of serous infiltration. In one case I have seen the left arm become suddenly cedematous, the left axillary vein being pressed upon. In these cases the eyes become staring and prominent, and the lips, nose, and features livid and turgid with blood, as well as cedematous, so as to greatly alter the expression of the countenance.

Pain of a dull aching character is experienced in the situation of the tumour, from the compression of the neighbouring structures. But, early in the disease, and among some of the first symptoms, the patient often experiences sharp shooting pains, apparently of a rheumatic or neuralgic character, in the arm and the side of the head and face, arising from pressure upon, and irritation of, the cervical and brachial plexuses of nerves. Taking up course of the ascending and descending filaments of the cervical plexus, the pain shoots up the side of the head and neck, over the shoulder and upper part of the chest; or, from pressure upon the brachial plexus, it radiates down the hand and arm, being usually especially severe about the elbow and fingers. The muscular power of the right arm also commonly becomes impaired.

Dyspnoea is of very common occurrence, and of very varying degrees of intensity, from slight difficulty in breathing up to fatal asphyxia. It may proceed either from irritation of the larynx, in consequence of compression of the recurrent nerve; or from pressure on the trachea or on the right bronchus. When it depends on laryngeal irritation, the voice is hoarse, husky, or whispering; and there is a dry, croupy, and paroxysmal cough, usually accompanied by expectoration of frothy serous mucus. In these cases, the

death the recurrent nerve will be found to be stretched out and greatly elongated by the pressure of the tumour (Fig. 203). Compression of the trachea, which becomes flattened and curved over to the left side by the protrusion of the tumour, is a common cause of dyspnoea, and is not unfrequently associated with the laryngeal irritation. More rarely by far, the right bronchus is compressed by the extension of the tumour downwards.

Dysphagia is of sufficiently frequent occurrence, and varies from slight uneasiness in deglutition to an impossibility in swallowing anything except fluids. I have never seen it occur without having been preceded by dyspnoea; and, in every instance that has fallen under my observation, it has been associated with laryngeal irritation. This coincidence of these two symptoms is readily explained by the anatomy of the parts, the recurrent nerve, lying between the artery and oesophagus, must suffer compression before the mucous canal can be interfered with.

Prognosis.—The prognosis of brachio-cephalic aneurism is in the highest degree unfavourable, though the disease frequently does not run a rapid course. If it extend upwards and outwards, the tumour may acquire a very large size before any very important organ or part is implicated; but if it press backwards and inwards, it may prove fatal at an early period. I know of no case in which such an aneurism, if left to itself, has undergone spontaneous cure, and but few instances in which the rupture of the sac has taken place. The most frequent cause of death is asphyxia, from spasmodic closure of the larynx induced by irritation of the recurrent nerve; or from pressure on the trachea.

Treatment.—There are several instances on record in which a properly conducted course of constitutional treatment has cured a patient; thus a case of Mr. Luke's was permanently cured by small and repeated bleedings, conjoined with the administration of digitalis. In connection with such treatment, distal pressure might be employed, as in a case that derived benefit from this plan in Mr. Syme's hands.

In aneurism of the innominate, the vessel is so short and the sac so situated that it is impossible to attempt to apply a ligature on the cardiac side of the tumour. What resource, then, does surgery offer in these cases beyond the employment of constitutional and dietetic means? It may be answered to this, that if these measures fail in arresting the disease, our choice must be between two alternatives; leaving the patient to his fate, or having recourse to the application of the ligature on the distal side of the tumour. On looking on the innominate artery with reference to the distal operation, we are struck by two peculiarities in the vessel, which must necessarily modify to a considerable extent not only the seat of the operation, but the principle on which it is conducted. The first peculiarity to which I allude is the shortness of the trunk, which makes it impossible to apply the

Fig. 203.—Aneurism of the Innominate Artery compressing and stretching the Recurrent Laryngeal Nerve and pushing the Trachea to the Left Side. (Back view.)

ligature to the vessel itself, but renders it necessary to deligate one or both of its terminal branches. The other peculiarity is, that under no circumstances can these vessels be so ligatured as to arrest the whole of the blood sent into the artery; for, although the circulation through the carotid may be entirely stopped, yet it is impossible, from the seat and extent of the disease, to tie the subclavian at any point except beyond the scaleni; hence that blood which is destined for the supply of the branches of this vessel—the vertebrals, the thyroid axis, the internal mammary, and the first intercostal—must continue to be propelled into and through the sac. Three distinct modifications of the distal operation have been proposed and resorted to for the cure of aneurisms in this situation: 1. Ligature of the Subclavian alone; 2. Ligature of the Carotid alone; and 3. Ligature of both Vessels with an interval of greater or less extent.

1. *Ligature of the Subclavian only* (Fig. 204, p. 624) has been practised in three cases, the results of which are exhibited in the accompanying Table; two were fatal, and the partial success of the third may be fairly attributed in a great measure to the accident of the carotid having been occluded. The results of this practice have certainly not been sufficiently favourable to justify the surgeon in repeating an attempt of this kind, opposed as it is to the known principles on which the distal operation effects a cure. For supposing, as we may safely do, with Mr. Wardrop, that only one-third of the blood that is sent into the innominate finds its way through the extrascapular portion of the subclavian, the remainder being destined for its branches and the carotid in equal proportions, what fact can be adduced or principle laid down from which we can expect to obtain the cure of an aneurism in close proximity to the heart, by cutting off so small a proportion as one-third of the supply of the blood sent into it?

ANEURISMS OF INNOMINATA TREATED BY LIGATURE OF SUBCLAVIAN ONLY.

OPERATOR.	SEX	AGE	RESULT.	CAUSE OF DEATH	REMARKS.
1. DUPUYTREN.	m	40.	Died on ninth day.	Exhaustion, following cough, and secondary hemorrhage.	Subclavian ligatured immediately above clavicle, tumour diminished, but pulsations continued. Aneurism of subclavian, with dilatation of innominate and aorta.
2. LAUGIER.	m	57	Died a month after operation.	Asphyxia.	Vessel ligatured immediately above clavicle. Aneurism of brachio-cephalic; aorta was dilated, and right carotid obliterated by the pressure of the tumour.
3. WARDROP.	f.	45	Died two years after operation.	Exhaustion.	Subclavian ligatured beyond scaleni, the pulsations in size of tumour diminished and respiration became freer, on the ninth day pulsation reappeared in right carotid, in which it had previously been absent. (We may regret the absence of operation to this circumstance.)

2. *Ligature of the Carotid only* (Fig. 205, p. 624) has been practised in nine cases, as recorded in the annexed Table, and in one case only does the disease

ANEURISMS OF INNOMINATA TREATED BY LIGATURE OF CAROTID ONLY.

OPERATOR.	SEX.	AGE.	RESULT.	CAUSE OF DEATH.	REMARKS.
1. EVANS.	m.	30.	Recovered living in 1863—thirty four years after operation.		Tumour diminished for a few days after operation, but at end of seven days it had increased of the sac not m, followed by obliteration of arteries of right arm and the branches of the carotid. At the end of a year tumour still existed, with constant pulsation. Next year the sac suppurated, and discharged much pus.
2. MOTT.	m.	55.	Died seven months after operation.	Asphyxia.	After operation, radial pulse on affected side disappeared; and tumour in neck was much diminished. After death, no external appearance of tumour, internally it was as large as a double fist.
3. ASTON KEY.	f.	61.	Died a few hours after operation.	Narrowing of vertebral arteries; brain not receiving sufficient blood for its functions.	Aneurism of innominata and of arch of aorta found. The orifice of left carotid nearly occluded, and vertebrals smaller than natural.
4. FERGUSON.	m.	56.	Died on seventh day.	Pneumonia.	Tumour and pulsation decreased after operation. Tumour nearly filled with firm laminated coagulum; no plug in carotid.
5. MORRISON.	m.	42.	Recovered from operation died twenty months afterwards.	Suddenly; cause not stated.	Aneurism of innominata and carotid found. Arch of aorta diseased. Right carotid dilated into a sac as high as part ligatured, and plugged by dense fibrinous laminae.
6. CAMPBELL.	m.	48.	Died on nineteenth day.	Pneumonia.	Tumour began to disappear after the vessel was ligatured. After death, aneurism of innominata and transverse portion of arch, and dilatation of aorta as far as diaphragm.
7. HUTTON.	m.	47.	Died on sixty-sixth day.	Bronchitis, inflammation, suppuration, and ulceration of sac into trachea.	Tumour diminished after ligature. Size and pulsation less. After death, tumour contained purulent matter, and grumous blood, had opened into trachea. Right carotid and subclavian contained firm coagula.
8. DU WRIGHT (Montreal.)	m.	70.	Died on sixtieth day.	Hemiplegia.	Tumour solidified by laminated fibrine. Subclavian pervious, with canal through tumour leading to it.
9. BROADBENT.	m.	50.	Died on one hundred and sixtieth day.	Exhaustion from secondary hemorrhage.	No alteration produced in tumour by the ligature. Secondary hemorrhage recurred several times.

appear to have been materially benefited; and in that instance the good effects can scarcely be attributed to the operation, but must rather be looked upon as an effort of nature to effect a spontaneous cure, the sac becoming inflamed and suppurating, and the arteries of the arm and head on the side affected undergoing obliteration. Mr. Key's patient died in consequence of the left carotid becoming occluded, and the brain being deprived of its proper supply of blood.

3. In three cases both the Carotid and Subclavian Arteries have been tied

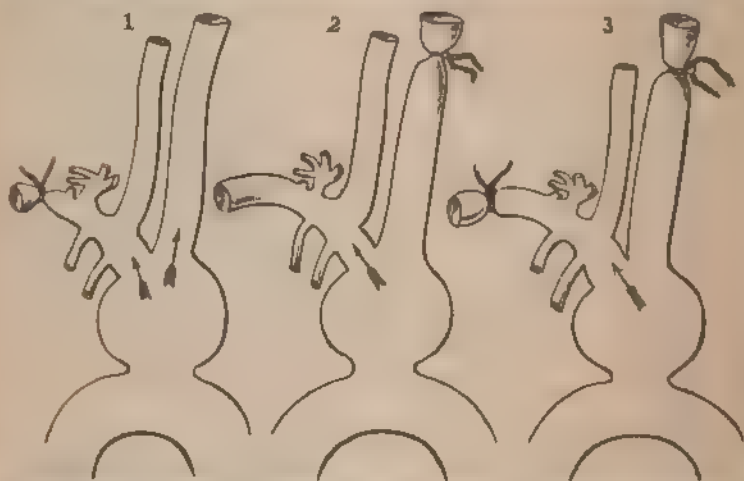

Fig. 204 — Brachio-cephalic Aneurism. Ligature of the Subclavian only.

Fig. 205 — Brachio-cephalic Aneurism. Ligature of the Carotid only.

Fig. 206 — Brachio-cephalic Aneurism. Ligature of the Subclavian and Carotid.

(Fig. 206). In the most favourable of these, that by Fearn, two years elapsed between the ligature of the carotid and that of the subclavian; the patient dying three months after the second operation: the sac was apparently filled with laminated conglulum, and appeared to be undergoing spontaneous cure. The

ANEURISMS OF INNOMINATA TREATED BY LIGATURE OF CAROTID AND SUBCLAVIAN.

OPERATOR.	SEX	AGE	CAROTID LIGATURED	SUBCLAVIAN LIGATURED	REMARKS.
1. FEARN.	f.	28.	Aug. 30th, 1836.	Aug. 2nd, 1838.	Died three weeks after second operation from pleurisy. Sac of aneurism of innominate filled with dense organised conglulum; except a channel of the size of artery for the passage of the blood.
2. WICKHAM	m.	55.	Sept. 25th, 1839.	Dec. 3rd, 1839.	Tumour diminished after ligature of carotid, and dyspnea ceased for a time, but symptoms returning, subclavian was tied. Relief of symptoms ensued, but tumour increased, and patient died two and a half months after first bursting of sac.
3. ROAST.	Carotid and subclavian simultaneously.		Death in six days. Occlusion of left carotid and right vertebral arteries—circulation of brain carried on by left vertebral merely.

third case is remarkable as being the only instance in which both the vessels were tied simultaneously, and from the patient having lived for six days after the occlusion of all the arteries supplying the brain except the left vertebral.

A *résumé* of the cases of aneurism of the innominate, in which the operation of ligaturing one or both arteries beyond the sac has been performed, having thus been given, the question arises whether these operations, or any of them, should retain a place in surgery. This question may be examined in two points of view: 1. As to the principle on which these operations are performed; and 2. As to their results in practice. For the success of the distal operation, it is requisite either that there be no branch given off from the sac, nor between it and the ligature; or that the current of blood through the sac be at least so far diminished as to admit of the deposition of laminated fibrine in sufficient quantity to fill it up, by a process similar to what happens in a case of aneurism treated by the Hunterian method. In order that this may be accomplished, it is certainly necessary that the greater portion of the blood passing through the sac be arrested; for if the current that is still kept up be too free, the tumour will continue to increase, as we have seen happen in cases of inguinal aneurism in which the femoral artery has been ligatured below the epigastric and the circumflex ilii, the current through which has been sufficient to feed the sac in such a way that a cure could not be accomplished. If, therefore, but one of the vessels leading from the brachio-cephalic, as the subclavian beyond the scapular, be tied, and but a third of the blood circulating through the main branch be arrested, are we justified in hoping that the circulation through the sac will be so influenced by the deprivation of this small quantity, that the remaining two-thirds of the blood, which will still pass through for the supply of the carotid and the branches of the subclavian, will gradually deposit those fibrinous laminae by which obliteration of the tumour is to be effected? Should we not rather expect that the larger current will be too powerful to allow the formation of these layers, and will continue to distend the sac in such a way as to prevent its contraction? Surely, if the comparatively small and feeble streams of blood, that pass through the epigastric and circumflex ilii, are sufficient to interfere with the cure of an inguinal aneurism after the distal ligature of the femoral, the strong current that sweeps through the carotid and the large branches springing from the subclavian, with the full force derived from close proximity to the heart, will be sufficient to prevent all lamination in an aneurism of the innominate. That the arrest of the circulation through one of these vessels only is not sufficient to influence materially the growth of the aneurism, is evident likewise from what is not unfrequently observed after death in cases of this kind—one or other of the vessels being found compressed and obliterated by the pressure of the sac, and yet no alteration in the tumour resulting. These cases, which are tolerably numerous, would of themselves have been sufficient to prove that something more than this amount of obstruction is required, in order to effect proper stratification of fibrine in the sac; and if we turn to the result of the eleven cases in which either the carotid or the subclavian has been ligatured, we shall find that in one case only, that operated on by Mr. Evans of Belper, has a cure been effected; and in this instance how was it accomplished? According to the principle on which it was attempted to be established! Certainly not; but, as will be seen by attention to the details of the case, and as has already been pointed out with much acuteness by Mr. Guthrie, by the accidental setting up in the artery of inflammation, which extended to the sac, and thus obliterated it.

In the only case (that of Mrs. Denmark) in which Mr. Wardrop tied the

subclavian for the cure of aneurism of the brachio-cephalic, there is some reason for doubt whether the arrest of the progress of the tumour was owing to the ligature of the subclavian artery, or whether it was not much influenced by the obstruction which existed in the carotid for nine days after the operation, during which time so abundant a deposit of laminated fibrine might have occurred as to arrest the progress of the disease for some length of time. In this case, also, Mr. Guthrie supposes it probable that the obliteration of the tumour might have led to its inflammation.

From a careful consideration of all the circumstances of the cases in which ligature of one vessel only has been employed for brachio-cephalic aneurism, we are, I think, fully justified in concluding that in seven of the cases the fatal result was accelerated, occurring as a consequence of the ligature of the vessel; in two the progress of the disease was in no way interfered with; in one it was arrested, the patient living for two years; and in one case only the disease was cured. The improvement in the last two cases was the result of accidental circumstances, which were unexpected, and unconnected in any way with the principles on which the operation was undertaken. These results would not, in my opinion, justify any surgeon in again undertaking either of these operations.

We have yet to consider the operation in which both arteries are ligatured. This double operation may either be performed with an interval between the application of the two ligatures, sufficient for the establishment of a collateral circulation; or the two vessels may be ligatured simultaneously. The former plan has been adopted in two cases; the latter in one only—not a sufficient number for any safe deduction. In one of the two cases in which an interval intervened between the two operations (that by Mr. Fearn), the tumour seems to have undergone a cure, being filled with dense laminated fibrine; but the patient died eventually of pleurisy. In the other case (by Mr. Wickham) no good results followed the operation, death occurring from bursting of the tumour. In the case in which both vessels were ligatured simultaneously, death occurred in consequence of the left carotid and right vertebral being accidentally occluded, and the cerebral circulation being then solely dependent on the left vertebral. As I have just said, these cases are not sufficiently numerous or free from modifying circumstances to enable us to draw any inference from them: we must therefore revert to the principle on which this operation should be undertaken. This will differ materially, according to whether the two arteries are ligatured simultaneously, or with a sufficient interval for the re-establishment of collateral circulation.

If an interval of two years, as in the first case, or even of two-and-a-half months, as in the second instance, be allowed to elapse between the ligature of the carotid and that of the subclavian, the operation reduces itself essentially to that of the ligature of a single artery, which, as has already been shown, is insufficient to induce those changes in the sac that are necessary for the accomplishment of a cure. If the patient survive the effect of the ligature of the carotid for a few weeks, sufficient time will be afforded for the proximal end of the subclavian, the vertebral artery, and the thyroid axis to have taken upon themselves a great increase of development, —the collateral circulation being carried on by them and not by the left carotid; so that by the time that the subclavian comes to be ligatured beyond the scaleni, the sac will still continue to be traversed by a current of blood for the supply of the branches of the subclavian, dilated to much beyond their normal size, in consequence of the task of supplying the right side of the neck, face, head, and brain being principally thrown upon them.

This current through the proximal end of the subclavian, increased as it will have been by the whole of that blood which is destined to supply the place of that which should pass by the carotid, will place the sac in nearly the same condition as if the subclavian also had been ligatured; and will consequently, for the reason that has already been given, be too powerful for us to expect a cure to take place in the course of its stream.

It now remains for us only to consider the simultaneous ligature of both vessels—an operation that has been but once performed, and then under such circumstances as to preclude our reasoning upon it, the patient having died from accidental occlusion of the left carotid and right vertebral arteries. In reasoning upon the simultaneous ligature of the two vessels, we must consider two points:—1. In what condition do we place the sac? 2. Is the danger of the patient much increased?

So far as the sac is concerned, it is impossible to place it in a better condition for the deposit of fibrinous matter; two-thirds of the blood flowing through it being arrested, and that only traversing it which is destined for the supply of the branches of the subclavian. It is by no means improbable that even this stream may yet be too large and forcible to allow the process of occlusion to take place, yet it is impossible still further to diminish it; and if the aneurism be sacculated, and project from one side of the artery, particularly to its internal or mesial aspect, it is by no means impossible that it may be sufficiently removed from the stream to allow of consolidation of its contents.

Would it add to the danger of the patient to ligature these two vessels simultaneously rather than separately? I think not. If the risk of a double operation is to be incurred, I cannot think that it would be positively increased by the two being performed at once, instead of at separate intervals; the whole of the vessels that serve to maintain the collateral circulation in the head and upper extremity—the vertebral, inferior thyroid, suprascapular and posterior scapular, and cervical—being left without interference.

ANEURISM OF THE CAROTID.

ANEURISMAL VARIX OF THE CAROTID ARTERY AND OF THE JUGULAR VEIN, as the result of punctures and stabs in the neck, has been met with in a sufficient number of instances to establish the signs and treatment of such a condition; and an instance is related by Mr. Mackmurdo, in which a communication was established between these vessels as the result of disease; but I am not acquainted with any case of *Varicose Aneurism* of these vessels having been recorded. The *Signs* of aneurismal varix in this situation present nothing peculiar; and the *Treatment* must be entirely of a hygienic character, no operative interference being likely to be attended by any but a fatal result. It is the more desirable not to interfere in these cases, as the disease does not appear to shorten life.

SPONTANEOUS ANEURISM OF THE CAROTID is not of very unfrequent occurrence: in Dr. Crisp's table of 551 aneurisms, 25 were of the carotid; and it ranks in order of frequency between those of the abdominal aorta and of the subclavian. It occurs more frequently in the female than any other external aneurism; thus, of the 25 cases alluded to, 12 were in women, owing probably to its seldom being the result of violence, but generally arising from disease of the coats of the vessel. This aneurism is also remarkable as occurring at earlier ages than most others: thus, Hodgson has seen it in a girl of ten; and Sykes, of Philadelphia, in one of eighteen. The right carotid is much more commonly affected than the left, and the upper portion of the vessel than the lower; indeed, the bifurcation is the

most common seat of aneurismal dilatation. The root of the right carotid not uncommonly is dilated; but I have never seen or heard of a case in which the left carotid, before emerging from the chest, has been affected.

SYMPTOMS.—A carotid aneurism in the early stage presents itself as a small, ovoid, smooth tumour, with distinct pulsation and bruit, and a well-circumscribed outline. It is commonly soft and compressible, diminishing in size on pressure, and expanding again with the usual aneurismal dilatation. As it increases in size, it becomes more solid, occasions shooting pains in the head and neck, and by its pressure on the pharynx, œsophagus, and larynx, produces difficulty in deglutition and respiration, when the salivary glands are much irritated. After a time, the cerebral circulation becomes interfered with, giving rise to giddiness, impaired vision in the corresponding eye, noises in the ear, and a tendency to stupor. These symptoms may each be owing to compression of the jugular, or to difficulty in the transmission of the blood through the tumour. The size that these aneurisms may attain varies greatly: usually they are confined to the space under the angle of the jaw, but not unfrequently they may occupy the greater part of the side of the neck. If they be allowed to increase without interference, death may happen, either by rupture externally, or into the pharynx or œsophagus; by asphyxia, from pressure on the larynx or recurrent nerve; or by starvation, from compression of the œsophagus.

DIAGNOSIS.—The diagnosis of carotid aneurism is without doubt more

difficult than that of any other form of internal aneurism: the best proof that it is, may, I think, be found in the fact that, out of 39 recorded cases in which the carotid artery has been ligatured for supposed aneurism of it or its branches, in 8 instances no such disease existed—solid cysts, or other tumours of the neck, having been mistaken for aneurism, and this by surgeons of great and acknowledged repute.

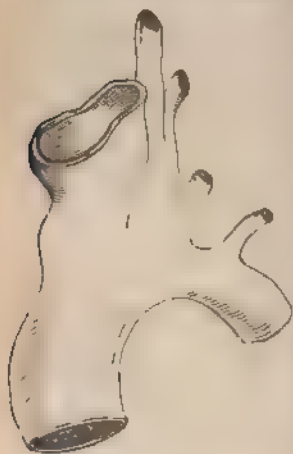

The diagnosis of aneurism of the lower part of the carotid from similar disease of other arteries at the root of the neck, as of the subclavian, vertebral, and brachio-cephalic, and the arch of the aorta, is surrounded by difficulties, which can only be cleared up by a careful stethoscopic examination of the part. In some aneurisms of the arch of the aorta, the sac rises up into the neck, so as closely to simulate a carotid aneurism, as in the annexed cut (Fig. 207); and this greatly

FIG. 207.—Aneurism of the Arch of the Aorta, simulating Carotid Aneurism.

increases the difficulty of the diagnosis. The principal affections of the neck, however, with which aneurism of the carotid may be confounded, are varix of the internal jugular, enlarged lymphatic glands, abscess, tumours, cysts in the neck, and pulsating bronchocele.

From varix the diagnosis may readily be made by attention to the following circumstances: that in varix the tumour is always soft; does not pulsate expansively; and diminishes in size during a deep inspiration, and on compressing the vein on its distal side.

Glandular tumours of the neck are often very difficult to distinguish from aneurism, more particularly when the artery passes through and is embraced by the tumour, so that the whole mass distinctly moves at each pulsation.

In these cases also there may be an apparent diminution in the size of the tumour on compression, by the artery within it being emptied, or by the growth receding into some of the cellular interspaces of the neck. But in the great majority of instances, attention to the globular, oval, and nodulated feel of glandular swellings, the possibility of raising them up and pushing them away from the vessel, which may best be done by feeling the carotid with the ends of the fingers of one hand, and then pressing upon the tumour with the other, will clear up the true nature of the case.

From *abscess of the neck* the diagnosis must be made on general principles: the coexistence of ill-defined hardness and of enlargement of the glands, of an inflamed state of the skin, the ready detection of fluctuation, and the absence of expansive pulsation in the tumour, will show that it is not aneurismal, however similar its other characters may be. It is also of importance to observe that an aneurism that fluctuates is always forcibly distended with strong pulsation, and can be materially diminished by pressure, neither of which circumstances can possibly occur in abscess. But if abscess may be mistaken for aneurism, the converse also holds good; and an aneurism may, unless care be taken, be mistaken for abscess—a far more fatal error. And there is one variety of false aneurism, that to which Mr. Liston has invited special attention, against which the surgeon must be carefully on his guard, on account of the many points of resemblance between it and aneurism: I mean the case in which an artery has given way into the sac of an abscess. In this case, fluctuation and pulsation will exist, although not perhaps of a distending kind. An important diagnostic mark will be, however, that the outline of an aneurism is distinctly defined and limited, while that of an abscess never is. Aneurism of the internal carotid has been found by Syme to simulate very closely *abscess of the tonsils*.

Tumours of various kinds—carcinomatous, fatty, and elastic—may occur in the neck, and cause some little embarrassment in the diagnosis from aneurism: thus Lisfranc, O'Reilly, and Kerr of Aberdeen have recorded cases in which the artery has been ligatured in such cases by mistake for aneurism. The diagnosis of such tumours as these must be effected on ordinary principles. I have in several instances met with a small, hard, distinctly circumscribed tumour, lying directly upon the carotid artery, and apparently connected with it and receiving pulsation from it, usually produced by a fit of coughing or laughing. This tumour, with the true nature of which I am unacquainted, remains stationary, and does not require any operative interference.

The thyroid body is not unfrequently the seat of pathological changes, that have been and may be mistaken for aneurism. These consist chiefly in a limited circumscribed enlargement of one of the lobes of the gland, which extends laterally over the common carotid, and receives pulsation from it. The most puzzling cases, however, and those in which mistakes may most easily be made, are instances of *pulsating bronchocele*, in which these tumours have an active and independent pulsation or thrill. In these instances, however, there are three points that will almost invariably enable the surgeon to effect the diagnosis. Thus the tumour, although principally confined to one lateral lobe, always affects the isthmus more or less. Then again, in bronchocele, that portion of the tumour is most firmly fixed which stretches towards the medial line; whilst in carotid aneurism the firmest attachment is under the sterno-mastoid muscle. The third point of difference is that, on desiring the patient to make an effort at deglutition, the enlarged thyroid body moves with the pharynx and trachea, and when it is

raised from the neighbourhood of the vessels, the pulsation in it ceases, whilst no effect is produced on an aneurism. *Cysts in the thyroid body* are of more common occurrence than pulsating bronchoceles, and sometimes equally difficult of diagnosis. Dupuytren has pointed out that, when these cysts are tapped, the pulsation often becomes stronger, and the fluid, which on first flowing is of a serous character, may at last become pure arterial blood, so that the surgeon may suspect that he has punctured an aneurismal tumour.

Aneurisms of the carotid are usually of slow growth, and may sometimes exist for a considerable number of years without giving rise to any special inconvenience: this is more particularly the case when they are seated at the bifurcation of the artery; when at the root, they are more likely to be attended by injurious pressure effects.

TREATMENT.—Since the time when Sir A. Cooper first ligatured the carotid, in 1805, the only means on which the surgeon relies for the cure of aneurism of this vessel is deligation of the artery at a distance from the sac. When the aneurism is so situated that a sufficient extent of healthy vessel exists between the sternum and the base of the tumour to admit of the application of a ligature, the Hunterian operation may be practised. If, however, the root or lower portion of the artery be so involved that there is no room to apply the ligature between the heart and the seat of the disease, the distal operation may be performed.

LIGATURE OF THE CAROTID.—When the surgeon can choose the seat at which to ligature the artery, he usually selects the part of the vessel which bisects the angle formed by the anterior edge of the sterno-mastoid with the omo-hyoid muscle. The artery is reached by making an incision, about three inches long, over its course upon the anterior edge of the sterno-mastoid, which is the directing line and a sure guide to the artery. After dividing the integument, the subcutaneous fascia, and cellular tissue, the sheath of the vessel is exposed. This must then be carefully opened, any branches of the descendens noni being avoided, and the ligature passed from without inwards, between the vein and artery. In performing this operation, subcutaneous vessels are occasionally wounded, which may bleed pretty freely; if so, they should be ligatured. When the sheath is opened, the jugular vein sometimes swells up considerably, so as to obscure the artery; but by being drawn aside with a retractor, or compressed by the assistant's finger, all difficulty from this source will cease. The pneumogastric is not seen, being drawn aside with the vein. If the aneurism have attained a very considerable size, extending low in the neck, and not leaving, perhaps, more than one inch of clear space above the clavicle for the surgeon to operate in, the difficulties are necessarily very greatly increased; and here the best plan will be to divide the tendon of the sterno-mastoid muscle, so as to give additional space. The external portions of the sterno-hyoid and sterno-thyroid muscles may likewise be cut across for the same purpose. The jugular vein in this situation lies considerably to the outside of the artery.

After ligature of the carotid artery, the blood is so freely conveyed to the distal end of the vessel, by the free communication subsisting between the arteries of opposite sides within the cranium, that a continuance and return of pulsation in the sac is of common occurrence. This condition, however, usually disappears after a time by the gradual consolidation of the tumour, and indeed may generally be looked upon as a favourable sign; being very seldom associated with those cerebral symptoms that, as will immediately be explained, commonly prove fatal after this operation. It is interesting to

observe that the collateral supply, after the ligature of the common carotid, is not afforded by any of the branches of the corresponding vessel of the opposite side, but by the subclavian artery of the same side. In a case related by Porter, in which the right carotid had been tied, the subclavian and vertebral arteries on the same side were enlarged to at least double their natural diameters, and the chief communications outside the skull took place between the superior and inferior thyroid arteries, which were enlarged; whilst inside the cranium the vertebral took the place of the internal carotid.

Suppuration of the sac is not of very uncommon occurrence after the ligature of the carotid for aneurism—sometimes even after so considerable an interval as eight months, as happened in a case related by Post. In the majority of these instances, the patient eventually does well; but death may result by the tumour pressing upon the pharynx and larynx, or by the occurrence of secondary hemorrhage, which may take place either from the part to which the ligature has been applied, or from the suppurated sac. In the first instance, it usually occurs about the period of the separation of the ligature; in the second, it may happen at a considerably later period, even after many weeks. Besides these, which may be looked upon as the ordinary accidents following the application of a ligature for aneurism, deligation of the carotid artery occasionally gives rise to serious and even fatal disturbance of the circulation within the cranium.

Effect on the Brain of Ligature of one or both Carotids.—Many experiments have been made by Mayer, Jobert, and others, upon the lower animals, with the view of determining the effect produced on the brain by the ligature of the carotid arteries. But the deductions from these are of no value whatever when applied to the human subject, for the simple reason (which appears to have been strangely overlooked), that in many of the lower animals on which the observations were made, as the dog and rabbit for instance, the common carotid arteries are of secondary importance so far as the cerebral circulation is concerned, being destined principally for the supply of the external parts of the head—the brain deriving its chief supply from the vertebrals, whilst in other animals, as the horse, the brain derives nearly the whole of its blood from the carotids, and but a very small quantity from the vertebrals. Hence, in one case the carotids may be ligatured without danger, whilst in the other their deligation is inevitably fatal. On turning to the result of observation on the human subject, we find, according to Norris, that of 140 instances in which the carotid artery was ligatured 32 were fatal, 18 of the deaths resulting from cerebral disease. The proportionate frequency of deaths from this condition, according to the cause that led to ligature, may be seen by reference to the following table:—

TABLE OF LIGATURE OF CAROTID FOLLOWED BY FATAL CEREBRAL DISEASE.

CAUSE OF LIGATURE.	NUMBER OF CASES.	DEATHS FROM CEREBRAL DISEASE.	DEATHS FROM OTHER CAUSES.
Aneurism	33	7	5
Wound	30	6	2
Erectile and other Tumours	42	1	5
Excision of Tumours	18	1	1
Cerebral Affections	6		
Distal Operation	15	1	1
	140	18	14

By this it will be seen that the most common cause of death after ligature of the carotid, is cerebral disease induced by the operation (as was, I believe, first pointed out by Dr. N. Chevers), and that this result appears to have followed the Hunterian more frequently than the distal operation. We should necessarily expect that, in those cases in which both vessels had been

CASES OF LIGATURE OF BOTH CAROTIDS.

OPERATOR.	AGE.	DISEASE.	DATES OF LIGATURE.	RESULTS.
1. PRESTON.	...	Epilepsy.	Right carotid tied Aug. 23; left carotid, Nov. 14.	Recovered.
2. PRESTON.	...	Epilepsy.	Tied at interval of month.	Recovered.
3. MACGILL.	...	Fungous tumour of both orbits.	Interval of a month.	Recovered.
4. MUSSEY.	20	Aneurism by anastomosis of scalp.	Left carotid, Sept. 20; right carotid, Oct. 2.	Recovered.
5. LANGENBECK.	...	Hemorrhage from superior thyroid.	Both at the same time.	Died next day.
6. MOLLER.	4½	Erectile tumour.	Sept. 13, and Jan. 28.	Recovered.
7. KÜHL.	53	Aneurism by anastomosis of scalp.	Left carotid first; right, forty-one days after.	Recovered, convulsions after each operation.
8. MOTT.	..	Disease of carotid.	Interval of fifteen minutes.	Coma, and death in a few hours.
9. ELLIS.	..	Secondary hemorrhage following gunshot.	Interval of four-and-a-half days.	Cured.
10. J. M. WARREN.	..	Erectile tumour of face.	Tied left, October 5; right, Nov. 7.	Cured.
11. VESPEAU.	29	Aneurism by anastomosis of both orbits.	Right carotid first, August, 1839, left, about three months afterwards.	Recovered.
12. BLACKMAN.	15	Fungus of nasal fossæ.	Right first; left, three weeks later.	Temporary loss of vision of left eye: recovery.
13. MUSSEY. (2nd case)	..	Erectile tumours.	Left first; right, one month after.	Temporary derangement of vision: recovery.
14. ROBERT.	...	Aneurism by anastomosis of forehead.	An interval of eight months.	Headache: temporary disturbance of vision: recovery.
15. ULLMANN.	20	Erectile tumour of orbit.	Left tied first; right one year afterwards.	Death on third day by hemorrhage.
16. BURNORF.	34	Aneurism by anastomosis and wound.	Left tied for the aneurism, five years afterwards the right, for a suicidal wound.	Disorganisation of right eye: recovery.
17. DUPUYTREN and R. BERT.	...	Aneurism by anastomosis of scalp.	Right carotid tied by Dupuytren in 1819, left by R. Bert for extension of disease, in 1867.	Delirium, hemiplegia of left side, and death.

ligatured, there would have been a greater tendency to cerebral disturbance than in those in which one only had been deligated. It would however appear, as is shown by the foregoing table (p. 632), that of seventeen instances in which the double operation has been performed, death happened but in two cases from this cause; while in another, in which convulsions took place, a fatal result did not occur, and three other cases were attended by mere temporary disturbance of vision.

After a careful examination of this subject, I think we are warranted in coming to the following conclusions. 1. Ligature of one carotid artery is followed by cerebral disturbance in about one fifth of the cases, more than one-half of which are fatal. 2. When both carotids are ligatured *simultaneously*, death has hitherto always resulted; as in the two cases in which Mott and Langenbeck ligatured these vessels, with an interval of but a few minutes between each operation. 3. When the two carotids are ligatured, *with an interval of some days or weeks*, the operation is not more frequently followed by cerebral disturbance than when only one is tied. 4. Pathological investigation has shown that, if the vessels be gradually and successively obliterated, the patient may live, although one carotid and one of the vertebral arteries have been occluded by disease and the other carotid ligatured, as in a case related by Rossi. 5. As in a case recorded by Dr. Davy, an individual may even live for a considerable time, though both carotids and both vertebrales be occluded—the cerebral circulation being maintained through the medium of the anastomoses of the intercostals and internal mammary arteries.

The frequency of the occurrence of cerebral disturbance, after cutting off the supply of blood sent to the brain through one or both carotid arteries, is well brought out in the statistics collected by Ehrmann. He finds that of 187 cases, in which one carotid was tied, in 42 instances cerebral disturbance of some kind ensued. If to these be added the cases in which both carotids were tied, and those in which the brachio-cephalic was ligatured, we get a total of 213 cases, of which 47 were attended by cerebral symptoms—or as nearly as possible 22 per cent.

The *Cerebral Symptoms* that arise from the ligature of one or both carotids may be such as depend upon a diminished supply of blood sent to the brain; consisting of twitchings, tremblings, or convulsive movements, syncope or giddiness, with paralysis, sometimes with complete homiplegia of the side opposite to that of the ligatured vessel, troubled vision, and deafness. In other cases, they appear to arise from increased pressure upon the brain—drowsiness, stupor, coma, and apoplexy supervening. To a third order of symptoms belong those that are of an inflammatory character, usually coming on a few hours after the operation.

The cause of these symptoms is certainly the disturbance of the cerebral circulation, induced by the ligature of the carotid. When a considerable portion of the supply of blood to the brain is suddenly cut off, two sets of symptoms may ensue—one *immediate*, the other *remote*. The immediate symptoms are those that generally result from functional disturbance of the brain, consequent upon too small a supply of arterial blood. They consist of syncope, trembling, twitches, giddiness, impairment of sight, and at last hemiplegia. After this condition has been maintained for a few days, the nutrition of the organ becomes materially affected, and softening of the cerebral substance takes place; giving rise to a new and more serious set of symptoms indicative of this pathological condition, such as convulsions, paralysis, and death. In other cases congestion may come on either by the interference with the return of blood through the jugular vein, or as a con-

sequence of that venous turgidity which we so commonly observe after the ligation of a main arterial trunk ; or perhaps coma may be induced by apoplectic effusion into a softened portion of the organ.

Inflammation of the brain may come on immediately after the application of the ligature, being apparently at once induced by the disturbance of the circulation. In other cases it occurs at a later period, as the result of alteration in the structure of the organ.

Effects on the Lungs.—Besides the brain, the lungs are not uncommonly secondarily affected after ligation of the carotid. To this condition special attention has been directed by Jobert and Professor Müller. The lungs appear to become greatly congested, and have a tendency to run into a low form of inflammation. The cause of this congestive condition of the lungs is extremely interesting. It cannot be owing to the simple obstruction of the passage of the blood through the carotid causing a disturbance in the balance of the circulation, and thus a tendency to internal congestion ; for if this were the cause, we ought to meet with it generally after ligation of the arteries of the first class. Nor can it be owing to any injury sustained by the eighth nerve during the deligation of the artery ; as in many of the instances in which it is stated to have occurred, there was no evidence of that nerve having been exposed or damaged, and every reason to believe the contrary, from the known skill of the operators. I am rather inclined to look upon the unusually frequent occurrence of pulmonary congestion after ligation of the carotid, as a secondary condition consequent upon a derangement in the functions of the brain and modulla oblongata, primarily induced by the disturbed state of the circulation through that organ : for we know that any cause which depresses the activity of the nervous centres tends to diminish proportionately the freedom of the respiratory movements, and thus, by interfering with the due performance of the act of respiration, disposes to congestion of the lungs, just as we observe to happen in injuries of the head, in apoplexy, and in the operation of the sedative poisons. It would appear from the detail of some of the recorded cases, as well as from Jobert's experiment, that blood-letting is of considerable service in the removal of this condition, and should consequently not be omitted.

LIGATION OF THE CAROTID ON THE DISTAL SIDE OF THE SAC.—Aneurism of the carotid artery, occurring low in the neck, does not admit of the application of a ligature on the cardiac side of the tumour. What, then, is to be done in such a case as this ? Should it be left to the remote chance of a spontaneous cure, or should it be subjected to surgical interference ? Spontaneous cure in carotid aneurism has never yet, I believe, been met with. The surgeon, therefore, must endeavour to treat the disease by ligation. Two plans of treatment are open to him—either to deligate the innominate artery, or to tie the carotid on the distal side of the tumour. The first alternative may fairly be set aside ; for not only are the cases in which it is possible to find room between the sternum and the sac extremely rare, but, even were such an instance to present itself, no surgeon would, I think, be justified in undertaking an operation which has never yet succeeded in the most skilful hands ; we are consequently reduced to the alternative of ligaturing the artery on the distal side of the sac. But although this operation is the only alternative that presents itself, yet its application in practice is attended by serious difficulties and perplexities ; for the surgeon must be able to satisfy himself that it is actually an aneurism of the root of the carotid with which he has to do, and that it is not the trunk of the innominate or the arch of the aorta that is affected. The difficulty in doing

this is far greater than would at first appear ; for, on examining the details of eight cases in which the distal operation has been performed for supposed carotid aneurism, three must be excluded ; as, after death, the tumour was found to arise from the aortic arch. In the annexed table will be found the

ANEURISMS OF ROOT OF CAROTID TREATED BY LIGATURE ON DISTAL SIDE.

OPERATOR.	SEX.	AGE.	RESULT.	CAUSE OF DEATH.	REMARKS.
1. WARDROP.	f.	63	Recovered.	Tumour diminished until fifth day ; then inflamed, suppurated, and burst. The patient recovered, and was alive three years after operation.
2. LAMBERT.	f	49	Successful so far as aneurism was concerned	Hemorrhage from upper part of artery.	Tumour diminished after operation, and became consolidated ; sac filled with firm coagulium, an lower part of artery closed, ulceration into artery, just above part ligatured ; vessel dilated where ligatured.
3. BUSH.	f.	36	Recovered.	...	Asphyxiation was imminent before operation ; tumour became rapidly diminished after ligature. Alive three years afterwards.
4. COLTON DE NOYON.	f.	63	Recovered.	Tumour and pulsation diminished. Alive and well three years afterwards.
5. LANE.	m.	35	Died 68th day.	Inflammation of lungs.	Tumour filled with layers of coagulium. Ulcerated opening communicating with apex of left lung.

result of five cases, in which the carotid artery has been tied for aneurism of its root on the distal side of the sac. I have excluded a sixth case, as there is reason to believe that in it the artery was not ligatured, but a portion of the sheath accidentally tied instead—an accident, by the way, which Sédillot has witnessed, and which Norris relates also to have occurred at the New York Hospital, and which I have known happen to a most excellent surgeon in the case of ligature of the femoral.

On analysing the five cases in which the trunk of the common carotid has been ligatured on the distal side of an aneurism of the root of that vessel, there are several points of interest that arrest our attention. Thus we find that in every case the tumour, immediately on the ligature being tightened, underwent a considerable diminution in its bulk, with corrugation of the integuments covering it, and considerable subsidence in the force of its pulsations. In one case—that of Bush—respiration, which before the operation had been attended with great difficulty, became easy ; and in another (that of Wardrop) inflammation of the sac, unattended however by any bad consequences, took place. It is not safe to deduce any general conclusion from so small a number of cases ; yet the result of these is so uniform, that I have no hesitation in stating it as my opinion that, whether we regard the principle on which this operation is founded, the amount of success which has hitherto attended it, the necessarily fatal result of these cases if left to themselves, or the absence of any other means that hold out

a reasonable hope of benefit, the surgeon is justified in resorting to the ligature of the trunk of the common carotid on the distal side of the sac, in cases of aneurism limited to the root of that vessel.

ANEURISM OF THE INTERNAL CAROTID.

The Internal Carotid Artery may be the subject of aneurism before or after it has passed through the carotid canal and entered the skull. The symptoms of these two classes of cases differ necessarily in almost every respect, as likewise do the termination and the susceptibility of the case to surgical interference.

EXTRACRANIAL ANEURISM.—When an aneurism affects the trunk of the internal carotid before its entrance into the skull, the symptoms presented by this disease do not materially differ from those of aneurism at the bifurcation, or of the upper part of the common carotid, except in one important respect, which was I believe first pointed out by Porter of Dublin—viz., tendency to the extension of the tumour inwards towards the pharynx, and to its protrusion into that cavity. The reason of this is obvious: when we consider the anatomical relations of the internal carotid artery, we at once see that its pharyngeal aspect is that which, if one may so term it, is the most superficial, and that between it and the surface the smallest amount of soft part intervenes—nothing lying between the vessel and the mucous membrane except the thin paper-like constrictor, some lax cellular tissue, and a few filaments of the superior laryngeal nerve; whilst externally there are interposed between it and the integument the layers of the cervical fascia, the margin of the sterno-mastoid, the digastric and three styloid muscles, and the styloid process.

When dilatation, therefore, of the vessel takes place, it has a necessary tendency to push forwards that part of its covering where it meets with least resistance; and this being to the pharyngeal side, more or less prominence will consequently be found in this cavity. In a case that occurred to Mr. Syme, this was especially well marked, the aneurism of the internal carotid simulating closely an abscess of the tonsil. In two cases related by Porter in the seventeenth volume of the *Dublin Journal of Medical Science*, this was one of the most marked features: the "appearance of the tumour (as seen by the mouth) were most alarming; the pulsation could be distinctly seen, and the blood almost felt under the mucous membrane; it seemed ready to give way and burst into the mouth every moment."

TREATMENT.—The treatment of these cases does not differ from that of aneurisms connected with the carotid arteries, and seated at the upper part of the neck; but we are not in possession of a sufficient number of facts to enable us to determine with any degree of precision what the result of surgical interference in them is likely to be. If we could give an opinion from the limited number of cases at present before the profession, we should feel disposed not to entertain a very favourable opinion of the result of the Hunterian operation, as applied to aneurism of the internal carotid outside the skull. This is doubtless owing to the situation of the aneurism against the mucous membrane of the mouth, being such that the surrounding tissues do not exercise a sufficient amount of pressure against the sac after the ligature of the vessel to allow the efficient deposition of lamellated coagulum, and consequent occlusion of the artery leading into it, which, in accordance with the principles that have been laid down in speaking of the Hunterian operation, are necessary to success.

INTRACRANIAL ANEURISM.

Aneurisms within the Skull may arise from any of the arteries that are met with in this situation, though some are much more liable than others to the occurrence of this disease. Of 62 cases noticed by Dr. Gull, the basilar artery was the seat of disease in 20 cases, and the middle cerebral in 15. In 8 of the remaining cases, the internal carotid was affected as it lay by the sella Turcica; and in 6 others the anterior cerebral artery was the seat of aneurism. The vertebral arteries and their branches were affected in 28 cases, and the carotids and their branches in 34.

The greater frequency of this disease in the basilar artery may probably be dependent on its large size, and the consequently greater impetus of the blood to it.

CAUSES.—The causes of intracranial aneurism are very obscure. It might be supposed that the comparatively small diameter of the arteries within the skull would render them little liable to the occurrence of spontaneous aneurism, were it not that the anatomical characters and physiological relations of these vessels predispose considerably to the occurrence of this affection; there being no other set of arteries in the body of the same size as these within the skull in which spontaneous aneurism so frequently occurs. This can only be accounted for by the thinness of their coats and the want of an external cellular sheath rendering them unable to support the increased pressure from within, to which they are occasionally subjected in consequence of the alteration in pressure of the cerebral circulation at different periods, the result of some variation in the relative quantities of the different fluids within the skull, or of determination of blood to the brain. This would more particularly be the case if their natural elasticity had already been impaired by the occurrence of atheromatous or other degeneration of their coats. As these changes are the natural consequences of advance in age, we shall find the tendency to the occurrence of this disease increase with advancing years. Thus, according to Dr. Gull, of 58 cases in which the patient's age is given, we find only 12 cases which occurred in persons under twenty-five, 5 of the patients being under twenty; of the remaining 46 cases, 13 occurred in persons under forty; of the remaining 33, 29 were met with between forty and sixty, and 4 in persons above sixty. Of the 58 cases, 35 were males, and 23 females.

The immediate exciting cause of the disease is most commonly involved in obscurity: sometimes it may be traced to a blow on the head, to a fall or concussion, or to excess in drinking; but more frequently the symptoms manifest themselves suddenly, without being in any way attributable to such external influences, and occur in vigorous and apparently healthy persons.

PATHOLOGY.—Intracranial aneurisms are almost always formed by the uniform dilatation of the whole of the calibre of the artery—the false or sacculated variety being rarely if ever met with: I am not acquainted with any instance of this. The coats of the arteries in this situation being very thin, and unprovided with any external cellular sheath that would support the impetus of the blood, rupture of the vessel would rather occur than partial dilatation, if one portion only of the circumference were diseased. Occasionally, though rarely, the dilatation is fusiform; when this does occur, it is probably confined to the basilar artery.

The disease would appear to be of slow growth, and the sac sometimes becomes filled with lamellated coagula so completely as to occlude the orifice of the artery from which it springs.

The size that aneurism in this situation attains before death results is sometimes considerable : thus, in a case of aneurism of the basilar artery, that occurred some years ago at the University College Hospital, the tumour was nearly as large as a walnut ; in another case, in the same hospital, it somewhat exceeded this size. Dr. R. W. Smith, in the *Dublin Journal of Medical Science*, vol. xxv., mentions a case of multilocular aneurism of the left posterior cerebral artery as large as a small apple ; and Serres, one as large as a hen's egg. On the other hand, they occasionally prove fatal by rupture before having reached more than a very small size—not larger than a pea or a nut.

It is seldom that more than one of the arteries of the brain suffer aneurismal dilatation. In the Museum of the College of Surgeons, however, are the preparations (Nos. 1687 and 1688) of an aneurismal dilatation of both internal carotid arteries, resembling "two bulbs about five-eighths of an inch in diameter, filling up the hollow on each side the sella Turcica, which were evidently dilatations of the carotid arteries ; and from their being filled with laminae of coagulated blood, there could be little doubt of their being aneurisms of these arteries. The one on the left side was the largest ; that on the right side communicated with the cavity of the artery, which was not the case with the other."

A case occurred in University College Hospital some years ago, under the care of Dr. Thomson, in which a somewhat similar condition existed. A man, forty nine years of age, had fallen on his head some months before admission into the hospital. Since then he had been garrulous, silly, and very irritable—becoming readily intoxicated. He suddenly became insensible and comatose, with vomiting and laborious breathing ; he could close both eyes, but the right pupil was dilated ; the left side was paralysed. He was treated for apoplexy, and became slightly better, but died in ten days from the first attack.

On examination, an aneurism a little larger than a hazel-nut was found on the trunk of the right carotid, where it gives off the middle cerebral artery, and another small one on the course of that artery. There was a globular aneurism on the corresponding artery of the opposite side ; the basilar artery was thickened, white, and opaque, as were also the other larger arteries of the brain ; there was softening of both anterior cerebral lobes, especially the right one.

The arteries of the brain are very commonly healthy in these cases. Out of four instances of intracranial aneurism that have fallen under my observation, the other vessels of the brain have been healthy in three cases, and atheromatous in but one. In one case I have seen aneurism within the skull associated with aneurism elsewhere—in the thoracic aorta.

PRESSURE-EFFECTS.—The pressure exercised by an aneurismal sac situated within the skull is always exclusively directed against the yielding cerebral substance, which is often extensively disorganised. The bones of the skull, however close their proximity to the sac may be, frequently escape, and seldom suffer much. This peculiarity in the effects of aneurism in this situation may be partly owing to the very dense and compact character of the inner layer of the skull, but is doubtless principally due to the very soft and yielding nature of the contents of the cavity. Absorption of the subjacent bone, however, sometimes takes place to a limited extent ; thus in one case (Moore's), the body of the sphenoid bone was indented and partially absorbed.

The parts comprised in each case will vary according to the situation of the tumour. But those that principally suffer are necessarily those seated

at the base of the brain, and forming the floor of the lateral ventricles. In Moore's case, one of the optic nerves was flattened by the pressure of the substance of the anterior lobe; the lamina perforata, the roots of the olfactory tract, the anterior part of the corpus striatum, and a considerable quantity of the neighbouring white matter of the anterior lobe, were removed. In a case by Lager, the portio dura of the right side was paralysed from this cause. In Dr. R. W. Smith's case, the floor of the third ventricle, the tuber cinereum, and the origins of the optic and olfactory nerves, suffered; the optic nerve of the opposite side was flattened and softened.

Besides the changes that take place in the cerebral substance as the result of pressure, important lesions may be met with as the effect of the interruption which the presence of the aneurism offers to the circulation in and nutrition of the cerebral hemispheres. Thus, in the case of aneurism of both internal carotids that has already been referred to as occurring at University College Hospital, there was white softening of both the anterior cerebral lobes; and this lesion was most marked on the side that corresponded to the largest aneurism, and where consequently, it may be supposed, the greatest amount of obstruction to the circulation existed.

SYMPTOMS.—The symptoms of aneurism within the skull are extremely equivocal; and, indeed, aneurism of large size may exist at the base of the brain without occasioning any symptoms whatever. An interesting instance of this occurred at University College Hospital in 1848. A man, thirty-seven years of age, died of pulmonary apoplexy and chronic pneumonia of the left lung, consequent upon the pressure of an aneurism of the commencement of the descending aorta on the pulmonary veins of that side. In examining the head after death, an aneurism of the basilar artery as large as a hazel-nut was met with, of which no suspicion had been entertained during life, there having been no head-symptoms whatever; the sac of the aneurism was very thin, and there was much atheromatous degeneration in the vertebral arteria.

The only symptoms that are of constant occurrence, when this disease goes on to a fatal termination, are those of hemiplegia and apoplexy. These may come on suddenly without any previous warning; or they may be preceded by a train of phenomena indicative of the existence of chronic disease within the cranial cavity.

The most constant of these phenomena is pain; which affects, however, great variety, both in extent and in character. It may be diffused, or may occupy a fixed point; it may be continuous or intermitting; it may be increased by movement, or accompanied by peculiar sensations, as of pulsation or of opening and shutting the top of the cranium.

The sight and hearing are often impaired. Dimness of sight, dilatation of one or both pupils, photophobia, diplopia, and loss of vision have been noticed in several of the cases recorded; ptosis has also been met with, from pressure on the third nerve by aneurism of the posterior communicating artery. Buzzing noises in the ears, and deafness, are also not uncommon symptoms; deafness, more particularly, appears to be a phenomenon of frequent occurrence.

The patient rarely loses the power of articulation and of deglutition; impairment of these functions, however, has been met with.

There may be paralysis of the side of the face, shaking palsy, or complete hemiplegia; or fits of an epileptic nature may occur. The mental condition may undergo changes indicative of chronic disease of the brain. There may be depression of spirits, listlessness, or, as was noticed in the case above

related, the temper may become irritable, and the patient be garrulous or silly. Insanity has been noticed in one case. As is always the case in cerebral affections, the gastric functions are often impaired.

But very frequently no premonitory symptoms manifest themselves; the patient being suddenly seized, when apparently in good health, with apoplexy, which terminates rapidly in death.

In some cases the presence of aneurism has been detected by a loud rough or "whizzing" noise being heard on the application of a stethoscope over one side of the head, and, perhaps, being audible to the patient. This sign, however, exists in but few cases; but when it does occur, it is unquestionably the most pathognomonic of all. I am not aware that it has been met with in any form of cerebral disease except intracranial aneurism.

Thus it will be seen by a reference to this list of symptoms that, with the exception of the whizzing noise, no special signs are afforded by aneurisms within the skull, which will enable us to distinguish between the symptoms occasioned by their presence and those of other tumours of the brain, and of organic cerebral disease.

CAUSES OF DEATH.—The fatal termination may occur from one of four causes.

1. The tumour may exercise such pressure upon the whole cerebral mass as to occasion death. This mode of termination is rare. I am acquainted with one case of this description, which is reported by Dr. Ruschenberger. The symptoms in this case were very remarkable, consisting of complete hemiplegia of the left side, with involuntary antero-posterior vibration of the head and body, and paralysis agitans of the right leg. The patient slept heavily, with loud anoring; he ate voraciously, but occasionally had considerable difficulty in deglutition and articulation; his intellect was clear, but very slow. After death, an aneurism of the basilar artery as large as a pigeon's egg, and containing an irregular very hard dry clot of blood, was found pressing on the pons Varolii. The sac had given way at one point, extravasation taking place into the substance of the pons, which was softened, and of a bluish colour.

2. The most frequent mode in which death takes place in these cases is by the sudden rupture of the sac and the extravasation of its contents into the cavity of the arachnoid and the meshes of the pia mater at the base of the brain, or into the lateral ventricles—either from the aneurism projecting into them and there giving way, or rupturing into these cavities by breaking down the intervening cerebral substance. When this mode of termination occurs, there are occasionally no warning nor premonitory symptoms of any impending danger; the patient being, apparently in good health, struck down by an attack of apoplexy which is speedily fatal. More frequently a series of those symptoms, that have already been mentioned as attending many cases of this disease, precede the fatal event for a longer or shorter time. When rupture of the sac and extravasation of blood takes place, death is inevitable; at least I am not acquainted with any case in which the appearance found after death converted me to the belief that the patient had even temporarily recovered from this condition.

Death from rupture of the sac appears to be most frequent in younger subjects. In the latter periods of life, aneurism is commonly associated with atheromatous disease of the vessels generally, which may cause death by softening and effusion of blood. According to Dr. Guil, of 20 cases occurring in persons under thirty-five years of age, 16 (or 80 per cent.) were fatal from rupture of the sac; while in 37 cases over thirty-five, death occurred from this cause in only 14, or 38 per cent.

3. Death may result from another cause than the pressure of the aneurismal sac or its rupture and the extravasation of its contents—viz., from softening or disorganisation of the substance of the brain to a greater or less extent, in consequence of the obstruction offered to the passage of the blood through the aneurismal vessel. In the case of aneurism of both carotids, already mentioned as having occurred at University College Hospital, this was the case; both anterior cerebral lobes were affected with white softening, and this condition was especially observable on that side on which the aneurism was largest.

4. Lastly, death may be produced by the mere irritation occasioned by the pressure of one or more aneurismal tumours within the cranium. Of this an interesting example is afforded by the history of a case of aneurism of both external carotids, contained in the Museum of the College of Surgeons, and related by Sir G. Blane in the *Transactions of the Society for the Improvement of Medical and Chirurgical Knowledge*, vol. ii. p. 192. In this case the patient, a lady aged 69, had suffered for four years from attacks of giddiness, headache, and imperfect vision; about sixteen months before her death she became insane, recovered, and then relapsed twice in the same state. After having regained her senses for some months, she became affected with giddiness, redness of the eyes, and violent maniacal delirium, which continuing for some weeks caused her death.

After death the following appearances were found. "Upon examining the body, there was no appearance in the brain itself that could in any way account for the symptoms. There was, indeed, a greater quantity of fluid than common in the ventricles, and the surface of it was moister than it is usually found in a sound state; but in all other cases which have occurred to me of organic affections of the brain proving fatal, except those which are sudden, such as apoplexy, there has been a preternatural quantity of fluid in its ventricles. There were also spicula of bone in the membrane forming the falx. The inner substance of the crura cerebri was of a brown colour, and more tender than natural. The optic nerves were smaller than natural, as if they had been wasted. The septum lucidum was more than usually dense.

"But the morbid appearance in this case, which was so singular, and to which the symptoms of complaint seem chiefly referable, was two bulbs, about five-eighths of an inch in diameter, filling up the hollow on each side of the Sella Turcica, which were evidently dilatations of the carotid arteries, and, from their being filled with laminae of coagulated blood, there could be no doubt of their being aneurisms of these arteries. The dissection was made by Mr. Hunter, assisted by Mr. Home, in the presence of Dr. Jenner and myself, and all concurred in the opinion that these tumours were aneurisms. The one on the left side was the largest. That on the right side communicated with the cavity of the artery, which was not the case with the other."

TREATMENT.—In the treatment of intracranial aneurism there is usually little to be done, the nature of the case not being sufficiently obvious in the majority of instances to justify active measures. Should, however, the loud rough whiz be distinctly audible over one side of the head, more especially about the base of the skull, or by application of the stethoscope to the mastoid process, and should symptoms of cerebral compression begin to manifest themselves, ligature of the carotid artery on the affected side may with propriety be practised. This has been successfully done in a most interesting and instructive case of intracranial aneurism by Mr. Coe of Bristol.

INTRAORBITAL ANEURISM.

Intraorbital Aneurisms were for a long time considered by surgeons to be of the nature of erectile tumours; but the error of this opinion has been pointed out by Mr. Busk, and more recently by Mr. Nunneley, who has conclusively shown that, except in those very rare cases in which a pulsating tumour of the orbit has been congenital, or has appeared shortly after birth, or has been associated with *naevoid* tissue developed in the eyelids, it must be looked upon as being a circumscribed aneurism. The vessel affected appears to be in some instances the ophthalmic artery itself; in other instances it would appear that the tumour is developed within the cranium, springing from the carotid artery, the ophthalmic being but secondarily affected.

CAUSES.—The causes of intraorbital aneurism are in some cases very obscure, in others it evidently and directly has originated from a blow upon the head. In the first class of cases, where the disease has been of spontaneous and not of traumatic origin, the patient has suddenly felt a crack or snap in the orbit, like the "crack of a whip," or the "snap of a gun," and the disease has then developed itself gradually. In the other or traumatic cases, the blow upon the head has usually been severe, attended in some instances with symptoms of fracture of the anterior part of the base of the skull. It is a remarkable circumstance that, in all the spontaneous cases on record, the disease occurred in women, and with one exception (a case of Mr. Nunneley's), appeared on the left side. The circumscribed intraorbital aneurism has been met with at all ages in adults, even in persons of advanced periods of life.

SYMPTOMS.—The first sensation experienced is, in spontaneous cases, that of a loud snap or crack in the orbit or head. This is followed by congestion of the conjunctiva, difficulty in opening the eyelids, a feeling of tension, and in some instances severe pain in and around the orbit. Loud whizzing bewildering noises are experienced in the head, and are much increased on stooping or lying down. In traumatic cases, a persistence of congestion of the conjunctiva, and the occurrence of noises in the head, are usually the first indications of the mischief that has occurred. In all cases, after a time, the eyeball becomes unduly prominent, and pulsation of a thrilling vibratory character can be felt in the orbit: on the application of the ear, a loud whizzing bruit is discernible, which extends widely over the side of the head. The eyeball itself falls into a state of chronic congestion; chemosis occurs, the cornea becomes opalescent, the aqueous humour turbid, and sight is impaired or lost. The bruit and pulsation are diminished or cease on compressing the carotid artery of the side affected.

TREATMENT.—The treatment of this formidable disease consists in the application of a ligature to the common carotid of the side affected. This operation has been highly successful. Out of 20 cases in which the operation has been performed, 14 have proved successful, there having been 3 deaths; 2 were only partially successful, and in 1 the pulsation continued unabated by the operation. Of 13 cases in which it has been done in England, 12 have been cured. In the case that proved fatal, death appeared to have resulted from accidental complications. In this instance—which is the only case that I am acquainted with where an opportunity has been afforded of making a dissection of the parts—it was found that the curve of the left carotid, just at the giving off of the ophthalmic, was diseased, and that the ophthalmic artery itself was dilated and atheromatous. In a very interesting case which I saw in M. Velpeau's wards in 1839, both orbits were

affected; and, as pressure on the right carotid arrested the pulsation and brunt in both, that artery was tied. But though the disease was cured in the left orbit by this operation, and temporarily arrested in the right, it reappeared in the latter situation, and was eventually cured here by the ligature of the left carotid.

ANEURISM OF THE SUBCLAVIAN ARTERY.

Aneurisms of the Subclavian occur in order of frequency between those of the carotid and of the brachio-cephalic arteries. They are most frequently met with on the right side, in the proportion of nearly three to one; and this would appear to be in a great measure dependent on their being occasioned by direct violence, or by repeated or prolonged exertion of the arm; thus they commonly occur from falls, blows upon the shoulder, or excessive fatigue of this extremity. From the fact of the aneurisms arising from external violence, we should expect to meet with them most frequently in males, and thus we do in a remarkable manner. Of thirty-two cases, I find only two occurring in females, and in both these instances the disease resulted from injury. The disease may be seated in any part of the vessel on the right side, though most commonly it is not dilated until after it has passed beyond the *scaleni*. On the left side, aneurism never occurs before the artery has emerged from the thorax; and then, as on the right, it most commonly happens in the third part of the course of the vessel.

SYMPTOMS.—An aneurism of the subclavian artery is characterised by a pulsating compressible tumour of an elongated or ovoid shape, situated at the base of the posterior inferior triangle of the neck, immediately above the clavicle. If it be small, it will disappear behind this bone on the shoulder being raised; as it increases in size, it fills up the whole of the space between the clavicle and the trapezius, often attaining a very considerable bulk. In consequence of the pressure which it exercises on the brachial plexus of nerves, there is pain, often attended by numbness, and extending down the arm and fingers, usually with some weakness of these parts. In some instances there is a spasmodic affection of the diaphragm, owing to irritation of the phrenic nerve. The external jugular vein is commonly distended and varicose, with oedema of the hand and arm, or even of the side of the body. The tumour does not increase rapidly in size, owing to its being tightly compressed by the surrounding parts; and, as the disease never extends inwards, it does not interfere with the trachea or oesophagus. In some cases it has been known to extend downwards and backwards, so as to implicate the pleura and the summit of the lung.

DIAGNOSIS.—The diagnosis of these aneurisms is usually easy, and presents no point of a special character.

RESULTS.—As subclavian aneurisms increase in size, they may become diffused, and burst either externally or into the pleural sac. In some instances a spontaneous cure has been observed.

TREATMENT.—The treatment of subclavian aneurism is in the highest degree unsatisfactory. The attempts at obtaining consolidation of the tumour by constitutional means, by *galvano-puncture*, or *compression*, have hitherto failed, except in some very rare instances. A case is reported by Yeatman of the cure of subclavian aneurism by *Valsalva's* plan in eighteen months; and another by Dr. Abellie, in which the tumour was consolidated by *galvano-puncture*. *M manipulation*, as recommended by Ferguson, has succeeded in the hands of Little, and undoubtedly deserves a trial in those cases, when we consider the extreme danger and almost universal want of success that attend other means of cure.

Ligature of the brachio-cephalic, and of the subclavian itself, before, between, and beyond the scaleni muscles, has been practised for the cure of this form of aneurism; it has likewise been proposed to apply the distal operation to the treatment of this disease, and to amputate at the shoulder-joint.

When an aneurism is situated on the right subclavian artery on the tracheal side of the scaleni, there is no way in which the flow of blood through it can be arrested, except by the ligature of the brachio-cephalic artery. When it is situated beyond the scaleni, or even between these muscles, the ligature of the vessel has been practised in the first part of its course before it reaches these muscles. For subclavian aneurisms on the left side, in these situations, no operation conducted on the Hunterian principle would be practicable.

Let us now proceed to examine the results that have attended these operative procedures.

LIGATURE OF THE BRACHIO-CEPHALIC.—The brachio-cephalic artery, as may be seen by the accompanying table, has been ligatured eleven times, and in every instance with a fatal result. In four other instances the operation has been commenced, but abandoned owing to unforeseen difficulties, and this by some of the most skilful operators that their respective countries can boast of.

Although, in reasoning on the propriety of performing an operation, it is not in general worth while to take into consideration the difficulties that a surgeon may encounter, provided the operation be at last practicable; yet, when we consider the fact of the ligature of the brachio-cephalic having been attempted, and in consequence of unforeseen and insurmountable difficulties left unconcluded in so large a proportion as one-fourth of the cases, and these in the hands of surgeons who were as well able as any to accomplish whatever was in the power of operative surgery to do, we may well hesitate upon the difficulties that beset the operation itself, before proceeding to the consideration of its results. The difficulties to which I allude do not consist merely in the position and anatomical relations of the vessel, but rather in the condition in which the artery and the adjacent structures may be found after the vessel is exposed. Thus, in Porter's case, the aneurism, which was a large one, occupied the whole of the inferior posterior triangle of the neck, being nearly six inches broad; as no pulsation was traceable in the vessels beyond the aneurism, it was useless to attempt ligature on the distal side. On exposing the brachio-cephalic, that vessel was found to be diseased, and it was not thought desirable to pass the ligature round it. In consequence of the exposure of the artery, however, the pulsation in the tumour gradually diminished, and at last ceased entirely, its bulk also becoming less.

In Key's case, in which it was impracticable to pass the ligature, it was found after death that the brachio-cephalic was diseased, being dilated immediately after its origin into an oblong tumour, which occupied the whole of the artery. It is remarkable that in this case, as in Porter's, inflammation seems to have taken place in the artery in consequence of the necessary handling to which it was subjected, and that the pulsation in the sac consequently diminished.

The difficulties of the operation are in themselves of serious magnitude; arising from the depth of the vessel, from its proximity to the centre of the circulation, and from the neighbourhood of large veins, which may become turgid, and a wound of which not only obscures the line of incision with venous blood, but induces a risk of the entrance of air into the circulation. But even when these have been surmounted, and the artery has been

CASES OF LIGATURE OF BRACHIO-CEPHALIC ARTERY.*

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
1. MOTT.	m.	57	Subclavian aneurism.	Died on 26th day.	Tied an inch below bifurcation. Ligature separated in fourteen days. Hemorrhage on twenty-fifth, stopped by pressure. Recurred on twenty-sixth.
2. GRAPPE.	Subclavian aneurism.	Died on 67th day.	Ligature separated in fourteen days. Died of hemorrhage.
3. HALL.	Subclavian aneurism.	Died on 5th day.	Artery was diseased and gave way. Bleeding arrested by plug: death from other cause.
4. DUPUY- TREN.	Died.	Case referred to as occurring in the practice of Dupuytren.
5. NORMAN.	Died.	..
6. BLAND.	m.	31	Subclavian aneurism.	Died on 18th day.	Hemorrhage came on on the 17th and 18th days. Ligature applied to upper portion of artery.
7. LILIAN.	Subclavian aneurism.	Died on 21st day.	Ligature separated on 17th day. Hemorrhage on 19th.
8. HUTIN.	m.	26	Hemorrhage from axilla after ligature of subclavian.	Died in 12 hours.	Punctured wound in axilla, for which subclavian was tied, secondary hemorrhage, and then brachio-cephalic tied.
9. ARENDT.	Subclavian aneurism.	Died on 8th day.	Inflammation of lung, pleura, and aneurismal sac.
10. COOPER (See Frem- onco).	m.	...	Subclavian and carotid aneurism.	Died on 9th day.	Upper end of sternum and inner end of clavicle removed. Dyspnea and retention of urine, pus in the right kidney.
11. COOPER.	m.	...	Subclavian and carotid aneurism.	Died on 34th day.	Bones removed as in previous case. Patient was apparently doing well, when secondary hemorrhage appeared. Immediate cause of death, hemorrhage, in consequence of removal of bandages by patient.

* N B.—The artery was cut down upon, but not actually ligatured, by Porter, Post, Aston Key, and Hoffman.

exposed, its coats may be found so diseased, or its calibre so increased, that it may be undesirable or impossible to pass a ligature round it. The failure in deligating the artery would, however, as we shall immediately see, appear to be less disastrous in its consequences than success in that attempt; for of the three cases that have just been referred to, in which this attempt was made and did not succeed, one was cured of the disease, the artery being obliterated by adhesive inflammation; and in another, Key's patient, an attempt to set up this action appears to have been made, the tumour becoming solid and ceasing to pulsate; whereas in every case in which the vessel was ligatured, a fatal result speedily ensued.

* These are all the cases of ligature of the brachio-cephalic artery the details of which I have been able to collect. This artery was also said to have been once ligatured by Kuhl and twice by Bland. In these cases I find in a short time, but, as I can find no historical record of them, I have omitted them in the above table. Garlin in his Report on Surgery (*Archiv für Klinische Chirurgie*, vol. vi. 1865) says, in speaking of Cooper's second case: "This is the fifteenth case of ligature of the innominate artery, and every one of them has proved fatal."

The results of the ligature of the vessel are then in the highest degree discouraging; for of the eleven cases in the table in which it has been done, not one recovered. In three more it is said it have been tried with speedily fatal results; and in four cases the operation, after being commenced, was abandoned. Death occurred from secondary hemorrhage in five cases; from inflammation of the lungs or pleura in one; from diseased kidney in one; and in three from causes that are not mentioned.

In one case, that of Hall, the artery was transfixed by the aneurism needle; hemorrhage occurred at the time, which was arrested by plugging, and did not recur, the patient dying from other causes. In three cases, those of Mott, Bland, and Lizars, the hemorrhage came on shortly after the separation of the ligature; but in Grafe's (the most successful) it did not occur for fifty-one days after this, the cicatrix in the artery having then probably given way under the influence of some imprudent movement on the part of the patient. In Cooper's second case, the patient appeared to be going on well for some weeks, when secondary hemorrhage appeared. Learning that nothing further could be done, the patient tore off the bandages when alone, and bled to death. With such results as these, there can, I think, be but one opinion as to the propriety of such an operation being again had recourse to. As its performance has hitherto in every instance entailed death, and, in all cases but one, a speedy death to the patient, it should without doubt be banished from surgical practice; and I can think of no circumstances that should induce a surgeon, in the face of the consequences that have hitherto invariably followed the application of a ligature to the brachio-cephalic artery for subclavian aneurism, again to have recourse to such a procedure.

LIGATURE OF THE SUBCLAVIAN.—If the aneurism be situated on the right subclavian artery, between or beyond the *scaleni*, that vessel has been *Ligatured on the Tracheal Side* of these muscles; on the left side this operation is not practicable, on account of the depth at which the artery is situated. When we consider the anatomical relations of that portion of the right subclavian which intervenes between the brachio-cephalic artery and the tracheal edge of the *scalenus anticus* muscle, we are at once struck with the great difficulties of this undertaking; and when we reflect on the position in which the ligature will be placed between the onward current of blood in the brachio-cephalic on the one side, and the regurgitant stream conveyed by the vertebral, the thyroid axis, the internal mammary and intercostal, into the subclavian, immediately beyond the seat of deligation on the other side, we can scarcely, in accordance with those principles on which the formation of a conglum within a ligatured vessel takes place, anticipate any but the most disastrous results.

In reference to the mere difficulties of the operation, Fergusson justly characterises it as the most serious in surgery: the proximity of the common carotid artery on one side, the internal jugular vein on the other, the vena innominata below, the par vagum and numerous small venous trunks in front, the recurrent laryngeal nerve and pleura behind, constitute relations of sufficient importance to justify Fergusson's opinion. But supposing these difficulties overcome, and the ligature applied, this must be situated, as has just been stated, in such a position, with a strong current of blood flowing upon each side of it, as to render the formation of an internal conglum, and consequently occlusion of the artery, impossible, and thus to lead inevitably to the occurrence of fatal hemorrhage on the separation of the ligature. Besides the danger of secondary hemorrhage from these causes, there would be the additional risk of the coats of the artery being diseased,

as we commonly find them in a more or less morbid state in the immediate vicinity of aneurisms; and, it being rendered insusceptible of healthy inflammation, ulceration and sloughing would take place along the track of the ligature, causing the probability of a recurrence of hemorrhage. Thus, in Coles's case it was found, on exposing the subclavian artery, that the aneurism had extended in such a way towards the carotid, that it was doubtful whether any part of the affected vessel continued sound. On exposing it fully, it was found that only a space of the vessel three lines in length remained free between the sac and the bifurcation of the brachio-cephalic, and it was in this narrow space that the ligature was applied.

The subclavian has been ligatured on the tracheal side of the scaleni muscles in eight cases, all of which proved fatal; seven from hemorrhage, and one from inflammation of the pericardium and pleura.

The cases are as follow.

SURGEON.	SEX.	AGE.	DATE OF DEATH.	CAUSE OF DEATH.
COLES.	m.	33	4th day.	Hemorrhage.
MOTT.	f.	21	18th day.	Hemorrhage.
HAYDEN.	f.	57	12th day.	Hemorrhage.
O'REILLY.	m.	39	13th day.	Hemorrhage.
PARTRIDGE.	m.	38	4th day.	Pericarditis and pleurisy.
LISTON.*	m.	..	13th day.	Hemorrhage.
LISTON.†	m.	...	36th day.	Hemorrhage.
COVILLIER‡	m.	..	10th day.	Hemorrhage.

Thus it will be seen that, while this operation is bad in principle, it is most unfortunate in practice. This table is, to my mind, conclusive as to the merits of the operation, the patient having in every case but one been carried off by secondary hemorrhage from the distal side of the ligature, in consequence of the close proximity of numerous collateral branches (Fig. 208); and in the exceptional case the operation, although performed with the utmost delicacy and skill, proved fatal from pericarditis and pleurisy before the period at which secondary hemorrhage might have been expected. Liston, in one case, ligatured the root of the common carotid, as well as that of the subclavian, hoping in this way to diminish the risk of the supervention of this fatal hemorrhage, by arresting the current of blood which, by sweeping into the carotid past the mouth of the subclavian, would necessarily wash away any coagulum that might be formed in this artery. But his expectations were not realised: hemorrhage took place as usual, and from that portion of the artery which lay on the distal side of the ligature, the blood having been carried into this part of the vessel in a retrograde course, through the connection existing between the vessels arising from it at

Fig. 208.—Ligature of the Subclavian in the First Part of its Course (Liston)

* In this case the carotid was also tied, but the hemorrhage came from the subclavian (Fig. 209).

† Fig. 208

‡ Carotid also tied.

this point, and those on the opposite side of the head and neck, as illustrated by the annexed cut (Fig. 209), taken from the preparation of the

Fig. 209.—Ligature of the Subclavian and Carotid for Subclavian Aneurism. (Liston)

case in the University College Museum. Indeed, this is the great danger to be apprehended after ligature of the subclavian artery on the tracheal side of the scaleni, depending as it does on the anatomical relations and connections of the vessel, which no skill on the part of the operator can in any way lessen, and which, in my opinion, ought certainly to cause this operation to be banished from surgical practice.

When an aneurism is situated on the subclavian artery, in the posterior inferior triangle of the neck, it is necessarily impossible to ligature that vessel beyond the scaleni, as there would not be sufficient

room for the exposure of the artery, which, even if laid bare, would in all probability be found in too diseased a condition to bear the application of a ligature.

Thus it will be seen that, in every case in which an aneurism of the subclavian artery has been subjected to operation, whether by ligature of the brachio-cephalic or of the subclavian itself internally to the scaleni, the result has been a fatal one. As this unfortunate termination to every case that has yet been submitted to surgical interference is in no way to be attributed to want of skill on the part of the operators—who have been, without exception, men greatly distinguished for the possession of this very quality—but is solely dependent on certain anatomical peculiarities in the arrangement of these vessels, by which their successful ligature has been rendered impossible, a repetition of these attempts, which may hasten the patients' death, can scarcely be considered justifiable. What then are we to do? Are we to leave patients labouring under aneurism of the subclavian artery to inevitable death, without making an effort to save them? Or does surgery offer other modes of treatment besides those just mentioned, by which we may hope to arrive at more successful results?

Without mentioning manipulation or galvano-puncture, which are certainly deserving of further trials in combination with appropriate constitutional treatment, three modes of treatment present themselves:—

1. Compression on the Artery where it passes over the First Rib, and consequently on the Distal Side of the Tumour.

2. Ligature of it on the Distal Side, above or below the Clavicle.

3. Amputation at the Shoulder-joint, and Distal Ligature of the Artery.

1. *Compression of the Artery on the Distal Side* of the sac could only be effected where it crosses the first rib, and consequently would only be applicable to aneurisms of the first part of this vessel. This plan has never been tried: partly, perhaps, on account of the difficulty in applying pressure in this situation, and partly, probably, on account of the want of success that has attended procedures of this kind when applied to vessels in other situations.

The difficulty in applying the compression might, I think, be overcome by the use of the instrument of which a representation is given by Bourgery.

and the efficiency of the compression would be materially increased by the employment of galvano-puncture at the same time, and in this way a coagulum might be formed in the sac. Although much ought not to be expected from this mode of treatment, yet I think it might with propriety be tried in cases of the kind that have been mentioned.

Dupuytren ligatured the axillary artery under the pectoral muscles for a case of subclavian aneurism, two arterial branches being divided in the incisions through the fat and cellular tissue; and the patient died on the ninth day. This is the only instance, to my knowledge, in which the distal operation has been attempted for the cure of this disease. It could not be expected to succeed; for between the ligature and the sac are the large and numerous alar, acromial, and thoracic branches of the axillary artery, which would continue to be fed by a current sent through the tumour, and thus preclude the possibility of its contents being sufficiently stationary for ultimate contraction and cure to result. Langier performed the distal operation in a supposed case of subclavian aneurism, which afterwards turned out to be one of the brachio-cephalic artery.

2. *Ligature of the Subclavian Artery in the Third Part of its Course*, on the distal side of the tumour, has been suggested, and may, perhaps, hold out some prospect of success in cases of aneurism situated between or internal to the scalem. In an aneurismal sac springing from the artery in this situation, the principal current of blood would, in all probability, be that which is destined for the supply of the upper extremity. Some of the branches arising from the artery before it has passed beyond the *scalemus anticus* would, doubtless, be more or less compressed, and thus obliterated, by the tumour; or they might be obstructed by an extension of the laminated fibrine over their orifices. If, therefore, the supply to the upper extremity could be cut off, there might be a possibility of those changes taking place within the sac which are necessary for the obliteration of its cavity. The principal obstacles to this desirable result would necessarily be the *transversales colli* and *humeri* arteries; which, being the two vessels that are more particularly destined to carry on the circulation in the upper extremity after the ligature of the subclavian, would necessarily, if not occluded, undergo dilatation, and thus continue to draw too large a current of blood through the sac for stratification of its contents to take place; and, if they were occluded, there would be danger of gangrene of the arm from insufficient vascular supply.

3. The above-mentioned difficulties are met by a plan of procedure, the suggestion of which has originated, I believe, with Mr. Fergusson, but which has not, to my knowledge, been had recourse to as yet. It is *Amputation of the Arm at the Shoulder-joint*, followed by *Distal Ligature of the Artery*—a desperate undertaking truly, but for a desperate disease, it must be remembered, and one that has never yet, under ordinary surgical treatment, been cured.

The artery might be ligatured before the amputation. "It is known," says Fergusson, "that amputation at the shoulder-joint is generally a very successful operation; so far as this wound is concerned, then, there might be little to apprehend, but the effect on the tumour is not so easily foretold. Ligature of the axillary artery on the face of the stump might here be reckoned like Brador's operation; yet there is a vast difference, for in the latter case the same amount of blood which previously passed towards the upper extremity, would still find its way down, and probably part of it would run through the sac; whereas, were the member removed, as the same quantity would no longer be required in this direction, the tumour might possibly be much more under the control of pressure. The

value of such a suggestion remains yet to be tested, however, and it would be futile to reason upon it at present. It might be a judicious venture first to tie the axillary or subclavian under the clavicle; and then, if it were found that the aneurism still increased, amputation might be performed, either immediately before or after the separation of the ligature."

Were a case of aneurism of the subclavian artery internal to the scaleni to present itself to me, the plan that I should adopt would be, first the employment of pressure on the vessel at the distal side of the tumour, if practicable; should this not succeed, I would, if the disease were situated between or internal to the scaleni, ligature the artery in the third part of its course; and, did that not succeed in checking the increase of the aneurism, I would perform amputation at the shoulder-joint, as recommended by Mr. Fergusson. Should the aneurism occupy the artery after it has passed the scaleni, I would not attempt the ligature of the artery below the clavicle; as it is an operation the result of which is not very satisfactory, and would not prevent a large current through the sac for the supply of the collateral circulation of the arm; but I would at once have recourse to amputation at the shoulder, and then ligature the vessel as near as possible to the sac. It is true that, even in this case, the ligature would be below the branches that are given off under the pectoral muscles; but, as the arm would be removed, they could not undergo any increase of activity for the supply of the collateral circulation of the upper extremity.

ANEURISM OF THE AXILLARY ARTERY.

This artery, though less commonly the seat of aneurism than other large vessels, such as those of the ham, the groin, and the neck, yet is sufficiently frequently diseased. This is due partly to its situation, its proximity to the shoulder-joint causing it to be subjected to the very varied, extensive, and often forcible movements, of which that articulation is the seat; and partly to the artery being deficient in that support which would be afforded it by an investing sheath, such as is commonly met with in arteries of corresponding magnitude. Amongst the most frequent causes of axillary aneurism, may be mentioned falls upon the shoulder or upon the outstretched hands, and in many cases the efforts made at reducing old standing dislocations, instances of which are recorded by Pelletan, Flaubert, Warren, and Gibson; the head of the bone in these cases having probably contracted adhesions to the artery, in consequence of which the vessel was torn during the efforts at reduction. Axillary, like subclavian aneurism, occurs more commonly on the right than on the left side, and is met with in especial frequency amongst men: of 37 cases, only 3 occurred in women.

SYMPTOMS.—In axillary aneurism, there are three sets of symptoms, attention to which will usually enable the surgeon to recognise the disease; these are, the existence of a tumour in the axilla, the pain that it occasions, and the affections that it gives rise to in the limb.

The precise situation at which an aneurism of the axillary artery presents externally, will depend upon whether it springs from that portion of the vessel that lies above, beneath, or below the lesser pectoral muscle. If from above, it will appear as a tumour seated immediately below the clavicle and occupying the triangular space between the upper margin of the lesser pectoral and that bone; if it be lower down, it will raise the anterior fold of the axilla, being prevented from extending much out of this space by the dense fascia that stretches across from one side to the other. The tumour, which is at first soft and compressible, has a whizzing bruit; and its pulsations, which are expansile, may be arrested by pressure upon the subclavian artery.

where it passes over the first rib. It usually increases with great rapidity, owing to the little resistance opposed by the loose cellular tissue in this situation, and most commonly extends downwards and forwards, causing the hollow of the axilla to disappear. In some rare instances, however, the tumour has been known to take a direction upwards under the lesser pectoral, and into the cellular interval above that muscle, or even underneath the clavicle into the acromial angle between it and the trapezius. Such a course for the aneurism to take is fortunately rare, as it presents a serious inconvenience in the ligature of the subclavian; and there is more than one instance on record, in which the sac has been punctured in the attempt to pass the needle round this vessel. When the aneurism is seated high up, it not unfrequently happens that the clavicle is pushed upwards by the pressure of the tumour beneath it—a complication of considerable moment in reference to the operation, the difficulties of which are greatly increased by it. The pressure of the tumour may give rise to serious consequences upon neighbouring parts; thus it may produce a carious state of the first and second ribs, and the compression of the brachial plexus of nerves will occasion pain and numbness in the upper extremity. In some cases the brachial artery beyond the tumour would appear to be obstructed, no pulsation being perceptible in it; and the compression of the axillary vein may occasion oedema of the hand and arm, with some diminution in the temperature of the limb; and these symptoms, if the tumour attain a very large size, may even amount to indications of impending gangrene.

DIAGNOSIS.—The diagnosis of axillary aneurism is usually readily made; there being but two diseases with which it can well be confounded, viz., chronic enlargement and suppuration in the glands of the axilla, and pulsating tumour of the bones in this region. From glandular or other abscess, the diagnosis is generally easy; but I have seen some cases in which, pulsation being communicated to their contents by the subjacent artery, it was somewhat difficult to distinguish the nature of the tumours. Here, however, the history of the case and its speedy progress to pointing will indicate its true nature. From medullary tumour, or osteo-aneurism of the head of the humerus, the diagnosis is not always so easy; and there are at least two instances on record in which the subclavian artery has been ligatured for disease of this kind on the supposition of its being an aneurism. In these instances it has, however, generally been observed that the tumour first made its appearance on the forepart of the shoulder, and not in the usual situation of axillary aneurism; that it was from the first, firm, smooth, elastic, but nearly incompressible; and that, although it presented distinct pulsation, there was no true bellows-sound, but rather a thrilling bruit perceptible in it. The most important diagnostic mark, perhaps, is the fact of these tumours forming a prominence in situations in which aneurisms of the axillary artery would not at first show themselves, as at the upper, outer, or anterior part of the shoulder. In more advanced stages, when the substance of the bone has undergone absorption and its shell has become thin and expanded by the outward pressure of the tumour, there is often a dry cracking or rustling sound perceived on pressure, which is never met with in cases of aneurism.

TREATMENT.—I am not acquainted with any instance in which an aneurism of the axillary artery, not arising from wound or injury, has undergone spontaneous cure, or been consolidated by constitutional treatment. Nor is it probable that compression can ever be made applicable to aneurisms in this situation; inasmuch as the pressure, that is brought to bear upon the subclavian, must necessarily at the same time influence the

whole or the greater part of the brachial plexus of nerves to such an extent as to be unendurable by the patient. Ligature of the artery is therefore the surgeon's sole resource in the treatment of these cases. The part of the vessel universally selected for the application of the ligature is, in accordance with the Hunterian doctrines, that which lies on the first rib beyond the scalenus anticus muscle; this part presenting the advantages of being sufficiently removed from the seat of disease to ensure the probability of the coats of the artery being in a sound state, of being by far the most accessible, and, when deligated, of allowing the collateral circulation by which the vitality of the arm is to be maintained to remain uninjured. Notwithstanding these obvious advantages presented by the ligature of the subclavian over that of the axillary artery, in other words, by performing Hunter's instead of Anel's operation for the cure of spontaneous axillary aneurism, there would appear to be a tendency in the minds of some surgeons to advocate the latter instead of the former of these operations; and to substitute for one that offers the advantages that have just been mentioned a procedure that is not only much more difficult in its performance, and that interferes with the collateral circulation, but that is practised upon a diseased part of the vessel, in dangerous proximity to the sac.

LIGATURE OF THE SUBCLAVIAN IN THE THIRD PART OF ITS COURSE.—In order to apply a ligature to that portion of the subclavian artery which intervenes between the acromial edge of the scalenus anticus and the lower border of the first rib, the patient should be placed in the recumbent position, the arm depressed as much as possible, and the head turned somewhat to the opposite side. The integuments of the lower part of the neck should then be put on the stretch by being drawn downwards over the clavicle, and an incision about four inches in length made upon the bone through the integument, the superficial fascia, and the platysma. When tension is taken off the part, this incision will be found to traverse the base of the inferior triangle of the neck; a vertical incision should then be made at right angles to, and falling into the centre of, the first, and the two flaps of integument and fascia should then be turned up. A quantity of loose cellular tissue will now be exposed, in which a venous plexus and the lower end of the external jugular vein will commonly be found. These vessels should be carefully avoided, and the cellular tissue dissected or scratched through with the point of a knife and a blunt probe; should any vein be wounded, a double ligature must be passed underneath it, or either end tied. If the transversalis colli or humeri arteries, as occasionally happens, should inconveniently traverse this place, they must be drawn out of the way with a blunt hook. By the combined action of cutting and scratching through the cellular tissue, the external edge of the scalenus anticus is reached; this is the "directing line" down which the finger is run until the tubercle of the first rib is felt. This is the guide to the artery, which will be found immediately above and a little behind it, covered, however, and bound down to the rib by a dense fascia. This must now be very carefully opened with the edge of the knife, and the needle passed from before backwards. In doing this, attention must be paid to the brachial plexus, situated above and behind the artery.

There are several points in connection with this operation that deserve special attention. In the first place, it is necessary that the shoulder should be depressed as far as possible, so as to bring the superior margin of the clavicle down. This is a matter of much importance; for, if the clavicle be thrust upwards by the pressure of a large aneurism, the surgeon will have to find the artery at the bottom of a deep narrow wound, instead of on a

comparatively plain surface. A case occurred to Sir A. Cooper, in which the attempt to ligature the subclavian artery for a large aneurism of the axilla was forced to be abandoned, in consequence of the clavicle being thrust up to too great a height to enable him to reach the vessel. The extent of the difficulty occasioned by this elevation of the clavicle must necessarily depend in a great measure upon the height at which the subclavian artery happens in any particular case to be situated in the neck. It is not uncommon to find it pulsating so high in the neck, that an aneurism of elevation of the clavicle by subjacent anillary aneurism might rise that was above the level of the vessel. In the majority of cases, however, it is situated below the level of the bone, or very slightly raised above it, so that, if the clavicle were thrust upwards and forwards, the vessel would be buried in a deep pit behind it. Dupuytren was of opinion that the artery coursed high in persons who were thin, with slender long necks; whereas, in thick, short-necked persons, with muscular shoulders, it was deeply seated. I have often verified the truth of this observation, both in dissection and in examining the pulsations of the vessel during life.

In order to obviate the difficulty that has occasionally been experienced in reaching the artery when thus buried behind an elevated clavicle, it has been proposed by Hargrave to saw through the bone. The most serious objection that can be raised against this practice is the fact of the clavicle being sometimes a part of the wall of the aneurism; but, supposing the surgeon could satisfy himself that this was not the case, I cannot see any objection to this procedure, provided any very great and insurmountable difficulty presented itself in getting the ligature round the vessel without it.

In passing the needle round the subclavian, care must be taken that some of the lower cords of the brachial plexus be not included in the loop: and indeed the mistake has more than once been committed of tying these nervous trunks instead of the vessel. Thus, Liston, in the first successful case of ligature of the subclavian in this country, passed the thread round the lower nervous cord; but, immediately perceiving his error, turned it to account by drawing aside the included nerve, and thus more readily exposing the artery. Dupuytren, in a case of aneurism of some years' duration, succeeded, after an operation that lasted one hour and forty-eight minutes, and which he describes as the most tedious and difficult he ever attempted, in passing a ligature round the vessel, as he believed. After the death of the patient, which occurred from hemorrhage on the fourth or fifth day, the fourth cervical nerve alone was found included in the noose. In a case related by Porter, it is stated that the artery communicated such distinct pulsation to the inferior nervous trunk, that there were no means of ascertaining whether it was the vessel or not, except by passing the needle under it.

In some cases, as has already been stated, the sac passes upwards below the clavicle into the inferior posterior triangle of the neck; when this is the case, the surgeon incurs the risk of puncturing it from its close proximity to the artery, as it lies on the first rib. This accident happened to Cusack while ligaturing the subclavian in the third part of its course, for a diffused aneurism of the axillary artery. An alarming gush of blood took place, which was arrested by plugging the wound; but the hemorrhage recurred on the tenth day, and the patient died. In a case related by Travers, in which the sac was punctured by the needle, which was being passed round the artery, the blood, which was arterial, did not flow per saltum, but

in a continuous stream. "The hemorrhage," Travers says, "was more terrific and uncontrollable than I have ever witnessed," and was not commanded by drawing the ligature tight. It was so great that it was doubtful whether the patient would leave the theatre alive, and was only arrested by plugging the wound with sponge-tents. The patient died of inflammation of the pleura. On examination, the aneurismal sac was found to have a pouch-like enlargement upwards, overlying the artery, where it had been punctured.

LIGATURE BETWEEN THE SCALENI.—If the sac encroach upon the neck, rising above the clavicle, or the artery be not sound in the third part of its course, it may be necessary to ligature it between the scalmi, dividing the outer half or two-thirds of the scalenus anticus. This operation should not be considered as distinct from ligature of the vessel in the third part of its course, but rather as an extension of that proceeding, if it be found, for the reasons just mentioned, unadvisable to tie the artery on the first rib; in this way it has been practised by Dupuytren and Liston. In its first steps, as far as the exposure of the scalenus anticus, it is the same as that for the deligation of the vessel in the third part of its course. When this muscle has been exposed, a director must be pushed under it, upon which it is to be divided to the extent of half or two-thirds its breadth, when it retracts, exposing the vessel. During this part of the operation, some danger may be incurred to the phrenic nerve, and to the transversales colli and humeri arteries; but if ordinary care be taken, this will not be very great. The phrenic nerve, as I have found by very frequent examinations on the dead body, lies altogether to the tracheal side of the incision, if that be not carried beyond one-half the breadth of the muscle; and should it appear to be in the way, it may readily be pushed inwards towards the mesial line, being only loosely invested by cellular tissue. I have, however, seen one instance in which the right subclavian artery was ligatured for a spontaneous cylindrical aneurism of the axilla, and the patient died on the eighth day, of pneumonia; on examination after death, the edge of the scalenus was found cut, and the phrenic nerve divided. Had the injury to the nerve in this case anything to do with the pneumonia? I do not think it improbable, as division of one phrenic, by paralysing to a certain extent the diaphragm, and so far interfering with the respiratory movements, must necessarily have a tendency to induce congestion of the lung, which would readily run on to inflammation of that organ. I have likewise heard of one case in which incessant hiccough followed this operation, and after death the phrenic nerve was found reddened and inflamed, having probably in some way been interfered with during the exposure of the vessel.

Another important point in reference to the ligature of the vessel in this part of its course, is the frequency with which a branch arises from the subclavian artery between the scalmi. When this peculiarity exists, there would probably be but a slender chance of the occlusion of the artery by ligature in this situation. The transversales colli and humeri arteries, though in some danger, whilst crossing over the scalenus anticus, may be avoided by keeping the incision in the muscle between and parallel to these vessels. One principal danger in ligaturing the subclavian artery at any point above the first rib, certainly arises from interference with the fine cellular tissue which lies between it and the scalenus muscles, separating it from the pleura, and which is continuous with the cellular membrane of the anterior mediastinum, being indeed the deep portion of the ascending layer of what Sir A. Cooper has described as the "thoracic fascia," and which tends to form the superior boundary of the chest, being continuous in the neck with the deep

corvical fascia. After the deeper layers of the corvical fascia have been opened, this fine cellular membrane presents itself; and, if inflammation be excited in it, the morbid action will readily extend by mere continuity of tissue into the thorax by the anterior mediastinum, invading ultimately the pericardium and pericardium. Hence, whenever it is practicable, the surgeon should keep the point of the needle close to that part of the artery which lies upon the first rib, as there is less risk here of opening into the deep cellular tissue of the neck.

ACCIDENTS FOLLOWING LIGATURE OF THE SUBCLAVIAN.—The general result of the ligature of the subclavian artery in the third part of its course, for spontaneous aneurism in the axilla, is by no means satisfactory. Thus, of forty-eight cases of aneurism of the axillary artery, not dependent upon any external wound, in which the artery was ligatured above the clavicle, I find twenty-three cures against twenty-five deaths. This result is so unfavourable, and so different, indeed, from what I anticipated, that I have been led to analyse carefully the causes of death. I find them as follow:—

Inflammation within the chest, &c.	10 cases.
Suppuration of the sac	6 "
Suppurative phlebitis	1 "
Hæmorrhage	3 "
Gangrene of hand and arm	1 "
General gangrene	1 "
Not stated	3 "
	<hr/> 25 "

Thus it will be seen that the two most frequent causes of a fatal result following the operation for axillary aneurism, are not those that are usually met with after the ligature of the larger vessels. It would therefore appear to be owing to some special condition, dependent either upon the application of a ligature to the subclavian artery in the third part of its course, or upon the situation and nature of the disease for which that operation is had recourse to; and the important point to be determined is, whether these conditions are the accidental or the necessary consequences of the application of a ligature in this situation for the cure of aneurism in the axilla.

Inflammation of the Contents of the Thorax proved fatal in 10 out of 25 cases, or 1 in 2.5, and is the most frequent cause of death, though not, I believe, the most frequent untoward complication of this operation. It might at first be supposed that, in this respect, the operations on the subclavian artery resembled other of the greater operations, after which pneumonia is so common a sequela; but, on closer examination, it will be found that this is not the case. Inflammation, when attacking the thorax or its contents after ligature of this artery for axillary aneurism, is not confined to the lungs, but very commonly affects the pleura and pericardium as well as, or even in preference to, these organs. It would, therefore, appear probable that it arose from causes that are essentially connected with this disease or operation. These are referrible to three heads.

1. Inflammation of the deep cellular tissue at the root of the neck may extend to the anterior mediastinum, the pleura, and pericardium. This would appear to have been the cause of death in a patient in whom Key tied the subclavian, and has been especially adverted to by that excellent surgeon in his relation of the case.

2. The sac may, by its pressure inwards, encroach upon and give rise to inflammation of that portion of the pleura that corresponds to its posterior aspect. This occurred in a case in which Mayo of Winchester operated,

and is more liable to happen if suppuration has taken place in the sac; when this happens, adhesion may take place between it and the pleura, or even the tissue of the adjacent lung; and the contents of the suppurated tumour may be discharged into the pleural cavity or air-tubes, and so coughed up. Of this curious mode of termination there are at least two cases on record: one by Bullen, in which the patient recovered; the other by Dr. Gross, in which the patient died from the escape of the contents of the sac into the cavity of the pleura.

3. Division of the phrenic nerve would necessarily, by interfering with the respiratory movements, induce a tendency to congestion and inflammation of the tissue of the lungs; and, although such an accident must be a very rare one in cases of ligature of the subclavian for axillary aneurism, yet it undoubtedly has occurred, as I have myself witnessed in one case.

Suppuration of the Sac is the most common, though not the most fatal, accident after ligature of the subclavian for spontaneous axillary aneurism. It was the immediate cause of death in six cases, and occurred in two of the patients that died of inflammation of the chest; it also took place in six cases that recovered: in all fourteen cases out of forty-five, or nearly one in three, — a much higher proportion than is generally observed in cases of ligature for aneurism.

What occasions this greater frequency of suppuration of the sac in axillary aneurisms than in those in other situations? The only cause to which it appears to be attributable is the great laxity of the cellular membrane in the axilla, which allows the tumour to increase so rapidly in size as to excite inflammatory action in the surrounding tissues, which may speedily run into suppuration. So long as the contents of the tumour continue fluid, they will necessarily excite less irritation on surrounding structures; but when once they have become solidified, whether by the gradual deposition of laminated fibrine, during the progress of the disease, or more suddenly, in consequence of those changes that take place in the contents of an aneurismal sac after the ligature of the artery leading to it, the indurated mass, acting like any other foreign body, sets up inflammation in the cellular tissue that is in immediate contact with it, and thus disposes it to run into suppuration. The more speedily the solidification takes place, the more disposition will there be to the occurrence of this accident; the neighbouring parts being unable to accommodate themselves to the sudden extension and compression they are compelled to undergo.

The period at which suppuration of the sac may be expected to occur in cases of axillary aneurism, after the ligature of the subclavian, must necessarily in a great measure be dependent on the state of the sac at the time of the operation. If inflammatory action have been already set up around it, it may happen in a few days after the artery has been tied. But if this morbid action have not already commenced, the period at which suppuration may most probably be expected is between the first and second month. The period at which suppuration and rupture of the sac take place does not influence the probable termination of the case to any material extent; as, in the cases that proved fatal, death occurred at various periods between the seventh day and the second month; in Aston Key's case, on the ninth day; in Mayo's, on the twelfth; in Belandini's and Grafe's, at the end of the first month; in Rigaudi's, at the sixth week; in B. Cooper's, in the second month. The recoveries, likewise, took place at all periods after the ligature of the vessel, between a few days, as in Porter's, and six weeks, as in Halton's case.

An axillary aneurism that has suppurated may burst either externally, or

into the lungs or pleura, or both. It is most usual for it to burst externally; the tumour enlarges, with much pain and tension; a part of the covering it becomes inflamed, fluctuation can be felt, and if it bursts the tumour will give way, discharging most usually a quantity of dark-coloured pus, mixed up with more or less tawny-brown and disintegrated coagulum and fibrinous deposit, and perhaps sooner or later followed by a stream of arterial blood.

Occasionally, but more rarely, the sac extending backwards becomes adherent to the pleura, and may give way into that cavity; or, by pressing against, may become incorporated with the lungs. Of this remarkable termination two instances are recorded, in one of which recovery took place.

The first case of the kind is one in which Bullen ligatured the subclavian artery for axillary aneurism. Eighteen days after the operation the tumour began to increase, and to take on the symptoms that are indicative of suppuration. On the twenty-sixth day, six or eight ounces of bloody pus were expectorated during a paroxysm of coughing, and the tumour suddenly diminished to one-half its size; it was now punctured, and five ounces of the same kind of matter let out with great relief. When the patient coughed, air passed into and distended the sac through an aperture between the first and second ribs, near their sternal extremities, through which the contents of the tumour had escaped into the lung. The discharge from the external aperture greatly decreased; the cough lessened; and finally, three months after the operation, the patient was quite well.

Dr. Gross tied the subclavian artery for axillary aneurism on the 18th of February. After the performance of the operation the contents of the tumour solidified, and its volume progressively diminished. On the 15th of March, the patient suffered from fever, and slight tenderness on the apex of the tumour was perceptible. On the 16th he was suddenly seized with intense pain in the chest, which was particularly severe at the base of the right lung, and extended up towards the axilla. The respiration throughout the right lung was bronchial, and there was dulness on percussion over the lower ribs; the aneurismal tumour had suddenly disappeared at the time of the attack. On the 18th, the patient experienced a sensation as if a fluid were passing from the pleuritic cavity into that of the aneurismal tumour; and, upon auscultating, a plashing sound was heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. On the 20th, he died. Upon dissection, the aneurism was found to communicate by an aperture, one inch and three-quarters in length and an inch and a half in width, with the pleural cavity; this opening was situated between the first and second ribs, and was obviously the result of ulceration and absorption, caused by the pressure of the tumour. Both ribs were denuded of their periosteum. The right side of the chest contained nearly three quarts of bloody serum, intermixed with laminated clots and flakes of lymph; the fibres of which had evidently been lodged originally in the aneurismal sac (*North. Am. Journ.*, 1845, p. 19).

Besides these cases, a somewhat similar one has been recorded by M. Neret, of Nancy. A patient was admitted into the hospital, labouring under hemoptysis, and on examination was found to have an aneurism of the left subclavian artery as large as a chestnut. He died shortly after admission; and, on examination, the aneurism was found to communicate with a large cavity in the upper part of the lung.

The cause of death in Dr. Gross's case was probably the fact of the sac opening and discharging its contents into the pleural cavity. This does not appear to have occurred in Bullen's, in which a communication was

established directly with the lung, the contents of the abscess finding exit through the air-tubes. The process here was analogous to what occasionally occurs in hepatic abscess when this opens through the lungs, adhesion having previously taken place between the opposed surfaces of the pleura.

The principal danger, and the most frequent cause of death after the suppuration of the sac, is the supervention of profuse arterial hemorrhage. This may either occur from the distal extremity of the artery opening into the sac, or from one of the large branches which serve to support the collateral circulation round the shoulder, such as the subscapular or posterior circumflex, coming off either immediately above or below the sac, or from the sac itself. When hemorrhage does not take place after the suppuration of the sac, it must be from the fortunate circumstance of the occlusion of the main trunk, where it opens into the tumour. It can scarcely be from the occlusion of the principal collateral branches; as there would, in this event, be a difficulty in the preservation of the vitality of the limb. It is easy to understand that, if the sac spring from the axillary, at a little distance above the orifices of the subscapular and circumflex arteries, all that portion of the main trunk which intervenes between the tumour and these vessels might be occluded, and thus hemorrhage be prevented on suppuration taking place; whilst the collateral circulation would take place uninterruptedly through these vessels. If this portion of the artery have not been occluded by inflammatory action, the safety of the patient must depend upon the accident of a coagulum or piece of laminated fibre being fixed or entangled in the mouth of the sac. This may prevent for a time the escape of arterial blood, which, on such a plug being loosened, may break forth with impetuosity, and either at once, or by its recurrence at intervals, carry off the patient.

Another danger may be superadded in these cases on the suppuration of the sac and the supervention of hemorrhage—namely, the occurrence of inflammation of the pleura, lung, and pericardium, from the extension inwards of the morbid action going on in the sac.

Secondary Hemorrhage does not frequently occur in cases of ligature of the subclavian artery in the third part of its course, except as a consequence of suppuration of the sac. I am acquainted with two cases only in which death occurred from the hemorrhage taking place from this artery at the part ligatured. One of these happened to Liston, and the preparation is preserved in the Museum of the College of Surgeons (No. 1695). In this case, it may be seen that the artery was diseased at the point ligatured, and that the bleeding occurred, as usual, from the distal side of the ligature.

Gangrene of the Hand and Arm is but seldom met with as a sequela of the operation we are considering. This is doubtless owing to the freedom of the anastomosing circulation between the branches of the transversales colli and humeri, and those of the subscapular, circumflex, and thoracic acromial arteries; as well as between the superior thoracic and the branches of the first and second intercostals and internal mammary, by which the vitality of the limb is readily maintained. The principal risk from gangrene would doubtless arise from the subscapular artery being in any way occluded or implicated in the disease, as it is on the anastomoses of this vessel that the limb is mainly dependent for its supply of blood. But, at all events, this danger is small, the only case in which it appears to have given rise to a fatal termination being one in which Collis tied the artery; gangrene of the limb came on after much constitutional disturbance of a low type, with rapid, weak pulse, thirst, sweats, restlessness, and delirium. In Bizard's case, there was sloughing of the sac, and pericarditis, the gangrene

being confined to two fingers; and in Brodie's case, it occurred in both the lower as well as in the upper extremities, and must, therefore, have proceeded from some constitutional cause altogether independent of the mere arrest of circulation through the subclavian.

TREATMENT OF INFLAMED AXILLARY ANEURISM THREATENING SUPPURATION.—The case of an axillary aneurism becoming inflamed, and threatening to run into suppuration before the surgeon has had an opportunity of ligaturing the subclavian artery, is one that is full of important practical considerations, and that admits of little delay; for if the sac ruptures, or be opened, fatal hemorrhage is the necessary and inevitable result. It would obviously be impossible, in a case of spontaneous aneurism, with any fair chance of success to lay open the tumour, turn out the coagula, and ligature the vessel above and below the mouth of the sac; the coats of the artery, being not only diseased, but still further softened by inflammation and supervening suppuration, would not be in a condition to hold a ligature. There are two other courses open—viz., ligature of the vessel, or amputation at the shoulder-joint; and in the selection of one or other of these, the surgeon must be guided by the progress the disease has made, the condition of the limb as to circulation and temperature, and the solidity or fluidity of the contents of the tumour.

If the tumour be of moderate size and circumscribed, and the arm of a good temperature and not very cedematous, *ligature of the artery* may hold out a reasonable chance of success. It is true that this is but a chance: for the blood will, immediately after the noose is tied, be carried by the suprascapular and posterior scapular arteries into the subscapular and circumflex, and by them into the axillary at no great distance from the mouth of the sac; or it may enter directly into the mouth of the latter if the profunda or circumflex should chance to take their origin from the dilated portion of the vessel. Hence, the only safeguard against the supervention of hemorrhage as soon as the sac has burst or been opened, or has discharged its contents, will be the occlusion by inflammatory action of that portion of the artery which intervenes between these two collateral branches and its mouth, or the accidental entanglement in the latter of a mass of laminated fibrine. Yet, under the circumstances as to the condition of tumour and limb that have just been mentioned, it would be but right for the surgeon to give the patient a chance of preserving his limb.

Should, however, hemorrhage occur on or after the discharge of the contents of the sac, the subclavian having previously been ligatured, what should be done? If the bleeding be moderate, an attempt should be made to arrest it by plugging the wound, and by the application of a compress and bandage. If it recur, or be so profuse as to threaten the life of the patient, what course should the surgeon then pursue? Two lines of procedure are open to him: either to cut through the pectoral muscles so as to lay the sac open fully, and attempt to include the bleeding orifices between two ligatures; or to amputate at the shoulder-joint.

If a surgeon were to undertake the first of these alternatives in a case of spontaneous aneurism, of which alone we are now speaking, he would, in all probability, find the part in such a condition as would prevent the possibility of his completing the operation he had commenced. After laying open a large sloughing cavity, extending under the pectoral muscles perhaps as high as the clavicle, and clearing out the broken down coagula and grumous blood it contains, in what state would he find the artery? Certainly, the probability would be strongly against its being in such a condition as to bear a ligature, even if it could be included in one. Its coats, in the immediate

vicinity of the sac, could not, in accordance with what we know to be almost universally the case in spontaneous aneurisms of larger size or old standing, be expected to be in anything like a sound, firm state, and would almost certainly give way under the pressure of the noose; or the vessel might have undergone fusiform dilatation, as is very common in this situation, before giving rise to the circumscribed false aneurism, in which case it would be impossible to surround it by a ligature; or, again, the subscapular or circumflex arteries might arise directly from, and pour their recurrent blood into, the sac or the dilated artery, and, as they would lie in the midst of inflamed and sloughing tissues, no attempt at including them in a ligature could be successfully made. Under such circumstances as these, the danger of the patient would be considerably increased by the irritation and inflammation that would be occasioned by laying open and searching for the bleeding vessel in the sac of an inflamed, suppurating, and sloughing aneurism, and much valuable time would be lost in what must be a fruitless operation; at the close of which it would, in all probability, become necessary to have recourse to disarticulation at the shoulder-joint, and thus remove the whole disease at once. I should, therefore, be disposed to have recourse to *disarticulation at the shoulder-joint* at once, in all cases of profuse recurrent hemorrhage, following sloughing of the sac of an axillary aneurism, which could not be arrested by direct pressure on the bleeding orifice, after the subclavian has been tied.

There is another form of axillary aneurism that requires immediate amputation at the shoulder-joint, whether the subclavian artery have previously been ligatured or not; it is the case of diffuse aneurism of the arm-pit, with threatened or actual gangrene of the limb.

LIGATURE OF THE AXILLARY ARTERY.—Should ligature of the axillary artery at any time be required, the vessel may be secured in two ways, in the space that intervenes between the lower margin of the clavicle and the fold of the axilla.

The first way is by an incision, either straight or somewhat semilunar, parallel to and immediately below the inferior border of the clavicle; this must be carried through the pectoral muscle, and when this is divided, some loose cellular tissue, in which the upper thoracic artery ramifies, is exposed. This must be scratched through cautiously, until the fascia covering the vessels is reached. On opening this, which must be done in the most careful manner by making a small aperture in it, and then passing a grooved director under it, the vein first comes into view. This must be drawn downwards, when the artery will be found immediately above and behind it in the deep hollow formed by the clavicle above, and the edge of the lesser pectoral below. This operation is an exceedingly difficult one, on account of the depth and narrowness of the wound and the muscular character of its walls, as well as from the embarrassment occasioned by the numerous venous and arterial branches which ramify across the space in which the artery lies. After the vessels have been exposed, the passage of the ligature round them will be greatly facilitated by bringing the arm to the side of the body, so as to take off all tension from the wound.

The safer and simpler operation consists in making an incision from the centre of the clavicle directly downwards, in the course of the vessels, to the middle of the anterior fold of the axilla. In this way the skin, superficial fascia, and greater pectoral muscle must be successively divided. The lesser pectoral will then be exposed; and the artery may either be ligatured below this, without further division of muscular substance, or, if it be thought desirable to deligate it under this, the muscle must be cautiously cut through. When

this is done, a very distinct and firm fascia will come into view ; this, being pushed up, must be carefully opened, when the artery and vein will be seen lying parallel to one another, the artery not being overlapped by the vein, as it is higher up. The vein having been drawn inwards, the aneurism-needle must be carried from above downwards between it and the artery. The great advantage of this operation is, that the wound is open and free, and that, consequently, the artery can be more readily reached in any part of its course. The disadvantage is the great division of muscular substance that it entails. This, however, need not leave any permanent weakness of the limb, as by proper position ready and direct union may be effected between the parts.

ANEURISM OF THE ARM, FOREARM, AND HAND.

Spontaneous aneurism rarely occurs below the axilla, yet it may occasionally be met with at any part of the upper extremity. Thus Palletta, Flajani, Pelletan, and others relate cases of spontaneous aneurism at the bend of the arm ; and Liston states that he once tied the brachial artery in an old ship-carpenter, who, whilst at work, felt as if something had snapt in his arm. Pilcher has recorded a case of aneurism under the ball of the right thumb, which was produced by repeated though slight blows with the handle of a hammer used by the patient (a working goldsmith) in his trade ; the radial and ulnar arteries were tied immediately above the wrist, and the disease was thus cured. Aneurism has also been met with in this situation after attempted reduction of the thumb. In the Museum of the College of Surgeons there is a preparation of a radial artery with a small aneurism, about the third of an inch in diameter, formed by the dilatation of all the coats of a narrow portion of one-half the circumference of the vessel, a little above the origin of the superficialis volæ. Spontaneous aneurism in the forearm is of extremely rare occurrence. A case has been recorded by Mr. Todd as occurring in a woman twenty-eight years of age, where a spontaneous aneurism in the forearm had existed for several years before the brachial was ligatured, when pulsation in the tumour ceased, though it continued solid and hard for some months after the operation. In 1849, a man was admitted into University College Hospital, for a tumour that presented all the characters of aneurism, situated in the upper third of the ulnar artery of the right forearm. The brachial was ligatured by Mr. Arnott, when pulsation and bruit ceased in the tumour, though slight enlargement of the arm continued for some time afterwards.

Rare as spontaneous aneurisms are in these situations, the traumatic forms of the disease are, as has already been stated (page 197), of frequent occurrence, and may require the ligature of the brachial, or of either of the arteries of the forearm.

TREATMENT.—In cases of aneurism below the axilla, direct pressure might be tried with advantage, provided the tumour be of small size and unattended by inflammation of the superjacent integuments. Compression of the trunk of the artery above the tumour is rarely applicable, on account of the pain that is induced by the pressure upon the neighbouring nerves which cannot be isolated from the artery. Besides this, the brachial artery is so mobile, and the humerus so small and round a bone, that the vessel cannot be steadily compressed against it for any length of time ; it will roll away from under the pressure, even if the patient could bear the pain of it.

LIGATURE OF THE BRACHIAL ARTERY.—The brachial artery may be ligatured in the middle of the arm, which is considered the seat of election of this operation, by making an incision, about three inches long, parallel

to and upon the inner edge of the biceps, which is the "directing line;" the fascia, which is exposed, must be opened carefully to a corresponding extent, when the median nerve will commonly be seen crossing the wound, this must be drawn downwards with a blunt hook, when the artery, accompanied by its two veins, will be exposed; these vessels must then be separated from one another, and the ligature passed and tied in the usual way. In performing this operation, the principal point to attend to is to cut down upon the inner edge of the biceps, which will be the sure guide to the artery. If the surgeon keep too low, he may fall upon the ulnar nerve and the inferior profunda artery, which might possibly be mistaken for the brachial; but by taking care to expose the lower fibres of the biceps in his early incision, he will avoid this error.

In the upper part of the arm, the brachial artery, where the axillary terminates in it, will be found lying immediately behind and covered by its vein. On drawing this to the inner side, the artery will be seen, the plexus of nerves being somewhat above and behind it. In ligaturing the artery in this situation, care must be taken to divide the integuments, which are extremely thin, with great caution; by rotating the arm outwards and bending the elbow, the artery will be thrown forward and rendered less tense, so that a ligature can easily be passed round it.

At the bend of the arm, the brachial artery may be reached by making an incision, about two inches in length, in a direction downwards and inwards, about half an inch internal to the edge of the tendon of the biceps. After carrying it through the skin and fascia, the vessel will be found accompanied by its veins, in the triangular space bounded externally by the biceps tendon, and internally by the pronator teres. In performing this operation the veins at the bend of the arm, with the filaments of the internal cutaneous nerve, must be divided to some extent, though they should be spared as much as possible. The artery will be found, about half an inch to the inner side of the tendon, accompanied by the median nerve, which is to its ulnar side.

LIGATURE OF THE RADIAL AND ULNAR ARTERIES.—These arteries should never, I think, be ligatured above the middle third of the arm, except in cases of direct wound. Any attempt at tying them in the upper part of the forearm will not only be attended with great difficulty, but with the danger of crippling the muscles in this situation, and thus impairing the after-movements of the arm. Ligature of the brachial artery may always be substituted advantageously.

The *Radial Artery* may be ligatured near the wrist, by making an incision, about two inches in length, half an inch to the outside of the tendon of the flexor carpi radialis—the "directing line;" when, after the division of the superficial and deep fascia, the artery, accompanied by its two veins, will be exposed, and may be tied in the usual way.

The *Ulnar Artery* above the wrist may be readily ligatured by making an incision about two inches in length, a little above and one-third of an inch to the radial side of the pisiform bone, parallel to the tendon of the flexor carpi ulnaris, which is the "directing line" to the vessel. After the fascia covering it has been divided, the artery, with its two accompanying veins, will be found to the radial side of the ulnar nerve.

CHAPTER XLIII.

ANEURISMS OF THE LOWER EXTREMITY.

INGUINAL ANEURISM.

AN *Iliac* or *Inguinal Aneurism* may arise from the external iliac, or from the common femoral artery; most frequently it springs from the latter, and, taking a direction upwards, pushes the peritoneum before it, and thus encroaches somewhat upon the cavity of the abdomen. The aneurism is commonly of the circumscribed false variety, though sometimes tubular. It never becomes diffused, for the reason long ago pointed out by Scarpa, that the femoral artery, above the edge of the sartorius muscle, is invested by so dense a sheath, and is so closely bound down to the neighbouring fascia, that, when dilated into an aneurism, it does not readily give way.

SYMPTOMS.—When first noticed, the aneurism is a small, soft, compressible tumour, with pulsation and bruit, and is generally attended by little pain or uneasiness. It rapidly enlarges, however, and may attain a considerable magnitude; being often somewhat lobulated upon the surface, owing to the unequal constriction exercised on it by the fasciæ under which it lies. At the same time, it usually becomes more solid; and the pulsation in it diminishes considerably, or even ceases entirely. As it increases in size, it compresses the saphena and femoral veins, thus giving rise to œdema of the limb; and, by stretching the genito-crural and some of the branches of the anterior crural nerve, it occasions considerable pain in the thigh and leg.

DIAGNOSIS.—The diagnosis of inguinal aneurism is not always so easy as might at first appear. It has most frequently been confounded with abscess in the groin, with carcinomatous tumours in this situation, and with osteo-aneurism. The diagnosis from abscess must be made on general principles; but in some instances it appears to be replete with difficulty, as there are not a few cases recorded in which aneurisms in this situation have been mistaken and punctured for abscess, an error that has in every instance proved fatal. The diagnosis of an inguinal aneurism, solidified by the deposition of laminated fibrine, and pulsating but indistinctly from a *pulsating encephaloid* or *osseous tumour* in the groin, is surrounded by the greatest difficulty, and cannot, I believe, with the means we at present possess, be accomplished with absolute certainty. The fact of the two diseases having in two instances been confounded during the last few years, by two of the most distinguished surgeons of the day, Mr. Stanley and Mr. Syme, is sufficient evidence of the difficulty attending their diagnosis.

TREATMENT.—It occasionally happens that inguinal aneurisms, even of a very large size, undergo spontaneous cure, or become consolidated by direct pressure conjoined with constitutional treatment; but these instances are of such rare occurrence, that such a result cannot be relied on in any one case. In the majority of instances the tumour, though it may have encroached on the abdomen, will not have reached too high for the external iliac to be ligatured; should it have done so, however, the surgeon may have to tie the common iliac artery; but in some instances even this may not be practicable, and his choice must lie between the slender chance offered by constitutional treatment and pressure, and the fearful alternative of ligaturing the aorta.

LIGATURE OF THE EXTERNAL ILIAC ARTERY was first practised by Abernethy, in 1796. Since that period it has been had recourse to in at least 100 instances for inguinal aneurism (Norris); of these seventy-three were cured, and twenty-seven died. In one remarkable case, both external iliacs were ligatured successfully at an interval of eleven months, by Mr Tait. In some few cases also, there was the complication of an aneurism in the ham with that in the groin. Of the ninety-two cases in which the aneurism was solely seated in the groin, seventy were cured, and twenty-two died. Death resulted from gangrene of the limb in eight, from secondary hemorrhage in four, from sloughing of the sac in three, from tetanus in three, and from causes of a more general character in four cases.

Pulsation returned in the sac in six cases; in some not until several weeks had elapsed after the operation; and in one instance only was this phenomenon followed by death. *Suppuration of the sac* was of frequent occurrence, happening in thirteen instances, doubtless owing to the large size that these

tumours are often allowed to attain before being subjected to surgical interference. It is remarkable, however, that in three cases only was this accident fatal; and in two of these three instances the sac had been opened before the operation, on the supposition of its being an abscess. *Secondary hemorrhage* occurred but in six cases, four of which proved fatal; a very small proportion when compared with what happens in other situations. This must doubtless be attributed in a great measure to the absence of any collateral branches springing from the trunk of the external iliac; the distance between the point ligatured and the epigastric and circumflex iliac arteries affording abundant space for the safe obliteration of the vessel. In one of the fatal cases, pulsation had previously returned in the sac; in the other three the patients died on the seventeenth, the twenty-seventh, and the forty-third days respectively.

Gangrene of the limb is the most common cause of death after deligation of this vessel. It occurred in nine instances, of which eight proved fatal; one being cured by amputation. The period at which the mortification supervened varied from the third to the fourth week. The principal cause of this gangrene is narrowing or obliteration of the neighbouring venous trunk, by pressure of the tumour. In the accompanying woodcut (Fig. 210), this is well illustrated; the vein opposite the aneurism being completely closed.

Fig. 210.—Obliteration of Femoral Vein by Inguinal Aneurism.

It is a very remarkable circumstance in the history of this operation that three deaths have resulted from tetanus, a most unusual occurrence after the ligature of arteries.

The ligature of the external iliac for aneurismal varix in the groin affords a striking contrast with that for spontaneous aneurism; the four cases recorded all proving fatal, two dying of gangrene, and two of hemorrhage. In these cases Guthrie has recommended that the tumour should be laid

organ, and the artery ligatured above and below the aperture in it. But, with whatever rapidity and dexterity such a proceeding may be accomplished in the groin, there will be great risk of such a loss of blood ensuing as to endanger the patient's life, there being great difficulty in commanding the artery above the seat of disease.

Aneurism occasionally takes place in the groin and ham of the same side; here the ligature of the external iliac will cure both diseases. Of four cases in which this complication occurred, the operation was successful in three; one patient dying of gangrene, and in him the popliteal aneurism was on the point of bursting at the time of the operation. In two of the three cases that recovered, pulsation returned in the inguinal aneurism, but disappeared after a time.

Operation.—There are two modes of tying the external iliac artery—the one originally practised by Abernethy, somewhat modified by Liston; and the other introduced by Sir A. Cooper.

Abernethy's method modified consists in commencing an incision two finger-breadths above, and somewhat to the inner side of, the middle of Poupart's ligament, and carrying it upwards and outwards to the extent of about four inches, so that it terminates at about three finger-breadths to the inner side of the anterior superior spine of the ilium. After dividing the skin and superficial fascia, the fibres of the external oblique tendon are carefully cut through. The internal oblique and the transversalis muscles are then cut through with great caution, when the transversalis fascia is reached, which is recognised by its dull-white appearance. A small portion of this membrane, at the lower angle of the wound, where it is thinned and expanded for the passage of the cord, is now carefully raised with the forceps and scratched through with the point of the scalpel. A director is then introduced, and passed underneath it, when it should be laid open upwards and outwards to the full extent of the wound; the whole of the inner side of the wound is next drawn towards the mesial line, the peritoneum being separated from its loose cellular connections in the iliac fossa by the surgeon's fingers; it must be kept out of the way by an assistant, who holds it up with a broad bent copper spatula. The artery may now be felt pulsating at the bottom of the wound, covered by a dense fascia, and having the vein lying to its inner side, and somewhat behind it. The investing sheath must be scratched through in two situations, and the needle passed from the inner side between the vessels, the ligature being then tied in the usual way.

In *Sir A. Cooper's operation*, an incision about three inches in length is made a little above and nearly parallel to Poupart's ligament, beginning above the inner margin of the abdominal ring, and ending near the anterior superior spine of the ilium. By this incision the tendon of the external oblique is exposed, and must be divided to the full extent of the external wound, when the spermatic cord will be seen passing under the lower edge of the internal oblique and transversalis muscles. Some loose cellular tissue and fascia has now to be scratched through; and the finger, being passed under the cord, will come into contact with the external iliac artery, close to the spot where the epigastric is given off from it; the upper side of the incision must now be well raised by a copper spatula, when the vessel will be exposed, covered by a cellular sheath, and having the vein to its inner side; the sheath must be cautiously opened, and the ligature passed in either direction.

On comparing the two operations, it would appear that the principal disadvantage of *Abernethy's* is, that it is apt to leave a tendency to hernial protrusion, in consequence of the abdominal wall being much weakened by

the free incisions through the muscular planes that are necessary ; the great advantage attending it is, that the external iliac may be ligatured at any part of its course, and that, if requisite, the incision may be even extended upwards, and the common trunk secured. In Sir A. Cooper's operation, the line of incision lies directly across the course of the epigastric artery, which, as well as the circumflex ilii, if it arise high, and the circumflex vein, which crosses the iliac artery at this point, and is often somewhat funnel-shaped, may be in danger of being wounded. The spermatic cord is likewise somewhat in the way in this operation. Dupuytren actually wounded the epigastric artery in one case ; and Houston had much difficulty from the circumflex vein in another instance. This operation has also the disadvantage, that by it it is impossible to prolong the incision upwards so as to deligate any portion of the vessel except that which lies immediately above the crural arch ; but the peritoneum is less disturbed than in the other case, and there is less tendency to hernial protrusion afterwards. As a general rule, I think we may conclude that, in cases of spontaneous aneurism, in which it might, from the size of the tumour or the diseased state of the vessels, be found necessary to apply the ligature to a higher point than was intended before the operation commenced, it will be safer to have recourse to Abernethy's plan, modified as above described, as in this way we shall be able to ligature the vessel at any part of its course ; whilst in cases of hemorrhage after amputation, or of traumatic femoral aneurism, in which the artery is not likely to be diseased, recourse should be had to Cooper's operation, more particularly if the patient be thin, and the abdomen flat.

In connection with the ligature of the external iliac artery, there are some practical points that deserve mention. Before the operation the colon should be emptied by means of an enema, and the pubes shaved. The incision in the abdominal wall must be sufficiently extensive, but should never be allowed to implicate the external ring, lest it give rise to a tendency to hernial protrusion. Care should be taken not to wound the peritoneum ; for although two patients in whom this was done by Post and Tait both recovered, yet it is of course a dangerous accident, and should if possible be avoided. The peritoneum must not be torn up more than is absolutely necessary, lest hemorrhage or subsequent peritonitis occur ; and especial care must be taken that the fascia transversalis be properly divided, otherwise the iliac fascia may be strapped up with the peritoneum, and the artery in this way dragged out of its normal situation into the upper and inner angle of the wound, occasioning great embarrassment to the operator, who may not be able to find it. Before attempting to pass a ligature round the vessel, the dense fascia covering it must be scratched through ; and, lastly, the sac must not be injured by having its peritoneal covering stripped off.

LIGATURE OF THE COMMON ILIAC.—If the aneurism in the groin extend so high that there is not sufficient space for the exposure and ligature of the external iliac artery, it becomes necessary to tie the common trunk. This may be done by extending the incision that serves for the ligature of the external iliac upwards and slightly inwards towards the umbilicus, to an extent corresponding to the degree of obesity of the patient, so that it assumes a somewhat semilunar form. Or a semilunar incision may be made from a point about two or three inches above the umbilicus, and carried downwards and inwards to a corresponding extent below it. The incision is then successively carried through the different planes of muscular fibre with great caution and on a grooved director, until the transversalis fascia is exposed ; this must be carefully opened and freely divided, so as to expose the peritoneum, which now comes bulging into the wound, pressing forward

its contents. This must be held aside, drawn upwards by the fingers of an assistant, and gently stripped from the iliac fossa by the surgeon carefully maintaining his hand beneath it. When he arrives at the bend of the iliac, he will readily be conducted to the external iliac artery, which guides him to the parent trunk. The ligature must then be passed under the artery, a slight scratch having been made through the fascia covering the vessel.

In planning the incision for the ligature of this artery, care should be taken that it be not carried too low down or too far forwards; nothing can be gained by doing so, and there is besides the additional risk of the circumference of the ilium or epigastric being wounded, as happened to Most, and as these are principal agents in the anastomosing circulation, their injury is a serious accident. Should any muscular branches bleed, they had better be ligatured, so as not to obscure the after-steps of the operation. The fascia transversalis should be opened at the lower part of the wound, where it is thinned for the passage of the cord, by pinching up a portion of it with the forceps, and drawing it carefully with the edge of the knife laid horizontally; it will be found to be much thicker and denser at the upper and outer part of the wound than in this situation. When the peritoneum is well drawn upwards to the mesial line by the assistant's finger or copper spatula, the ureter, which crosses the artery in this situation, will be carried up with it, so as not to be seen at all. In this stage of the operation, the patient should be turned on his sound side, in order to prevent the intestines from falling over and pressing the peritoneum into the wound.

In determining the length of the incision, and calculating the point at which he would expect to meet with and ligature the artery, it is a matter of the very first importance for the surgeon to remember the *different bearings of the parts in the neighbourhood of the vessels*, and the *relative frequency with which the origin and termination of the artery correspond with certain fixed points* that may readily be detected.

The points of importance are the relations of the vessels to the lumbar vertebrae, to the crest of the ilium, and to the umbilicus. The ordinary place of division of the abdominal aorta is on the body of the fourth lumbar vertebra, or on the intervertebral disk below it; according to Quain, this was the case in three-fourths of the bodies he examined, or in 156 out of 196. In regard to the relations between the situation of the bifurcation of the aorta and the crest of the ilium, we find it, according to the same anatomist, to have ranged in about four-fifths of the cases about half an inch above and below the level of the highest point of this part of the bone. With reference to the umbilicus no definite rule can be laid down; but in general terms it may be stated that the bifurcation of the aorta is a little to its left. As a general rule, that given by Hargrave is perhaps sufficiently good for ordinary purposes. If a point be taken about half or three-quarters of an inch below and a little to the left of the umbilicus, and a line be drawn on each side from this point to the centre of Poupart's ligament, we obtain about the direction of the common and external iliac arteries. On dividing these lines into three equal parts, the upper third will correspond to the primitive trunk, and the lower two-thirds to the external iliac, and the junction of the upper with the middle third to the bifurcation of the common iliac artery.

The point of division of the common iliac artery is, in the majority of cases, between the middle of the fifth lumbar vertebra and the middle of the sacrum, both points inclusive; and if it be not in this situation the division will probably be lower down.

The length of the vessel varies greatly; according to Quain, in five-

sevenths of the cases it ranged between one-and-a-half and three inches.

Results.—Writing in 1852, I stated that when we look at the depth at which this artery is situated, its great size, and proximity to the centre of the circulation, and consider the force with which the blood rushes through it, we cannot but be struck with the success which has attended its ligation. Of 17 cases in which it had been tied, 8 were cured, and 9 died; in 11 of the cases the ligation was applied for aneurism, and of these 7 recovered. The 4 that died perished rather from the magnitude and extent of the disease than from the effects of the operation; and it is remarkable, as showing the power of the anastomoses in maintaining the vitality of parts, that in no instance did gangrene ensue. Since this period the operation has been performed many times, but with much less satisfactory results. Dr. Stephen Smith, of New York, published the statistics of this operation in 1860, giving the details of 32 cases; of these, he says, 25 died and only 7 recovered. I think the numbers should be 24 and 8; as in one case (Bushe's), the patient (an infant) died two months after the operation, the ligation having separated and the artery being occluded, and thus the deligation having succeeded. Gurlt of Berlin, in reproducing Smith's tables, adds 2 cases, both fatal. To these must also be added a fatal case by Dugus of Charleston, and two in which the operation has, within the last two years, been performed successfully in this country; once by Bickersteth of Liverpool, and once by Syme, in a remarkable case of iliac aneurism, in which that distinguished surgeon laid open the sac and tied the arteries (the common, external, and internal iliacs) opening into it. These cases increase the total number to 37, of which 9 recovered and 28 died; in 9 of the cases the peritoneum was wounded, and of these 8 proved fatal.

Of 13 cases in which this vessel was tied for hemorrhage, 12 proved fatal; of 17 in which it was deligated for aneurism, 7 recovered; and of the remaining 7, of which 6 were for disease (malignant, &c.) only 1 recovered.

LIGATION OF THE AORTA.—It is impossible not to contemplate with admiration the man whose mind was the first to conceive, and whose hand was the first to carry out, the determination to apply a ligation to the abdominal aorta; and who, guided by pathological observation and physiological experiment, dared to arrest at once the circulation through the main channel of supply to the lower half of the body, trusting to the collateral circulation for the maintenance of the vitality of the parts thus suddenly deprived of blood. Sir A. Cooper was the first to place a ligation on the aorta, in 1817. Since that period the operation has been four times performed; viz., by James, of Exeter; by Murray, at the Cape of Good Hope; by Monteiro, at Rio Janeiro; and by South, of London.

In Sir A. Cooper's case, the inguinal aneurism had burst, and the vessel was tied about three quarters of an inch above its bifurcation, by making an incision three inches in length through the abdomen, a little to the left of the umbilicus, the fingers being passed between the convolutions of the intestines, and the peritoneum covering the artery being scratched through. The patient survived forty hours. James ligatured the aorta much in the same way as Sir A. Cooper did, in a case in which he had previously employed the distal operation for an inguinal aneurism; but without success, the patient speedily dying. Murray ligatured the vessel by making an incision on the left side, in front of the projecting end of the tenth rib, and carrying it downwards for six inches, to the anterior superior spine of the ilium. The parts were then carefully divided to the peritoneum, which was separated from the iliac fossa and the psoas muscle, when, with great difficulty, and

by scratching with the end of an elevator and the finger-nails, room was made for the passage of the ligature round the artery, which was tied three or four lines above its bifurcation. The patient died in twenty-three hours. The most interesting case on record is that by Monteiro, who tied the aorta for a large false aneurism on the lower and right side of the abdomen ; here the incision was made much as in Murray's case, and the artery ligatured with great difficulty. The patient lived till the tenth day, when he died of secondary hemorrhage. In South's case, the artery was tied behind the peritoneum by an incision on the left side of the abdomen. The patient died in forty-three hours.

In this operation, there are not only all the dangers attendant upon the ligature of arteries of the first magnitude, but also the risk of producing fatal peritonitis, whether the abdomen be cut through, or the vessel sought for by stripping up the peritoneum from the iliac fossa ; and it appears to me that a patient suffering from so large an inguinal aneurism as to justify ligature of the aorta, would have a better chance of recovery, or rather of prolongation of life, by the adoption of proper constitutional treatment, together with pressure upon the tumour and the distal ligature or compression of the artery.

ANEURISM OF THE INTERNAL ILIAC AND ITS BRANCHES.—Aneurism of the *Trunk of the Internal Iliac Artery* is extremely rare. The only case with which I am acquainted is one related by Sandifort. The three principal branches of this artery—the *Gluteal*, the *Sciatic*, and the *Pudic*—have all occasionally, though rarely, been found affected by this disease. Of these branches, the gluteal has been most frequently found aneurismal, the sciatic next, and the pudic least frequently ; indeed, I am acquainted with only one instance of aneurism of this vessel. It is the Preparation 1701 in the Museum of the College of Surgeons ; and it exhibits an aneurism of the trunk of the pudic, nearly an inch in diameter, full of fibrinous laminæ.

Aneurisms of the Gluteal and Sciatic Arteries may be either traumatic or spontaneous.

The symptoms of these aneurisms present nothing peculiar. A circumscribed pulsating tumour at the posterior part of the gluteal region, presenting the usual character of aneurism, would not in general leave much doubt as to the true nature of the case. In some instances, however, the diagnosis might not be quite so readily made out, as happened in a remarkable case in which Guthrie ligatured the common iliac artery for a large pulsating tumour in the gluteal region, which presented all the characters and signs of aneurism, but which proved, on the death of the patient eight months after the operation, to be a pure enccephaloid tumour.

LIGATURE OF THE INTERNAL ILIAC.—This vessel was ligatured for the first time in 1812. The operation was performed by Dr. Stevens of St. Croix, on a negress, who suffered from an aneurism of the nates, supposed to be of the gluteal artery, but found after her death three years subsequently to take its origin from the sciatic. Dr. Stevens in this case made an incision five inches long on the left side of the abdomen, carefully dissected through the parietes, separated the peritoneum from the iliac fossa, turned it on one side, together with the ureter, and passed a ligature round the artery without much difficulty. Since that time the operation has been done nine times ; in 4 cases with success, by Aremdt, White, Mott (who accidentally wounded the peritoneum), and Syme ; in 5 cases unsuccessfully, by Atkinson of York (whose patient died on the nineteenth day of secondary hemorrhage), by Altmüller, by Thomas, by J. K. Rodgers, and by Higginson.

The success that has hitherto attended this operation is certainly remark-

able, when we take into consideration the depth at which the artery is situated and its great size ; it must, I think, be accounted for by the fact that, although in these cases the patient runs the ordinary risks attendant on the ligature of the larger pelvic arteries from the exposure and handling of the peritoneum, yet he is saved the danger resulting from the supervention of gangrene ; the anastomosis between its branches and that of the neighbouring vessels being so free, and the course traversed by the blood so short, that no difficulty can arise in the maintenance of the collateral circulation.

The steps of the operation necessary for the exposure of the internal iliac artery are precisely analogous to those requisite for the ligature of the common trunk. When the vessel is reached, it must be remembered that both the external and the internal iliac veins are in close relation to it ; the one being to its outer side, the other behind it. As these vessels are large, and their coats thin, it is necessary that they should be separated by the finger-nail, or the blunt end of an aneurism-needle, before the ligature is passed round the artery ; care must also be taken not to put the vessel too much on the stretch in applying the ligature, lest the ilio-lumbar artery be ruptured. As the length of the artery varies much, usually ranging between one and two inches, and as when it is short it has a tendency to be placed deeply in the pelvis, it would, I think, be more prudent, and occasion less chance of secondary hemorrhage, for the surgeon, under such circumstances, to ligature the common trunk.

FEMORAL AND POPLITEAL ANEURISMS.

We have, in the preceding section, considered aneurisms affecting the groin, which are by no means of very unfrequent occurrence. Aneurisms of the thigh are, however, much less frequently met with ; but those in the ham are very commonly encountered. Thus, out of 551 cases of aneurism recorded in the British medical journals of the present century, Dr. Crisp has found that 137 affected the popliteal, and only 66 the femoral artery. Of these 66, 45 were situated either in the groin or upper part of the thigh, and 21 only were truly femoral, or femoro-popliteal. The reason of this difference in the frequency of the occurrence of aneurism in different parts of the vessel, may be accounted for by attention to its anatomical relations. In looking at the main artery of the lower extremity, in its course from Poupart's ligament to where it terminates in the interior and posterior tibials, we see that it may be divided in relation to the muscular masses that surround it, into three principal portions : 1. That which is situated between Poupart's ligament and the anterior margin of the sartorius, which may be considered *inguinal* ; 2. That which intervenes between this point and the aperture in the adductor tendon, which may be considered *femoral* ; and, 3. That division of the vessel which corresponds to the ham, and which may be considered *popliteal*. Of these three divisions, the first and last are comparatively superficial, and, being unsupported by muscle, readily expand ; while the central portion of the artery is closely surrounded on all sides by muscular masses, and is less likely to be dilated into an aneurismal tumour. We also find that the inguinal portion of the vessel is closely and firmly invested by a dense and resistant fibro-cellular sheath, and is well supported by the fascia lata ; whilst in the popliteal space the artery is merely surrounded by the ordinary cellular sheath, and receives no aponeurotic support. This difference in the connections of these two parts of the vessel may, to a certain extent, explain the greater frequency of aneurism in the ham than in the upper part of the thigh.

ANEURISM OF THE DEEP FEMORAL ARTERY is of extremely rare occur-

rence; indeed, I am acquainted with two cases only. One of these is recorded by Bryant as having occurred in the practice of Cock at Guy's Hospital. The aneurism was situated at the origin of the deep femoral artery; the external iliac was tied, but the patient died nine weeks after the operation. Fig. 211 is taken from a patient who died of pneumonia, under Dr. Garrod's care, very shortly after admission into the hospital. On examination after death, a large tumour of the thigh, which had not been very closely examined during life, proved to be a circumscribed aneurism of the deep femoral artery.

ANEURISMS OF THE SUPERFICIAL FEMORAL AND POPLITEAL ARTERIES.—These commonly occur about the middle period of life, and are almost invariably met with in males, being at least twenty times more frequent in them than in women. Both sides are affected with equal frequency, and occasionally at the same time. According to Crisp, sailors would appear to be more liable to this variety of the disease than any other class. These aneurisms are most frequently sacculated; in the ham they are always so, but in the thigh they are sometimes tubular.

SYMPTOMS.—The symptoms of *Femoral Aneurism* present nothing peculiar; the tumour usually enlarging with considerable rapidity, with all the characteristic signs of the disease, and assuming a pretty regular ovoid shape. *Popliteal Aneurism* usually commences with stiffness and a good deal of pain about the ham and knee, which I have more than once seen mistaken for rheumatism; there is also a difficulty in straightening the limb, which is generally kept semi-flexed. The tumour increases usually with great rapidity, and has a great tendency to become diffused; these conditions will, however, materially depend on the side of the artery from which it springs. When it arises from the anterior aspect, next the bone, it increases slowly, being compressed by the firm structures before it. In this case, however, there is the great danger that, by its pressure upon the bones and knee, it may give rise to caries and destruction of the joint. When it springs from the posterior part of the artery, where it is uncompressed, it increases rapidly, and may speedily diffuse itself. The diffusion of an aneurism in this situation may take place in two directions. If it be femoro-popliteal, it may give way into the general cellular tissue of the thigh, the blood diffusing itself as high perhaps as Scarpa's triangle. When it is confined to the ham, it may either give way under the integuments, and into the superficial structures of the limb, or else under the deep fascia of the leg, where it will compress the posterior tibial nerve and artery. In all cases, the diffusion of popliteal aneurism is likely to be followed by gangrene.

DIAGNOSIS.—The diagnosis of popliteal aneurism has to be made from chronic abscess, from bursal enlargements, and from solid tumours. In distinguishing it from chronic abscess, no serious difficulty can well be experienced; but it may happen that, when an aneurism has suppurated, considerable difficulty arises in determining its true nature; whether it be merely an abscess or not. On such cases as these the state of the circulation in the lower part of the limb will throw much light. *Bursal tumours*, often of large size and multilocular, are not unfrequently met with in the ham; but

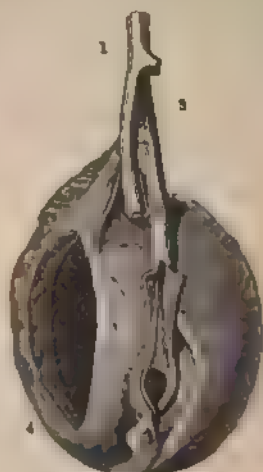

Fig. 211.—Aneurism of Deep Femoral Artery.

- 1 Common Femoral.
- 2 Superficial Femoral.
- 3 Deep Femoral. 4 Aneurism.

I have never found any great difficulty in determining their true nature, their elasticity and roundness, together with their mobility and want of pulsation, being sufficiently indicative of their character. The most serious diagnostic difficulty may arise from confounding solidified aneurisms of the ham with *solid tumours*, either of a sarcomatous character, or springing from the tibia and femur; and I have known one case of aneurism in this condition, in which amputation was performed on the supposition of its being a solid tumour (Fig. 191).

TREATMENT.—The treatment of femoral and popliteal aneurism may be conducted either by ligature, or by compression of the vessel leading to the sac. As a general rule, for the reasons already stated, compression should be employed in preference to the ligature; but yet cases may arise when, from the failure of compression, or for other reasons, it may be necessary to ligature the femoral artery.

LIGATURE OF THE COMMON FEMORAL.—In looking at the femoral artery, it might at first be supposed that the common trunk, situated superficially between the inferior edge of Poupart's ligament and the origin of the deep femoral, would be the most convenient situation for the application of the ligature; but experience has shown that deligation of the vessel here is in the highest degree unsuccessful. This arises from the shortness of the trunk, rendering it necessary to tie the artery between and in close proximity to those collateral branches that will constitute the most direct and immediate agents in the anastomosing supply,—viz., the circumflex ili and the deep femoral, so that the internal coagulum would not readily form. In addition to this, however, a number of small inguinal branches, such as the superficial epigastric and circumflex ili, the superficial and deep external pudic, and very commonly one of the circumflex arteries of the thigh, more especially the internal, arise from the common trunk in its short course, and these vessels, though small in size, constitute a source of great embarrassment to the surgeon during the operation, for, if wounded near their origin, they bleed most furiously, and are a cause of considerable danger afterwards, by interfering with the proper plugging of the vessel. Of twelve recorded cases, in which this artery has been tied, it would appear that three only succeeded; whilst in the remaining nine instances secondary hemorrhage occurred, which proved fatal in three, and in six was arrested by the ligature of the external iliac. This operation, I think, therefore, ought to be banished from surgery; and, in all those cases of aneurism that are situated above the middle of the thigh, and in which sufficient space does not intervene between the giving off of the deep femoral and the upper part of the sac for the application of a ligature to the superficial femoral, the external iliac should be tied, unless compression can be employed.

LIGATURE OF THE SUPERFICIAL FEMORAL.—The superficial femoral artery, in its course from the origin of the deep femoral to the aperture in the tendon of the adductor, is divided by the crossing of the sartorius muscle into two portions of unequal length, which have different relations to neighbouring structures. The upper division of the artery, which lies above the anterior margin of the muscle, is of most interest to the surgeon, as it is in this part of its course that it is invariably ligatured in cases of aneurism. It is true that John Hunter, in the operation which he introduced for popliteal aneurism, exposed and tied the vessel in the lower third of the thigh, but his example has not been followed by modern surgeons, on account of the far greater difficulty in reaching the vessel here than in the first part of its course.

The superficial femoral, where it lies in Scarpa's triangle, being merely covered by the common integument, the superficial fascia, and the fascia

lata, may be reached by as simple an operation as any that the surgeon has to perform for the ligature of the larger vessels. An incision, from three-and-a-half to four inches in length, should be made from a point two inches below Poupart's ligament, and as nearly as possible midway between the anterior superior spine of the ilium and the symphysis pubis, and carried downwards in a direction parallel to the axis of the limb. The skin and superficial fascia having been divided, the *fascia lata*, which is here very thin, is exposed and opened to the same extent as the incision in the integuments; the inner margin of the sartorius now comes into view, and immediately to the inner side of, and perhaps slightly overlapped by this, is the sheath of the vessels; this must now be cautiously opened, the long saphenous nerve being respected, and the aneurism-needle unarm'd passed between the artery and vein, from within outwards, about four inches below Poupart's ligament; it should then be threaded and withdrawn, and the ligature tied. The edges of the wound must now be brought into contact by a couple of stitches and two strips of plaster; the limb being semi-flexed, somewhat raised, laid on its outer side, and wrapped in soft flannel or cotton-wadding. The severe pain which is usually complained of about the knee after the tightening of the ligature, may best be relieved by a full dose of opium.

In this operation there are several points of considerable importance that require special attention. The ligature should always be applied about four inches below Poupart's ligament, so that sufficient space may intervene between the origin of the deep femoral, which is usually from one or two inches below the crural arch, and the point deligated, to admit of the formation of a proper coagulum in the vessel. It has, indeed, happened that the ligature has been placed within three-quarters of an inch of the origin of the deep femoral, without any injurious consequences resulting. The proper point, however, for the deligation of the artery is that indicated, which is usually the very spot at which the sartorius crosses it; though, if this muscle be very broad, it may be necessary to draw it to the outer side, and tie the vessel below it. In cutting down upon the artery, the saphenous vein, or any parallel branch, should if possible be avoided. After the sheath has been opened, it will sometimes be found that a rather large muscular branch is given off from the artery at about the part where it was intended to ligature it; if so, this must be carefully avoided, as well as any small veins that cross the main trunk in this situation.

The femoral vein, which lies behind and somewhat to the inner side of the artery, is best avoided by passing the needle from within outwards between the two vessels; the inner side of the sheath being at the same time put upon the stretch by drawing upon it with a pair of forceps. After the needle has been brought up on the outer side of the artery, a small portion of the sheath will sometimes be found to be pushed up by it; this must be divided by being carefully touched with the point of the scalpel, when the needle may be carried round the vessel.

Results — Ligature of the femoral artery for popliteal aneurism is an operation that has been so frequently performed, that surgeons seldom think of recording cases of this description, unless they present complications or sequelae of unusual interest or severity; hence but little importance can be attached to any statistical deductions from reported cases as to the fatality of the operation, although they may serve as a rough estimate of the proportion maintained between the different accidents, such as hemorrhage, gangrene, &c., that follow it. That the ligature of the femoral artery is attended with more success than that of any of the other large trunks, can admit of no doubt. This is not only in accordance with the general experience of

surgeons, but is confirmed by the statistics of published cases, even without making allowance for the probability of more of the unsuccessful than successful having been recorded. Thus of 110 instances, collected by Dr. Crisp, in which the femoral artery had been ligatured for popliteal aneurism, only twelve are reported to have died; amongst these, four deaths occurred by secondary hemorrhage, three by gangrene, and the others by phlebitis, tetanus, chest-disease, &c. Higher rates of mortality are, however, given by other authors; thus, Norris states that nearly one in four die after this operation; Hutchinson finds that of thirty-three cases operated on in London, ten were fatal, five deaths resulting from gangrene.

ACCIDENTS.—*Wound of the Femoral Vein* is without doubt the most serious accident that can happen in the operation for ligature of the superficial femoral artery, and is one of which there is especial risk when recourse is had to this operation for aneurism; as in this disease the fine cellular tissue which naturally connects the two vessels often becomes thickened and indurated, in consequence of inflammatory action having extended upwards from the sac to the sheath of the vessels. It is best avoided by passing the needle in the way that has been already recommended, unarmed, and without the employment of force. This accident is almost invariably fatal, there being but very few instances on record in which patients have survived it; death usually resulting from diffuse phlebitis, or the superintention of gangrene. The true cause of the fatal result in these cases was first pointed out by Halwen, who showed that, when the vein is wounded by the aneurismal needle, it is transfixated at two points, between which the thread is drawn across; and when this is tied, a segment of the vein is necessarily included with the artery in the noose. It is this inclusion of the ligature within a portion of the vein, where it acts like a seton, and keeps up constant irritation, that prevents the occurrence of adhesive phlebitis, and occasions diffuse inflammation in the interior of the vessel; and it is consequently this circumstance, and not the mere wound of the vein, that determines the great fatality of this peculiar accident. Guided by this view of the mechanism of the injury, the indications in its treatment become obvious. They consist in removing the ligature at once, and thus, by taking away the main source of irritation, converting the wound into a simple puncture of the vessel, which readily assumes adhesive action. The surgeon should, therefore, as soon as the accident is perceived, withdraw the ligature, and, opening the sheath about half-an-inch higher up, re-apply it to the artery there. The hemorrhage from the punctured vein readily ceases on the application of a compress.

The occurrence of *Secondary Hemorrhage* after the ligature of the superficial femoral is a troublesome accident, and one in which the surgeon, to use Fergusson's expression, "will most assuredly find himself in an eventful dilemma;" and in which it is necessary that his line of action should have been well considered beforehand, as he may not have much time to spare for reflection when such an event takes place. In cases of this kind four lines of treatment present themselves, viz.: the employment of pressure; ligature of the vessel at a higher point; deligation of the bleeding apertures in the wound; or amputation of the limb.

Pressure may be applied by placing a graduated compress of lint or compressed sponge over the bleeding orifices, and fixing it there firmly by a horse-shoe tourniquet. This means, although extremely uncertain, occasionally succeeds; should it not do so, however, and bleeding recur a second time, it is useless to continue it, as experience has shown that the hemorrhage will continue until the patient is worn out.

Location of the superficial femoral at a higher point, or, if the artery have been cut too high for this, the deligation of the external iliac, presents itself as a probable means of arresting the hemorrhage. Such an operation, however, is fraught with danger, and has, I believe, invariably been followed by gangrene of the limb. It might at first be supposed that the limb would not be placed in a worse situation after the ligature of the external iliac, whether the superficial femoral had been previously tied or not; the anastomosing channels remaining the same in either case. But in reality it is not so, for, although the blood might find its way through the epigastric, the circumflex ilii, the gluteal and sciatic arteries, into the deep femoral and its branches, yet from this point the difficulty of its transmission through the trunk would be materially increased. If the superficial femoral be open, it serves as a direct and easy channel for the conveyance, to the vessels of the leg and foot, of the blood brought by the anastomoses. But when the superficial femoral is tied, this blood must find its way through a second chain of anastomosing vessels,—those intervening between the branches of the deep femoral and the articular arteries of the knee; and here the real difficulty would arise, its impulse not being sufficient to overcome the obstruction to its passage through these small channels, which might not probably be still further obstructed by the pressure of the aneurism. Should the anastomosing circulation be sufficiently free to maintain the vitality of the limb, it is not improbable that the recurrent blood would escape from the distal side of the ligature, and thus keep up the hemorrhage exactly as in case of wound. It appears indeed that the femoral artery, in a case of secondary hemorrhage after the application of the ligature, is in very much the same condition as an artery which has been wounded, and in which the bleeding, having been suppressed for some days, has returned with violence; and I think the best course for the surgeon to pursue is the same practice that he would follow in the event of secondary hemorrhage occurring from a wounded vessel, viz., by cutting down upon the bleeding part and applying a ligature to it. That such an operation is surrounded with difficulties cannot be doubted; yet none would present themselves that care and skill might not overcome. The surgeon would certainly have to cut into a part infiltrated with blood, in which the different tissues could not readily be distinguished, and the vessel when reached would be found to be soft, friable, and granulating, yet by free dissection above and below the wound, a portion of it might at last be exposed, where its coats would hold a ligature; or should this not be found, the wound might be firmly plugged from the bottom with compressed sponge; or the bleeding aperture might be touched with the actual cautery. Should these means fail, it would, I think, be safer to amputate the limb, than to endeavour to arrest the hemorrhage in any other way.

Gangrene of the Limb is perhaps the most frequent source of danger after ligature of the femoral artery for popliteal aneurism. It seldom occurs, however, unless the tumour be of considerable magnitude, have become disorganised, or otherwise interfere seriously with the circulation through the limb. I have, however, seen it follow the operation where the popliteal aneurism had not attained a larger size than that of an orange; but, in this case, there was much œdema of the limb, and congestion of the veins before the operation; and on examination afterwards, it was found that the popliteal vein had been obliterated by the pressure of the tumour. The gangrene may, in some cases, be prevented by the treatment that has been pointed out at page 185. When it has fairly declared itself, there is necessarily no resource left but amputation, and this operation is sufficiently successful; for

I find that of fourteen cases in which it was done, there were ten recoveries, and but four deaths.

The *Return of Pulsation in the Sac* after the operation for popliteal aneurism is by no means of frequent occurrence; yet it has been met with in some instances, and *Secondary Aneurism* has also been found in this situation. In these cases the patient should be put upon a careful dietetic plan, the limb be kept elevated and at rest, and pressure applied by means of a compress and bandage, or a horse-shoe tourniquet. In this way cures have been effected by Wishart, Turner, Briggs, and Liston. In conjunction with such treatment, or in the event of its not sufficing, the compression of the common femoral artery as it passes over the pubic bone would in all probability effect a cure. Should it not do so, and the tumour continue to increase, threaten to suppurate, or to occasion gangrene, amputation would be the sole resource.

DOUBLE POPLITEAL ANEURISM.—In cases of this kind the artery has been occasionally ligatured with advantage on both sides, either simultaneously, or, with more safety, consecutively. But these cases appear to me especially adapted for the employment of pressure, so as to avoid that disturbance of the balance of the circulation which is certain to ensue when one vessel is ligatured, and which may act injuriously upon the opposite aneurism. When the popliteal aneurism is conjoined with a similar disease in the groin, ligature of the external iliac is the proper course to pursue, and will effect a cure of both affections.

DIFFUSE POPLITEAL ANEURISM.—When a *circumscribed* popliteal aneurism suddenly becomes *diffused*, the patient is seized with faintness or sickness, with pain, numbness, and a hot trickling sensation in the limb, the temperature of which falls at the same time that its bulk increases, and the integument assumes a white, shining, mottled appearance, with more or less purplish discoloration. This condition usually occurs after a circumscribed aneurism has existed in the ham for some weeks or months, and on the occurrence of some sudden exertion. In some cases, however, the disease appears to have been diffused from the very first, the coats having given way, and extravasation having taken place into the cellular tissue of the limb, without the previous consolidation of the parts around the artery, or any attempt at the formation of a sac. In these cases the extravasation into the limb may either be conjoined with much œdema; or it may be confined to the cellular tissue of the ham, and to the upper and back part of the leg, or extend downwards under the muscles of the calf. When the patient comes under the observation of the surgeon, the tumour is found to be solid, elastic, and irregular, without pulsation or bruit; the limb œdematous, cold, and congested. The diagnosis of this form of aneurism is often extremely difficult, and there is great danger of confounding it with simple extravasation into the calf, with abscess, or, possibly, with malignant tumour of the leg.

Treatment.—The danger attending on popliteal aneurism is greatly increased by its becoming diffused. Under these circumstances the ligature of the artery usually affords but a slender prospect of success, the collateral vessels being so compressed and choked by the pressure of the effused blood as not to admit of the circulation being carried on through them; hence, in many of these cases, the only resource left to the surgeon is to amputate the limb.

AMPUTATION FOR DIFFUSE POPLITEAL ANEURISM.—The question of *Amputation* in cases of diffuse popliteal aneurism is not very easily submitted to any very positive or definite rules, except where the independ-

ing gangrene is so evident as not to admit of doubt. There are, however, certain general considerations that may guide the surgeon in deciding on this point.

1. In some cases the sac has either given way to a very limited extent ; or else its walls, having become thin and expanded, are yielding rapidly under the pressure of the blood, becoming confused with the surrounding parts. Here we should ligature the artery without delay ; for although it is but seldom that a limb can be saved when once the blood has become infiltrated into the general cellular tissue, yet it is possible that such a fortunate occurrence may happen.

2. In other instances the aneurism has not from the first been very distinctly circumscribed. It has followed the infliction of some mechanical injury, and in the course of a week or two has acquired a considerable size, without definite or distinct limitation, being solid or but little compressible. Such a case as this can scarcely be considered, strictly speaking, a diffuse aneurism ; but yet, if by *circumscribed* we mean that the blood is contained in a defined cyst with walls, it scarcely complies with such a definition, the fluid blood being rather prevented from escaping widely by a temporary barrier of coagula entangled in the loose cellular tissues of the part, and the vessel being ruptured to a considerable extent, or completely torn across. Here we are certainly justified in having recourse to compression or ligature with a good prospect of success.

3. When the ham is occupied by a large, rapidly increasing tumour, extending perhaps some way down the calf and up the thigh, and encroaching on the knee, the skin covering it being more or less discoloured, there being no pulsation perceptible in the tibial arteries, and the veins of the limb being full and even somewhat congested, the foot oedematous and several degrees in temperature below that of the opposite limb, the difficulty of coming to a decision is considerable.

In such a case as this, I think that the existence or non-existence of pulsation of a distensible character is a circumstance of very great importance, and may serve to guide the surgeon.

If there be distinct impulse of a distending character, which can be arrested by compression of the femoral artery, with some diminution of the size of the tumour, it is an evident indication that blood is being transmitted through the sac, and that this contains some fluid blood. Under these circumstances it will, when the artery is tied, subside to a considerable extent, thus allowing more space for the conveyance of the collateral circulation ; and it would be but right to give the patient the chance of preserving his limb by ligaturing the vessel.

If, however, the tumour have, from the very first time when it attracted the patient's notice, been more or less solid and incompressible ; and, though it may at an early period of its existence have pulsed, if this pulsation have suddenly ceased, the aneurism at the same time having undergone rapid and great increase of bulk with much tension and lividity of the integuments, oedema and coldness of the limb, with a tendency perhaps to vesication and ulceration of the skin covering the tumour, there is no resource left but amputation.

It must however be borne in mind, that the aneurism may become diffused, and extensively so, without any very great change in the shape and size of the limb. It is only when the sac ruptures in such a position that the blood is effused into the general cellular tissue of the limb or under the skin, that much tension of the integuments and increase in the bulk of the part takes place.

4. When a rupture occurs in a part of the sac that is more deeply seated, the blood is extravasated underneath the deep fascia of the leg, and is bound down by this and by the superincumbent muscles; and disorganisation of the interior of the limb may be the result, without much, if any, change in its bulk or in the colour of the integuments, but with excessive deeply seated pain. There must always be considerable risk, in such a case as this, of confounding the arterial disease with solid tumour; and the diagnosis can be effected only by a reference to the early history of the case, and more particularly to the existence or absence of pulsation at this period. Indeed, the existence or non-existence of pulsation in these cases, is of the very utmost importance in reference to the question of treatment. The pulsation may have ceased in a case of diffuse popliteal aneurism, in consequence of the blood that has been extravasated being so confined and bound down by the fascia and muscles under which it is effused, that it compresses or seals the mouth of the artery leading into the sac, to such an extent as to arrest the passage of blood through it, either wholly or so that it enters in a feeble stream, of insufficient force to communicate impulse to the fluid that has been extravasated into the limb. This pressure may, as in the case of which an illustration has been given (Fig. 191), be confined to the deep parts of the limb and not give rise to much, if any, general tension of it, the blood being confined below the deep fascia, where it communicates the sensation of a hard solid elastic tumour devoid of pulsation; attention should consequently not be too exclusively directed to the state of general tension of the surface of a limb, as this is by no means necessarily an indication of the state of the parts beneath. But the surgeon should rather look to the presence or absence of pulsation. If pulsation still exist, the blood continues to find its way into the sac, and most probably through it, the tension of the parts not having yet reached its maximum. If there be no pulsation, he may be sure that the entrance of blood into the diffused aneurism has ceased in consequence of compression exercised on the mouth of the artery leading to it, by the tense condition of the surrounding and enveloping tissues re-acting on the mass of blood effused beneath them. In such a state of things as this, the vitality of the lower part of the limb can only be maintained by the blood that may find its way through the anastomosing channels; and this may, if the tension of the limb be not general, the extravasation being confined below the deep fascia, be sufficient for this purpose. If surgical interference be delayed in such a case as this, the deep fascia will soon give way by rupture or ulceration, and the blood will be infiltrated into the general cellular tissue of the limb; and then, by compressing those collateral branches that have hitherto maintained a feeble circulation in it, will infallibly occasion gangrene. If, on the other hand, ligature of the main artery be had recourse to, the anastomosing circulation, which may have been barely sufficient to keep up a feeble vitality in the leg and foot, will be so much interfered with that gangrene of the limb inevitably ensues. The only resource, therefore, that is left in these cases is to amputate at once, in order that the patient may be saved the shock of the constitutional disturbance occasioned by the setting in of mortification, as well as the pain and risk of a previous unnecessary operation.

5. When gangrene threatens, the leg and foot having become cold, the skin being either pale, tallowy and mottled, or discoloured, of a purplish hue, with perhaps vesications and much cedema, whether the ligature have been previously applied to the femoral artery or not, or whatever the condition of the aneurism may be, whether circumscribed or diffused, the patient will stand a better chance of ultimate recovery by having the limb removed at

once above the knee. The part at which amputation should be performed in these cases is a point deserving some consideration. If the femoral artery have been ligatured, the thigh should be amputated on a level with the ligature, the artery being cut just above this. In this way the double risk which the patient would otherwise run of secondary hemorrhage from the seat of the ligature, as well as from the face of the stump, will be reduced to a single chance of hemorrhage from the stump. If the amputation be the primary operation, it should be done at the lower third of the thigh, provided the extravasation be confined to below the knee; or higher up, if the effused blood have extended above this joint.

ANEURISM OF THE TIBIAL ARTERIES.

Aneurisms of the Tibial Arteries are extremely rare, except as the result of wound, yet they are occasionally met with; and in the museum of St. George's Hospital is a preparation of a small aneurism of the posterior tibial. These aneurisms sometimes, however, require ligature either for injury or for disease.

LIGATURE OF THE TIBIAL ARTERIES.—The *Posterior Tibial Artery* may be tied in two parts of its course; either behind the ankle, or in the calf of the leg. Behind the ankle, it may be reached by making a semilunar incision three inches long, about three-quarters of an inch behind the inner malleolus, towards which its concavity should look. After dividing the integument and superficial fascia, the deep fascia, which is usually single, but may be double, must be laid open; this closely invests the vessel, nerve, and tendons in this situation; under it the artery will be found accompanied by two veins, from which it must be separated before the ligature is passed. Anterior to the vessel, and nearer the bone, are the tendons of the flexor digitorum communis and tibialis posticus muscles; behind, are the nerve and the tendon of the flexor proprius pollicis.

In the middle of the leg, the posterior tibial artery should be tied only for wound in that situation. Under such circumstances no regular operation can be performed, but an incision of sufficient length, taking the wound for its centre, should be made through the gastrocnemius and soleus, parallel to their fibres, when, after these have been cut through, the deep fascia will be exposed. This must next be opened, when the artery will be found, accompanied by its veins, and having the nerve to the outer side. From the depth at which the vessel is situated, and the free incisions that it is necessary to make through muscular parts, it is extremely difficult to apply the ligature in this situation. The later steps of the operation may be much facilitated by flexing the leg on the thigh, and extending the foot so as to relax the muscles.

The *Anterior Tibial Artery* may be tied in several situations; but, like the posterior tibial, it should not be ligatured in the upper or middle parts of the leg, except for injury. The difficulties of the operation are lessened as the ankle is approached, where the artery becomes superficial, and may easily be secured.

In the upper third of the leg the artery lies deeply between the tibialis anticus and extensor communis digitorum muscles, surrounded by veins, and having its nerve to the outside. If it be ever found necessary to tie it in this situation, the incisions requisite to expose it should be made at least four or five inches in length; and especial care should be taken not to cut into the muscular substance, but to open the first intermuscular space to the outside of the tibia, at the bottom of which the vessel will be found. In the middle third of the leg, the artery is crossed by the

extensor pollicis, and will be found between the tibialis anticus and this muscle; it is best reached here by keeping well to the outside of the tibialis anticus.

The *Arteria Dorsalis Pedis* may be felt pulsating, and may readily be secured, as it runs forward from the ankle-joint to reach the space between the first and second metatarsal bones, lying between the tendon of the extensor pollicis and that of the extensor brevis digitorum.

CHAPTER XLIV.

ANEURISM BY ANASTOMOSIS, AND NÆVUS.

ANEURISM BY ANASTOMOSIS.

Aneurism by Anastomosis is a disease of the arteries, in which the vessels become excessively elongated, tortuous, and serpentine; sometimes they assume a varicose condition, being dilated into small sinuses, and are always very thin-walled, resembling rather veins than arteries in structure. This kind of dilatation of the vessels will give rise to pulsating tumours, often of considerable size, and of a very active and dangerous character. They may be situated in almost any tissue or organ of the body, but are most commonly met with in the submucous and subcutaneous cellular tissue, and most frequently occur in the upper part of the body, especially about the scalp, orbit, lips, and face; but they have been met with in other situations, such as the tongue, and even in internal organs, as the liver; and I have seen very active growths of this kind on the uates and foot. In some cases, aneurism by anastomosis occurs in bones, in which it forms a special disease, and is not uncommonly associated with encephaloid. Indeed, there is certainly a great tendency for aneurism by anastomosis and encephaloid to run into one another; the limits between them not being very clearly defined, especially when they occur in connection with osseous tissue. It will generally be found that the arteries leading to, though at a considerable distance from the aneurism by anastomosis, are tortuous, enlarged, with thin and expanded coats, and pulsate actively; in fact, constituting that condition that goes by the name of *Circoid Dilatation* of the vessels.

Aneurism by anastomosis forms tumours of varying magnitude and irregular shape; they are usually of a bluish colour, have a spongy feel, are readily compressible, not circumscribed, and have large tortuous vessels running into and from them on different sides. Their temperature is generally above that of neighbouring parts; and a vibratory or purring thrill, amounting in many cases to distinct pulsation, may be felt in them. This pulsation or thrill is asynchronous with the heart's beat, may be arrested by compressing the tumour or arteries leading to it, and returns with an expansive beat on the removal of the pressure. The bruit is often loud and harsh, but at other times of a soft and blowing character. These growths rarely occur in infancy, but generally make their appearance in young adults, though they may be met with at all periods of life, often as the consequence of an injury of some kind.

DIAGNOSIS.—It is of importance to effect the diagnosis between *ordinary aneurism* and that by anastomosis. In many cases the situation of the tumour at a distance from any large trunk, as on the scalp, the outside of

the thigh, or the gluteal region, will determine this. Then, again, the outline of the growth is less distinct than in true aneurism; and tortuous vessels will be felt leading to it from different directions. The swelling also is doughy, and very compressible; but when the pressure is removed, the blood enters it with a whiz and thrill, not with the distinct pulsating stroke that is found in aneurism. The pulsation, not so forcible as in aneurism, is more heaving and expansive. The bruit is louder, more superficial, sometimes having a cooing note. By pressure on the arteries leading to the tumour, these signs are usually not entirely arrested, though diminished in force, the blood entering it from the neighbouring parts, and in a less direct way.

TREATMENT.—The treatment of aneurism by anastomosis must depend upon the size and situation of the growth. When it is so placed that it can be *ligatured* or *excised*, as on the lip, or when of small size, about the neck, face, or scalp, it should be removed in one or other of these ways. I always prefer, in cases of *nævus*, the ligature, applied as will immediately be described, as being the safest, and upon the whole the readiest mode of getting rid of such a tumour. If excision be practised, it is necessary to be very careful to cut widely of the disease; if it be cut into, fearful hemorrhage may ensue, which can only be arrested by pressure, and which in several instances has proved fatal.

If the disease be very large and extended, as is commonly seen on the scalp, or if deeply seated, as in the orbit, neither ligature nor excision of the tumour can be practised, and it becomes necessary to starve it by cutting off its supply of blood. This may be done either by *ligaturing the principal branches leading to it, or the main trunk of the limb or part.*

Simple ligature of the arterial branches leading to the tumour has never, I believe, been followed by success; at least, in ten recorded instances in which it has been had recourse to, the disease has not in one instance been cured. It has, however, been successfully conjoined by Dr. Gibson in two cases of aneurism by anastomosis of the scalp, with incisions made round the tumour at intervals between the principal feeding arteries, which at the same time were tied.

The *main trunk* leading to the tumour has been ligatured in a considerable number of cases. The brachial and femoral arteries have been tied for disease of this kind situated on the extremities, and in some instances with success; but the carotid is the vessel that has been most frequently deligated, in consequence of the tumour being so commonly situated on the scalp and in the orbit. This operation has been done in twenty recorded cases, and in five instances both the carotids were ligatured at intervals of several weeks. In all of those cases in which the double operation was performed, the patients ultimately recovered. In some of the cases in which one carotid alone was tied, the disease, being seated upon the scalp, was not cured; and it was afterwards found necessary to have recourse to ligature of the tumour, to excision, and to other means of removal; indeed, when seated upon the scalp, this disease appears to be more intractable than in any other part of the body, owing probably to the freedom of the arterial supply from the numerous vessels that ramify in this region. Here, however, much benefit might be derived after ligature of the carotid, by adopting the plan suggested by Dr. Gibson of tying the feeding arteries, and making incisions between them down to the bone. The ligature of the carotid has answered best for diseases of this kind in the orbit; of thirteen instances in which the artery has been tied for aneurism by anastomosis in this situation, a cure was accomplished in the majority.

NÆVUS.

This disease, under which are included those various affections termed *Mother's Marks*, *Erectile Tumours*, and *Vascular Growths*, constitute an important and interesting section of surgical affections. It appears to consist essentially in an excessive development of the vascular tissue of a part, and differs greatly as to nature, cause, and treatment; according as the arterial, the capillary, or the venous elements of the tissue predominate. The predominance of the arterial tissue we have already considered, under the head of Aneurism by Anastomosis; it now remains for us to describe the Capillary and Venous Nævi.

CAPILLARY NÆVI appear as slightly elevated but flat spots on the skin, of a bright red or purplish tint, and having occasionally granular or papulated elevations, with some larger vessels ramifying on their surface. They often spread superficially to a considerable extent; they are usually situated on the face, head, neck, or arms, but occasionally, though more rarely, on the back, the nates, the organs of generation, and the lower extremities; they are, I believe, always congenital, though often at birth of a very small size, not larger than a pin's head, from which they may spread in the course of a few weeks or months to patches an inch or two in diameter. In many cases no inconvenience results from this disease except the deformity it entails; but occasionally, more especially when the growth is at all prominent, there is a great disposition to ulceration of an unhealthy and hemorrhagic character. When bleeding occurs, it is usually in a trickling stream, and without any degree of force.

VENOUS NÆVI are of a dark purple or reddish colour, usually very prominent, and often forming distinct tumours of considerable size, which may either be smooth and ovoid, or else somewhat lobulated. On compressing a growth of this kind, it subsides to a certain extent, feeling doughy, soft, and inelastic, and on the removal of the pressure fills up again. In some cases, when consolidated by inflammation, or containing cysts, it cannot be lessened in bulk by pressure. These nævi are usually of about the size of half a walnut, but sometimes much larger. I have removed them from the nates and the back fully as large as an orange. They less frequently occur upon the head and face than the capillary form of the disease; most of the instances that I have seen have been met with in the lower part of the body, about the nates, back, lower extremities, and organs of generation.

Subcutaneous nævi are occasionally met with, of a mixed character, forming soft, doughy, and compressible tumours, which may be recognised by being capable of diminution by pressure, on the removal of which they slowly fill out again to as large a size as before; they also become distended when the child screams or struggles, and are usually of an oval shape, smooth and uniform. The skin covering the tumour is often unaffected; at other times it is implicated in an oval patch on the most prominent part of the growth, and occasionally the surrounding veins are bluish and enlarged.

STRUCTURE.—Capillary nævi appear to be composed of a congeries of small tortuous vessels, of a capillary character; venous nævi appear made up of thin tortuous veins, dilated into sinusses and small pouches. In the midst of these sinusses, cysts are not uncommonly found, sometimes containing clear, at other times a dark, sanguinolent fluid. These cysts are probably venous sinusses, the openings into which have become occluded.

TREATMENT.—In the treatment of nævus, the first point to be determined

is whether the case should be left to nature, or whether operative measures should be had recourse to. In deciding this point we must be guided by the size, situation, and character of the morbid growth. If this be small, cutaneous, and superficial, so situated that it occasions little or no disfigurement, and if it show no tendency to increase, it may be left without interference; when it may eventually shrivel and disappear, or become converted into a kind of mole. In some cases this process may be hastened by the application of tincture of iodine or liquor plumbi. In other cases, again, the nævus, though cutaneous and superficial, is so widely diffused over the surface, that no attempt at its removal or destruction can be entertained with prudence.

But if the nævus be large, if it be subcutaneous, or if it increase in size, or if it be so situated as to occasion disfigurement, then means must be adopted for its removal by operative procedure.

Operations for the removal of nævi may be conducted on four principles:—1, to excite adhesive inflammation in them, and so to produce plugging and obliteration of the vascular tissue of which they are composed; 2, to destroy the growth by caustics; 3, to remove it with the knife; or, 4, to remove it by ligature. Each of these different plans of treatment is peculiarly applicable when the disease assumes certain forms, and affects certain situations.

1. When the nævus is of small size, and occurs in such situations that its destruction by caustics, or removal by knife or ligature, would be attended by serious deformity, as when it is seated about the eyelids, upon the tip of the nose, at the inner angle between the eye and the nose, or about the corners of the mouth, it is best to endeavour to procure its obliteration, by exciting adhesive inflammation in it. This may be done in various ways. If small, the nævus may be vaccinated. If it be larger, the most convenient plan consists, perhaps, in passing a number of fine silk threads across the tumour in different directions, and leaving them in for a week or two at a time, until they have produced sufficient inflammation along their tracks, then withdrawing them, and passing them into other parts of the tumour. In this way its consolidation may gradually be effected. Another very useful plan is to break up the substance of the growth subcutaneously, by means of a cataract-needle, or tenotome, and in the intervals between the different introductions of this instrument to keep up pressure upon it. In other cases, again, the requisite amount of consolidation will be induced by passing acupuncture-needles into the nævus, and then heating them by means of a spirit-lamp, or by injecting the perchloride of iron into it by means of a small glass syringe with a screw-piston rod and a fine sharply-pointed nozzle (Fig. 212). In all these different ways the surgeon may succeed in curing the disease.

Fig 212.—Syringe for Injecting Nævus.

2. When the nævus is small, very superficial, of the capillary character, with an exceedingly thin covering of cuticle, and so situated, as upon the arm, neck, or back, that a moderate amount of scarring is of little consequence, it may most conveniently be removed by the free application of nitric acid. This should be well rubbed on by means of a piece of stick; and, after the separation of the slough produced by it, its application must

be repeated as often as there is any appearance of the granulations springing up, which will occasionally happen at one angle of the wound, and is indicative of a recurrence of the vascular growth.

3. When the nevus is of large size, constituting a more or less distinct tumour, and is of a somewhat venous character, it may occasionally be excised. In doing this, however, care should be taken to cut wide of the disease; and no operation with the knife should be undertaken unless the growth be either so situated, as upon the lip, that the parts may readily be brought or compressed together, or upon the nates or thigh, and of a very indolent and venous character. It is especially when the nevus is of the lipomatous or cystoid character, that excision may be advantageously practised.

4. As a general rule, it is far safer and more convenient to extirpate the growth with the *ligature*; and this, indeed, is the mode of treatment that is most generally applicable to tumours of this kind in whatever situations they may occur, as it effectually removes them without risk of hemorrhage, and leaves a sore that very readily cicatrises.

The ligature requires to be applied in different ways, according to the size and situation of the tumour. In all cases, the best material is firm, round, compressed whip-cord. This should be tied as tightly as possible, and knotted securely, so that there may be no chance of any part of the tumour escaping complete and immediate strangulation. It is well, if possible, not to include in the noose any healthy skin, but to snip across with a pair of scissors, that portion of integument which intervenes between the cords that are tied together; at the same time, care must be taken to pass the ligatures well beyond the limits of the disease.

When the tumour is small, an ordinary double ligature may be passed across its base, by means of a common suture-needle; and, the noose being cut and the thread tied on either side, strangulation will be effected. When it is of larger size, and of round shape, the most convenient plan of strangulating the tumour is that recommended by Liston. It consists in passing, by means of long nevus-needles, fixed in wooden handles, and having the eye near their points, a double whipcord ligature, in opposite directions across the tumour; then cutting through either noose, and tying together

the contiguous ends of the ligature until the whole of the growth is encircled and strangled by them. In doing this, a few precautions are necessary: thus, the first nevus-needle should be passed across the tumour unarmed (Fig. 213, a), and used to raise up the growth somewhat from the subjacent parts. The second needle, armed (Fig. 213, b) as represented in the woodcut, carrying the whipcord ligature by means of a piece of suture-silk, should be passed across the tumour in the opposite direction to, but

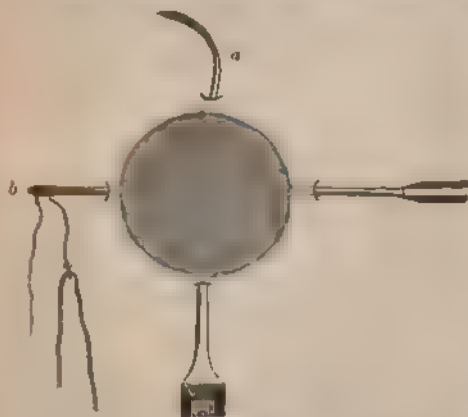

Fig. 213.—Application of Nevus needles.

underneath the first needle; the needle (b) being withdrawn, the ligature

is carried across; and, the first one having been armed in the same way, carries its noose through the tumour as it is drawn out. The two nooses having then been out, an assistant must seize, but not draw upon, six of the ligature ends; the surgeon then having divided the intervening bridge of skin, ties pretty tightly, in a reef-knot, the two ends that are left hanging out; as soon as he has done this, he proceeds to the next two, and so on to the last (Fig. 214). When he ties these, he must do so with all his force, especially if the tumour be large, as by drawing on them he tightens all the other nooses, and draws the knots towards the centre of the growth, which is thus effectually strangled. He then cuts off the tails of the ligature. After the tumour has sloughed away, which happens in a few days, if properly and tightly strangled, the sore is treated on ordinary principles. If the nævus be altogether subcutaneous, the skin covering it should not be sacrificed, but, being divided by a crucial incision, may be turned down in four flaps, and the ligature then tied as directed.

Fig. 214.—Nævus tied.

In some cases, the nævus is so flat and elongated that the application of the quadruple ligature, as above described, cannot include the whole of it. Under these circumstances, I have found the ligature about to be described eminently useful, having successfully employed it in a great number of instances. Its great advantage is that, while it completely and very readily strangles the tumour, it does not inclose an undue quantity of integument, and thus does not produce a larger cicatrix than is necessary for the eradication of the disease. It is applied in the following way. A long triangular needle is threaded on the middle of a whip-cord about three yards in length; one half of this is stained black with ink, the other half is left uncoloured. The needle is inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumour, and transversely to the axis of the same. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered; it is next carried across the base of the tumour, entering and passing out beyond its lateral limits, so as to leave a series of double loops, about nine inches in length on each side (Fig. 215). Every one of these loops should be made about three-

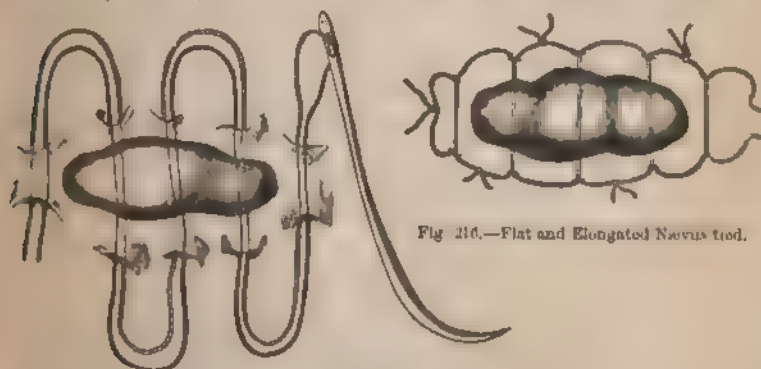

Fig. 216.—Flat and Elongated Nævus tied.

Fig. 215.—Ligature of Flat and Elongated Nævus.

quarters of an inch apart, including that space of the tumour; and the last loop should be brought out through a fold of healthy integument beyond

the tumour. In this way we have a series of double loops, one *white*, and the other *black*, on each side (Fig. 216). All the *white* loops should now be cut on one side, and the *black* loops on the other, leaving hanging ends of thread of corresponding colours.

The tumour may now be strangulated by drawing down and knotting firmly each pair of *white* threads on one side, and each pair of *black* ones on the other. In this way the tumour is divided into segments, each of which is strangulated, by a noose and a knot: by *black* nooses and *white* knots on one side, by *white* nooses and *black* knots on the other (Fig. 216).

The cicatrix resulting from the removal of a *nævus* is usually firm and healthy; but in some instances, I have seen it degenerate into a hard warty mass requiring subsequent excision. The ligature may be used successfully at all ages. I have repeatedly tied large active *nævi* in infants a month or two old, without meeting with any accident.

NÆVI IN SPECIAL SITUATIONS.—*Nævi* of the *Scalp* are more frequent than in any other situation, except, perhaps, the face. When occurring on those parts that are covered by hair, they are almost invariably prominent and subcutaneous; when seated on the forehead, or on the bare skin behind the ears, they are often cutaneous. The ordinary subcutaneous *nævus* of the scalp is readily removed by the application of the *quadruple ligature*. In general, it is better not to attempt the preservation of any of the integument covering the growth. It is true that, when removed, a clean white cicatrix is left which never covers itself with hair; but this contracts, and in after-life becomes but little visible. The attempt to dissect down the skin that covers the *nævus* is not only troublesome, but is attended by a very considerable, and possibly a dangerous amount of hemorrhage. Those flat *nævi* that are situated behind the ear are best treated by the free application of fuming nitric acid.

Nævus of the *Fontanelle* is the most important variety of the scalp-*nævus*, and constitutes a somewhat formidable disease. A large purple tumour is situated within the anterior fontanelle, rising and falling with the pulsations of the brain communicated to it, and becoming distended and tense when the child cries. The tumour is evidently close upon the membranes of the brain, and may be looked upon almost as an intracranial rather than a scalp-tumour. The close proximity of the tumour to the brain and its membranes often deters practitioners from interfering with it; and I not unfrequently see cases in which the parents of the child have been counselled not to allow any operation to be practised, lest death should result. Yet this tumour, so formidable in appearance, and so deeply seated, close upon the brain, and as it were within the cranium, may be removed with the most perfect safety by the *ligature*. I have often tied *nævi* in this situation, and have never seen any ill consequences, not even a convulsive fit, occur. The danger, then, from the mere strangulation of the tumour in this situation cannot be great; but there is another and a special danger, *viz.*, the risk of wounding the membranes of the brain in passing the ligatures under the base of the tumour. If *nævus* needles, or sharp pointed instruments of any kind be used, this accident will be very likely to occur; and, if this were to happen, inevitably fatal consequences must ensue. This accident may always be avoided by operating in the following way. A puncture is made in front of the tumour through the healthy scalp. An eyed probe, armed with a double ligature, is then pushed through this opening across the base of the tumour, and its end is made to project on the opposite side beyond it; here another puncture is made, and the probe and ligature together are drawn through. The same procedure is adopted across the tumour ant-

ways. In this way, a quadruple ligature is passed across the tumour in two opposite directions; the ends are then disengaged, and the ligature is tightened in the ordinary way.

Nævi of the Face are of very common occurrence, and usually cause much disfigurement. The treatment to be adopted necessarily varies greatly, according to the nature of the *nævus*, whether cutaneous, subcutaneous, or both; and especially according to its situation. The same plan, which is advantageously adopted in one part, may be altogether inapplicable in another. We shall, accordingly, consider the treatment of these vascular growths, as they affect the eyelids, the nose, the cheeks, and the lips.

Nævus of the Eyelids is usually cutaneous, consisting of a discoloration or staining, as it were, of the lid, without any material swelling of it. Such a disease is, I think, better left untouched; it cannot, of course, be removed either by the knife or by caustics, without producing worse results; and, as the skin is always deeply involved, milder means are inoperative, or possibly equally destructive. I have heard of sloughing of the eyelid being occasioned by the use of astringent injections in such cases; though, if the *nævus* were subcutaneous, and constituted a distinct tumour, passing perhaps into the orbit, injection with the perchloride of iron might advantageously be adopted.

Nævus of the Nose may occur in two situations—at the root, or towards the alæ and apex. When seated at the root of the nose, upon the bridge, or at the lower part of the forehead, between and perhaps extending above the eyebrows, it is often subcutaneous, and may attain a very considerable magnitude. In cases of this kind, I have found the *quadruple ligature* the readiest means of removal; and, although the part included may be of large size, the resulting cicatrix is wonderfully small and narrow, usually becoming horizontal, so as to fall into the folds of skin naturally existing in that situation. In the case of a little girl about three years of age, brought to me some years ago by my friend Dr. Gerber, I removed a *nævus* that was cutaneous as well as subcutaneous, and as large as a walnut, from this situation, by means of the quadruple ligature, with the most satisfactory result, the resulting cicatrix being remarkably small; and in another little girl, from the bridge of whose nose I removed, some years ago, a *nævus* as large as a marble, very little scarring or deformity resulted. In both these cases, the *nævus* was cutaneous as well as subcutaneous. If the skin be not affected, injection of perchloride of iron may be advantageously employed in such cases. When the tip and alæ of the nose are affected, the *nævus* being cutaneous, we can seldom do much to improve the appearance of the patient. In such cases, I have tried breaking down the *nævus*, and the galvanic caustery, without any material benefit; the destruction of the tissues soon afterwards leading to deformity in the organ. When the *nævus* is subcutaneous, occupying the tip, alæ, and columella nasi, injection with perchloride of iron is the only means that I have found of real service. In doing this, care must be taken not to throw in too much of the liquid, lest sloughing result.

Nævi of the Cheeks may occur in three distinct forms. 1. There may be a simple cutaneous *nævus*, a mere staining of the skin, a "mother's mark." This admits of no treatment; and the subject of it must submit to continue through life to exhibit the characteristic discoloration. 2. The elevated cutaneous *nævus* is raised above the surface, and is of a deep purplish red or plum colour, covered with a very thin integument. In this form of the disease, I think that the application of concentrated nitric acid is the best means of extirpation. By one or two free applications of the caustic,

the nævous growth is removed, and a dense white cicatrix, presenting little disfigurement, is left in its place. 3 The nævus may involve the whole thickness of the cheek, being scarcely, if at all, cutaneous. Nævi of this kind cannot, of course, be extirpated, either by the knife, ligature, or caustics, lest the cheek be perforated, and the most serious disfigurement ensue. In such cases as these, we must endeavour to obliterate the structure of the nævus by exciting inflammation in it by means of setons, or by breaking down the structure of the growth with cataract-needles or a fine tenotome. In a case which I attended some years ago, with my friend Mr. Bartlett of Notting Hill, a large and deeply seated nævous growth, which occupied one cheek, was cured by having a number of fine silk threads passed across it in different directions; and then being gradually, piece by piece, broken down with a cataract-needle, no disfigurement whatever being left.

Nævi of the Lips require different treatment, according as they occupy the margin or have involved the whole substance of these parts. When seated at the margin, as projecting and somewhat pendulous growths, they may very readily be removed by a double or quadruple ligature, according to their size. This was the practice pursued in the case from which the accompanying drawings (Figs. 217, 218) were taken, where a most excellent result was

Fig. 217.—Nævus of Lower Lip:
Front View

Fig. 218.—Nævus of Lip:
Side View

obtained by the use of the ligature, followed at a later period by injection of perchloride of iron into some of the more widely diffused parts of the nævous growth. When the nævus involves the whole thickness of the lip, such measures are not always available. If it deeply invades the substance of the lips, an operation somewhat similar to that for the removal of a canceroid growth might be practised; the whole substance of the lip being cut through widely on each side, and the edges of the incision brought together with hare-lip pins. Such an operation is only practicable when the disease, though deeply seated, does not spread to any very great extent laterally. When it does, the whole of one-half of the lip, for instance, being involved, the use of the knife, especially in young infants, would be too hazardous, on account of the probability of serious hemorrhage; and other means must be employed. I have tried the use of setons, and of injections with perchloride of iron; but not with any advantage. When the whole substance of the lip is involved, inclusion and strangulation of the morbid mass by means of the ligature is seldom available, the amount of sloughing being very great, and the child, absorbing the putrescent matters from the sloughing mass which results, incurring the danger of being poisoned from this source. In an infant with a very large nævus, including one-half of the lip, which I ligatured at the hospital some years ago, death appeared to result from this cause. One of the most formidable cases of nævus of the lip that I have ever had to do with, and in its results the most satisfactory, was sent to me about nine years ago, by Dr. Budd of Barnstable. The patient, a little girl five months old, was noticed at birth

to have a red streak on the right side of the upper lip ; this rapidly developed into a large tumid purple nevus, which, when the case came under my

Fig. 219.—Large Nevus of Upper Lip.
Front View.

Fig. 220.—Large Nevus of Upper Lip.
Side View.

observation, was of about the size of a large walnut, involving the whole of the structures of the lip, from the cutaneous to the mucous surfaces : it was of a deep mulberry colour, and extended from the median line of the lip to the angle of the mouth (Figs. 219, 220). The integuments covering this growth were exceedingly thin, and the tumour itself was in the highest degree vascular and active. Excision appeared to be out of the question ; the ligature presented little to recommend it ; injections with the perchloride of iron and the introduction of setons were successively tried, but neither of these means produced any effect on the tumour, which commenced to extend upwards into the nostril. I accordingly determined on using caustics. Nitric acid was first employed ; but, as this did not produce sufficiently deep impression on the growth, I had recourse to the potassa cum calce. By means of this, the tumour was gradually removed ; the hemorrhage which occasionally resulted being restrained by pressure. Notwithstanding the amount of tissue destroyed, the resulting cicatrix was small, resembling that of a badly united hare-lip. Three years afterwards, the child was brought to me again, and I was much struck by the wonderful improvement that had taken place since the removal of the nevus. The lip was smooth, the cicatrix in a great degree worn out, and comparatively little disfigurement was left in the countenance of an exceedingly pretty and engaging child. Finding, however, that the lip was still drawn or tucked in by a very dense band of cicatricial tissue, which caused a depression of the ala on that side, I divided this, and the result was of the most satisfactory character.

Nævus of the Tongue is of rare occurrence. I have, however, successfully operated by means of the écraseur in one case, in which the whole of the free extremity of the organ was involved (Fig. 221). The particulars will be found in Chapter lvi.

Nævi of the Organs of Generation are occasionally met with in the female, but rarely in the male. The only instance of *Nævus of the Penis* with which I have met occurred in the case of a gentleman thirty-two years of age, who consulted me some years ago for a growth of this kind, as large as a walnut, situated under the reflexion of the preputial mucous membrane. It had existed for many years without giving any annoyance, but, as it had of late begun to enlarge, and occasionally to bleed, he was desirous to have it removed. This I did by applying the quadruple ligature, after having dissected down to the mucous membrane.

Nævi of the Vulva and Pudendum are by no means of very unfrequent

Fig. 221.—Nævus of the Tongue.

occurrence. We have had several instances of this kind in the Hospital of late years. They are usually of a venous character, often attain a large size, and may sometimes involve the integumental structures on the inside of the thigh, or on the perineum, as well as the vulva. When the growth is confined to the vulva, it is best removed by the ligature. Some time ago, I removed in this way a large venous pendulous nævus, as large as two or three flattened walnuts, from the left labium of a little girl six years of age. In this case I found it most convenient to employ the continuous ligature. The same means were had recourse to in order to extirpate a large nævus from the labium of a child three years of age; but in this case the disease extended to the integuments of the perineum and inner side of the thigh, and was here removed by the application of strong nitric acid, after the larger growth had separated.

On the *Extremities, Neck, and Trunk*, every possible variety of nævus occurs. When the disease is flat, consisting rather of staining of the skin than of any actual tumour, it may commonly be treated successfully by the application of the strong tincture of iodine; or, should it be thought desirable to remove it, this may be effected by rubbing it with strong nitric acid. If the nævus assume the form of a tumour, it will almost invariably be of a venous character, and then removal by means of the ligature should be effected. If the growth be round, the ordinary quadruple ligature may be employed, if flat or elongated, the longitudinal continuous ligature is preferable.

NÆVOID LIPOMA.—This is a form of nævus with which I have occasionally met, but which does not appear to have attracted much notice, although I find that Nélaton speaks of it. It is a tumour in which the nævoid structure is conjoined with or deposited in a cellulo-fatty mass. This disease is invariably seated upon the nates, back, or thigh. It occurs as a smooth, doughy, indolent tumour, incompressible, not varying in size or shape, without heat, thrill, or pulsation of any kind, possibly having a few veins ramifying over its surface, but no distinct vascular appearance. It is usually congenital, or has been noticed in early childhood; and continues without any very material change in shape, size, or appearance, until the inconvenience or deformity occasioned by it requires its removal. This is best effected by the knife. After removal, the tumour will be found to be composed of a cellulo-adipose basis, having a large number of veins ramifying through it, so as to constitute a distinct vascular element, communicating with small cysts containing a bloody fluid. The tumour has occasionally a tendency to recur after removal. In one case I have operated three times for the removal of a large growth of this description, situated on the buttock, and extending forward towards the perineum. The first operation was performed in 1851; the second, in 1856; and the patient, now eighteen years of age, has again (1863) presented himself, with a recurrence of the growth, in an ulcerated state, in the cicatrix of the former operations. The situation in which I have seen such tumours occur, where they gave rise to most inconvenience, and where their removal has required the greatest care, has been the anterior part of the thigh, just below Poupart's ligament, close upon and almost in connection with the femoral vessels. In a case of this description, which was sent to me by my friend Dr Edwards of Antigua, the patient, a gentleman of that island, had suffered from a chronic solid oedema of one of his legs for some years, apparently dependent upon the pressure exercised upon the axillary and femoral veins by an elongated indolent tumour just below Poupart's ligament, and over the course of these vessels. This tumour had existed from childhood, and presented the signs that have just been given as charac-

toristic of the disease under consideration. It was removed by an incision parallel to Poupart's ligament, some careful dissection being required to separate it from the femoral sheath, more particularly towards the inner side, where a prolongation of the tumour dipped down by the side of the femoral vein, doubtless compressing that vessel, and so disposing to the occurrence of the œdema of the limb. After removal, the tumour was found to consist of a mass of condensed cellulose adipose tissue, with much vascular structure intermixed, and some small cysts. The œdema gradually subsided; and when the patient left England, about three months after the operation, the limb had nearly regained its normal size, being but little larger than the sound one.

HEMORRHAGIC DIATHESIS.

In connection with diseases of the arteries, it may be stated that in some constitutions it is found, though fortunately very rarely, that there is a great tendency to very troublesome, indeed almost uncontrollable bleeding, from trivial wounds; life being put in jeopardy, or even lost, by the hemorrhage resulting from the extraction of a tooth, the opening of an abscess, lancing the gums, or some equally slight unimportant surgical procedure. The blood does not flow in a jet, but continues to trickle in an oozing stream, apparently from the capillaries rather than from the arteries of the part. In these cases also there is a great tendency to an inordinate amount of ecchymosis from very slight contusion, the cellular tissue becoming rapidly filled with fluid uncoagulable blood.

CAUSES.—The "hemorrhagic diathesis" appears to be connected with or dependent upon one of three distinct conditions.

1. It may be congenital, and not unfrequently is hereditary, especially in the male line, in persons otherwise robust and strong, without any apparent derangement of health, or morbid condition, innate or acquired, to account for it. In such cases the family peculiarity is usually recognised, and well known to those liable to it.

2. The hemorrhagic diathesis may occur in individuals from some fault in the solid constituents of the body. In persons who are "out of condition," with soft and flabby texture, the tissues have lost their normal contractile power, and are too readily torn by external violence. In such individuals slight blows may be followed by extensive extravasation, and trivial wounds by abundant and continuous hemorrhage. The bleeding in these cases appears to be favoured by the laxity of fibre interfering with the proper contractility of the divided vessels.

3. The hemorrhagic diathesis may be dependent upon a morbid state of the blood itself, in consequence of which it has lost its coagulability, the fibrine being insufficient in quantity. This is especially apt to occur as a consequence of diseases that produce a diffuent state of the blood, such as chronic jaundice, albuminuria, scurvy, &c.

The last two conditions are not unfrequently associated together, the blood-vessels being insufficiently contractile, and the blood too poor in fibrine, when excessive hemorrhages are apt to occur from the most trifling wounds. In cases of this kind, care must be taken not to make any surgical wounds if they can possibly be avoided; though it is a remarkable fact, that the hemorrhagic tendency here described seems only to have been met with after trivial injuries of the kind above mentioned, and not to have been encountered in any really serious surgical case.

TREATMENT.—In the treatment of the diathesis, little can be done. It has been proposed to administer saline hydragogue purgatives, with a view

of inspissating the blood. I should, however, imagine that an improvement of the general health, by careful attention to food, exercise, &c., would be the best means of increasing the plasticity of this fluid. In the event of the occurrence of actual bleeding, the employment of pressure, the application of the actual cautery, or the use of the perchloride of iron, will constitute the best means of arresting the hemorrhage. In some cases the electric cautery may be advantageously substituted for the knife, when it is desirable to remove parts in persons suffering from this diathesis. By this means the smaller amputations even may be performed, as has been successfully done by Mr. Marshall.

CHAPTER XLV.

DISEASES OF THE NERVOUS SYSTEM.

NEURITIS.

Inflammation of the Nerves, or Neuritis, is not of very unfrequent occurrence, being usually the result of rheumatic inflammation, of wounds, or strains. When rheumatic, it principally affects the nerves of the face and of the lower extremity.

SYMPTOMS.—These consist of tenderness on pressure along the course of the nerve, and severe continuous pains ramifying down its trunk and branches, with occasional violent exacerbations, especially on moving or touching the part, and at night; there is usually swelling along the course of the trunk, and some constitutional pyrexia. When chronic, this condition may readily be confounded with neuralgia; of which, indeed, it constitutes one variety. On examination after death, in these cases, the sheath of the nerve will be found injected and swollen, and the nervous tissue softened.

TREATMENT.—This consists in the employment of antiphlogistic means, cupping or the application of leeches, according to situation, poppy, or belladonna fomentations, and local emollients. When the neuritis is rheumatic, the acetous extract of colchicum is the best remedy; when it is of a more chronic and nocturnal character, iodide of potassium, either alone or in combination with sarsaparilla, may advantageously be given.

NEURALGIA.

Neuralgia frequently occurs in surgical practice, either complicating other diseases, or as a distinct affection simulating closely various organic lesions, more especially of joints and bones.

SYMPTOMS.—The pain in neuralgia is the essential symptom, and in fact constitutes the disease itself. It may be of two kinds; either following anatomically the course of a nerve and the distribution of its filaments; or affecting a considerable portion of the surface without reference to any special nerve. It is of all degrees of severity, sometimes moderate, sometimes unendurable, even by those who possess the greatest fortitude; when severe, it usually comes on suddenly, with a kind of shock, and continues of a sharp darting or tearing character, coursing along the trunk or ramifications of the affected nerve, the distribution of which may often be distinctly indicated by the direction the pain takes. It is often accompanied by other sensations, such as a tickling, smarting, or creeping feeling on the affected surface, in some instances relieved by pressure, in others increased by the slightest

touch or movement of the part. Occasionally there is spasm in the muscles supplied by the affected nerve; in other cases, there are heat and redness of the surface, with increased secretion from the neighbouring organs, as a flow of saliva or tears when the nerves of the jaw or eye are implicated. The duration of an attack may vary from a few moments to many days or months. The pain is most commonly intermittent or remittent; often irregularly so, but in some instances the periodicity is well marked.

SITUATIONS.—This disease may affect almost any part of the body; it is most commonly seated distinctly in the trunk and branches of a nerve. The divisions of the fifth pair are especially liable to be affected; the pain may extend to the whole of the branches of this nerve on one side of the head and face, but more commonly it is confined to one of its principal divisions, such as the infraorbital, which is especially liable to be affected; in many instances it is seated in the temporal and dental nerves. Not unfrequently some of the terminal twigs alone of one of these nerves, become the seat of intense pain; thus occasionally the affection is found limited to a patch on the cheek, brow, or temple, from which it scarcely ever shifts. The posterior branches of the dorsal spinal nerves, and the intercostals, are also very commonly affected, though not to the same extent as the fifth pair. In other cases the whole of an organ, or part, becomes the seat of neuralgia, though no one nerve may appear to be distinctly implicated; thus the testes, the breast, the uterine organs, or one of the larger joints, as the hip or knee, are occasionally the seats of severe suffering of this kind. An extreme degree of cutaneous sensibility is a marked feature in the affection in some cases; the patient wincing and suffering severely whenever the skin is pinched or touched, however lightly.

CAUSES.—The causes of this very painful disease are very various; they may be constitutional or local. It seldom occurs in strong and healthy individuals, but is almost invariably associated with want of power, unless it be occasioned by some local mechanical cause. *Depressing influences* of all kinds are especially apt to produce it; thus, debilitating diseases, mental depression, and particularly exposure to malaria, are common occasioning causes; those forms of the disease that arise from malarial influences, or from exposure to simple cold and wet, usually assume a very intermitting or periodical character, and are commonly seated in the nerves of the head. The *hysterical temperament* very frequently disposes to the spinal and articular forms of neuralgia. There is no constitutional condition with which neuralgia is more frequently associated than with *anæmia*: hence its frequency in females. As Romberg says, "Neuralgia is the prayer of the nerve for healthy blood." Various sources of *peripheral irritation*, as loaded bowels, the irritation of worms, carious teeth, uterine disease, and calculus, may be recognised as producing some of the more obscure varieties of the disease.

Neuralgia may also arise from any compression exercised upon the trunk of a nerve; and in this way, indeed, some of the more intractable forms of the affection have their origin. Thus, thickening of the neurilemma, the pressure of a tumour of any kind, or of a piece of dead bone, may give rise to the most intense pain in the part supplied by the irritated nerve; and it is not improbable that in many of the cases of neuralgia in the branches of the fifth, pain may be owing to periosteal inflammation, or to some other disease of the osseous canals through which these nerves pass.

DIAGNOSIS.—The diagnosis of neuralgia, though usually effected without any difficulty, is in some cases a little embarrassing, as the pain may occasionally simulate that of organic disease or inflammation of a part. From organic disease of the part that is the seat of suffering, such as the hip, the

knee, the testis, or the breast, this disease may usually be distinguished by the co-existence of cutaneous sensibility, the existence of the hysterical temperament, and the absence of the other signs that would accompany lesion of structure in the part affected. From inflammation the diagnosis is usually sufficiently easy, by attending to the intermittent character of the neuralgic pain, to its occurrence in hysterical temperaments, and to the absence of the constitutional symptoms of inflammation. But occasionally, when local inflammatory irritation is conjoined with the neuralgia, the diagnosis is truly difficult. Here the presence of cutaneous sensibility and the relief of the pain by firm pressure will indicate neuralgia; whereas, in inflammation, there is no tenderness of surface, but the suffering is aggravated by deep pressure.

TREATMENT.—The treatment of neuralgia must have reference to the cause of the disease, and will be successful or not according as this may be more or less readily removed. So long as the conditions that primarily occasion the disease subsist, the pain is likely to continue: and if these conditions be irremovable, the disease may be looked upon as necessarily incurable, though the suffering may be alleviated by appropriate means. When it arises from any central nervous affection, there may be fear of the ultimate occurrence of disease of a more serious type, such as epilepsy, insanity, &c.

When it occurs as the consequence of anemia, or in the hysterical temperament, the administration of the more stimulating and stronger preparations of iron, such as the sulphate or the sesquichloride, or the *mistura ferri composita*, either alone or in combination with quinine, with attention to the state of the bowels and of the uterine functions, and a general tonic regimen calculated to brace and improve the general health, such as sea-bathing, the cold douche, or sponging, will be found to be of essential service. In some of these cases the combinations of zinc, especially the valerianate, with the fetid gums, will remove the disease when iron does not influence it much. At the same time, the application or inunction of belladonna or acouite plasters and liniments may be of service. When the neuralgia is distinctly periodical, quinine in full doses, or the liquor arsenicalis, will usually effect a speedy cure. When it is rheumatic, occurring in debilitated subjects, and attended by distinct nocturnal exacerbations of pain, no remedy exercises so great an impression upon it as the iodide of potassium, especially when administered in combination with quinine.

In the more severe and protracted forms of the disease, relief may be occasionally obtained by attention to the state of the liver and digestive organs, by a course of some of the more purgative mineral waters, and by the occasional administration of aloetics or croton oil, followed by tonic remedies.

Local applications of a sedative kind, such as chloroform, belladonna, opium, &c., are often useful adjuncts to constitutional treatment. Perhaps the readiest mode of affording relief locally is that introduced by Dr. Alexander Wood of Edinburgh. This consists in injecting a few drops of a strong solution of morphia into the skin of the part affected, by means of the syringe figured at p. 683. Not more than half a grain of morphia should be injected at a time, and the action of this small dose is often very powerful. More than this, I believe, would be unsafe; but the injection may be repeated, if necessary, at intervals of an hour. In some cases of simple neuralgia, Pulvermacher's galvanic chain has afforded relief.

In many cases all these means, however, are unfortunately unavailing, and the sufferer is doomed to an existence of constant pain, except when the disease appears to cease of itself, or has its intensity blunted by the adminis-

tion of the more powerful sedatives, such as morphia externally, or opiate or atropine externally. In these distressing cases the sufferer is only to grasp at any means of relief that is held out to him, and section of the affected nerve is not unfrequently recommended as a last chance of the cural of the disease. It is clear, however, that such an operation, though occasionally productive of temporary relief, cannot in many cases be expected to benefit the patient materially; for by it the cause of the neuralgia is not removed, and it can consequently only be of service when the pain is peripheral, occasioned by some local irritation existing between the part cut and the terminal branches of the nerve. If the neuralgia depend on any central cause, or on local irritation existing higher up than the point divided, it must eventually be useless. Thus, if the source of irritation exist in the central branches of the infraorbital nerve, the division of this trunk might be useful, but if the pain be occasioned by any pressure to which this nerve may be subjected in its passage through its canal by a carious state of the bone, or by disease of the periosteum, it would be unavailing; though it is a remarkable fact, that it not unfrequently happens after these operations that there is a temporary cessation in the pain for a few weeks or months. In some of these cases, however, the pain shifts its seat from the branch operated on to another division of the same trunk; thus, if the infraorbital nerve been divided, the submental nerve becomes the seat of pain. Or this may be accidental, as it were, to the point at which the nerve was divided; thus, after amputation for neuralgia of the knee, the pain may return in the stump, and again when this is removed a second or even third time.

The nerves on which section has been most frequently performed are the infraorbital and the submental. Should it ever be thought necessary to do so, it would be proper not only to divide the nerve, but to excise a portion of it, otherwise reunion will speedily take place, and, the continuity of the nerve being re-established, the operation will fail. The procedure simply consists in cutting down on the trunk where it escapes from the foramen, isolating and dissecting out a portion of it; in doing this, no great difficulty can be experienced by any one possessing moderate anatomical knowledge.

NEUROMA.

By *Neuroma* is meant a tumour connected with a nerve. This tumour may vary from the size of a millet-seed to that of a melon; it is usually sessile, and composed of fibrous tissue; but when it attains a large bulk, a cavity may form in it, containing a yellowish or brownish serous-looking fluid, apparently owing to the disintegration of the central portions of the mass. In shape it is usually oval or oblong, the long axis corresponding to the course of the nerve (Fig. 222); it grows slowly, and is moveable transversely, but not in the direction of the nervous trunk on which it is seated; it has no appearance of malignancy, and, however large it becomes, it never contracts adhesions to the integument nor involves its structure. Neuroma commonly only affects the nerves of the cerebro-spinal system; but Bérard has met with one case of the disease on a ganglionic nerve. The nerves of special sense are but very rarely the seat of this disease. Indeed the only recorded case with which I am acquainted of a neuroma connected with one of these nerves, is one described by Dr. Lidel of New York, of a neuroma of the optic nerve filling up the orbit, flattening and protruding the eye, and extirpated together with the contents of the orbit by that surgeon.

Most commonly the tumour is single, and then is usually attended with very severe lancinating or neuralgic pain, which extends, however, only to

the parts below the tumour, and is commonly paroxysmal. This pain is evidently owing to the stretching of the nervous twigs as they pass along the convexity of the growth. When acute and painful, the tumour commonly goes by the name of the *Painful Subcutaneous Tubercle*, and is then usually met with from the size of a pin's head to that of a cherry-stone, commonly seated upon the limbs, and most frequently in connection with one of the nerves of the lower extremity; but it may be situated upon the arm, the trunk, or even on the scrotum and cheek, where, however, it is not so commonly met with. Wherever neuroma occurs, it is acutely and intolerably painful on being touched, and is usually tender as well.

Fig. 222. — Neuroma, with Nervous Filaments spread out over Tumour.

STRUCTURE.—The painful subcutaneous tubercle is composed of a white or greyish fibrous mass developed in the neurilemma, and having nervous filaments stretched through or over it. The nervous trunk above and below the tumour is normal; it is only where it comes into contact with the neuroma, and is exposed to its pressure, that it undergoes the change indicated. It is a very remarkable fact that, though neuromatous tumours when single, or when but two or three exist, are most acutely painful, yet, when they are generally diffused over the body, they lose their sensibility, and are unattended by any inconvenience except such as arises from their numbers and bulk. The number of masses thus formed is often amazingly great; thus, in one of Dr. R. W. Smith's cases, described in a monograph which contains the fullest and most accurate account of this disease, he counted in the two lower extremities alone more than 250 of these tumours, besides those in other parts of the body. In another case related by him, there were upwards of 200 small neuromata scattered over the sides of the chest and abdomen, 450 on the right lower extremity, and upwards of 300 on the left; altogether probably not less than 2000 of these growths in "this unprecedented case."

Traumatic Neuromata may arise from the wound or partial division of nerves, and occasion the most intense agony. Sometimes growths of this description, of a fusiform shape, and varying from a cherry-stone to a pigeon's egg in size, are met with in stumps after amputations; in many instances they are unattended by inconvenience, but occasionally give rise to a very severe degree of pain.

TREATMENT.—The treatment of painful neuromata, whether of an idiopathic or traumatic character, or existing in stumps, consists in their excision. After removal, the part supplied by the nerve, which is usually necessarily divided, becomes paralysed for a time, but may eventually regain its sensibility. In some cases, however, by cautious dissection, the tumour may be removed from the nerve that is in contact with it, without cutting this across. This has been done in the case of neuromata of the sciatic nerve and its divisions. When these tumours are numerous, they should not be interfered with; and, if unattended by pain, they need not be excised unless their bulk prove inconvenient.

TETANUS.

Tetanus is a disease consisting essentially in an excited state of the spinal cord and the medulla oblongata, in fact of the whole true spinal system,

ing rise to painful and continued spasms of the voluntary muscles and the diaphragm, alternating with incomplete relaxation, and usually terminating fatally. This, which is one of the most serious and distressing diseases to which the nervous system is liable, is in the great majority of instances of a *Traumatic* nature, being the consequence of some wound that implicates or irritates a portion of the peripheral nervous system; the local irritation so produced being propagated to and exciting the nervous centres, the excitation of which becomes persistent, and continues after the local cause has been removed, inducing reflex muscular movements in various parts of the body. The irritation of the nervous system, however, that induces tetanus, may arise from other sources besides surgical wounds, assuming the *Idiopathic* form of the disease; thus, for instance, the presence of worms in the intestinal canal, exposure to cold and wet, the ligature of the navel in infants, and even the uterine irritation following abortion, have been known to occasion it. These causes, however, rarely give rise to it in this country, and we must consequently regard it as a disease chiefly arising from traumatic lesion of some kind.

Tetanus may occur at all ages, from the earliest infancy to an advanced period of life. In hot climates it is common amongst newly born infants, in the form of *Tetanus Neonatorum*. In this country it rarely occurs at the very early period of life, but is common in young adults. I have most frequently observed it between the ages of 16 and 25, and after that in old people, but it may occur at any period of life. It is far more common amongst males than females—in the proportion of about four to one. Season of the year seems to exercise little influence over it. It occurs in all states of the atmosphere, and at all periods of the year; but is certainly most common when the weather is suddenly changeable—alternating from heat to cold.

CAUSES OF TRAUMATIC TETANUS.—Tetanus may be occasioned by injuries that do not give rise to breach of surface; thus I have known it occur in a child who was suddenly thrown down upon its back by another at play; and Dr Reid mentions a case produced by the stroke of a whip. But in the great majority of cases, it is directly occasioned by a wound of some kind. Generally a nervous twig has been lacerated, divided, or inflamed; thus, in a case of tetanus following a wound of the knee, in a patient who died in University College Hospital, a small branch of the internal cutaneous nerve was found to have been injured, and was inflamed; and in another patient who died of tetanus about sixteen days after treading on a rusty nail, a black speck was found on the internal plantar nerve, where it had been wounded by the nail. In another case under my care, in which tetanus resulted from a bruise of the back, and terminated in death, the injured nerve (a dorsal branch) was found lying bare and reddened in the wound; and, on tracing it up to the spinal cord, its sheath was found to be much injured, ecchymosed, and with a large vessel running down it. In another instance, in which tetanus followed a wound of the wrist, the external cutaneous nerve was found in a similarly inflamed state.

The kind of wound, as well as its situation, doubtless influences materially the occurrence of the disease. Though it certainly more frequently follows punctured, torn, and lacerated, than clean-cut wounds, yet it occasionally complicates these, even when the result of surgical operations; thus, it has been known to follow the removal of the breast, amputations, the ligature of the larger arteries, and the operation for hernia. The minor surgical operations also are not free from the possibility of this dangerous complication. It has been observed after the operation for fistula in ano, the ligature of

piles and varicocoele, the removal of nasal polypi; and I have even seen a fatal case resulting from the introduction of an issue. Burns are a class of injuries that are peculiarly liable to be followed by tetanus. It is the common belief, both in the profession and out of it, that wounds of the hands and feet, and more especially of the ball of the thumb and of the great toe, are more likely to be followed by tetanus than those in other situations. I think the truth of this opinion may be doubted; though it is not improbable that tetanus may occur more frequently after injuries of these regions than of other parts of the body, simply because punctured and lacerated wounds are more common here than elsewhere. It cannot well be supposed to be owing to the tendons and fasciæ that abound here, as Hunter imagined; for it is seldom, if ever, met with after operations for tenotomy, which are so commonly practised on the feet.

Tetanus may occur in all *constitutions*—in the strong and robust, and in the feeble and emaciated. It is especially apt, however, to occur in feeble and debilitated individuals, and, indeed, may be looked upon as a disease of debility; hence any condition that lowers the tone of the nervous system is especially likely to occasion it. When it occurs in persons who are otherwise strong and in the prime of life, it will be found that they have been exposed to causes of depression influencing the nervous system. It is loss of nervous tone, and not muscular weakness, that disposes to this disease. Thus, in tropical climates, as in some of the West India Islands, and amongst the marshes of Cayenne, it occurs with peculiar frequency, the most trifling scratches or punctures being followed by the disease. Mr. Poland, who has exhausted the statistics of tetanus, states that the mortality from it is in London '025, whereas in Bombay it is 2·5 per cent. of the total deaths. It is interesting to observe, that the natives of hot climates are far more liable to this disease than Europeans resident there.

In military practice tetanus is of common occurrence. Its frequency varies much in different campaigns and under different circumstances. In the Peninsular War, it was estimated to occur in the proportion of about one case in every 200 wounded; in the Schleswig-Holstein war, according to Stromeyer, once in about 350 cases. In the Crimea it appears to have been of rare occurrence. Alcock's estimate of one to every 79 wounded is evidently too high. After naval engagements, the mortality has often been high. Sir G. Blane states that, after Rodney's action, out of 810 wounded 20 were attacked with tetanus, being one in 40. All army surgeons are agreed, that sudden changes from heat to cold are amongst the most frequent causes of tetanus amongst the wounded. Thus Larrey states that, after the battle of Moskowa, although the number of wounded was immense, there were few cases of tetanus, the heat being very great and continuous; whilst after Bautzen, where the wounded were left on the field all night exposed to severe cold, more than 100 had tetanus; and after the battle of Dresden, when great heat was followed by much wet and cold, the wounded suffered most severely. So, after some of the Indian battles, as Chillianwallah and Ferozapore, where the wounded lay exposed to cold nights after very hot days (M'Leod), tetanus was of very frequent occurrence. Hennen states that a draught of air, whether hot or cold, directly blowing on the patient, is the most fertile cause of tetanus.

Tetanus at times appears to occur *epidemically*. It often happens that not one case occurs in a hospital for some years, and then several in close succession or simultaneously.

PERIOD OF OCCURRENCE.—Tetanus may take place at any period after the infliction of the wound that occasions it. In hot climates especially, it

may occur very speedily ; thus, Dr. Robinson relates the case of a negro servant in the West Indies, who scratched his finger with a broken plate, and died of tetanus in a quarter of an hour. It is very seldom, however, in temperate climates, that it supervenes before the fourth or fifth day, usually from that to the tenth day. Larrey, who had great experience of this disease during Napoleon's campaigns in Egypt, met with it most frequently between the fifth and fifteenth days after the infliction of the wound. According to the experience of the surgeons of the Peninsular War, under whose observation many hundred cases came, the disease does not show itself after the twenty-second day ; but though this may be the general rule, Sir G. Blane has related a case in which it took place as late as a month after the infliction of the wound. It is stated that it may occur after the cicatrisation of a wound is completed ; when this happens, the disease must rather be looked upon as being of an idiopathic character, accidentally occurring in a person who has been recently injured.

FORMS.—Tetanus may be *Acute* or *Chronic* ; being in some instances fatal in the course of a few hours, but usually lasting for three or four days. Poland states that at Guy's 51 per cent. of the cases were fatal before the fifth day after invasion. If the patient survive this time, the disease will commonly run on to the eighth or tenth day, and occasionally even for a longer period than this ; thus, S. Cooper mentions a case in which it continued in a soldier for five weeks after amputation. The more chronic it becomes, the better is the chance of recovery ; indeed, if the patient survive the tenth day, the prospect of a favourable issue to the case is materially increased. As a general rule, those cases are the most fatal which are most active in their symptoms ; the danger being in the ratio of the acuteness of the attack, both as to severity and also as to rapidity of invasion after injury.

SYMPTOMS.—The invasion of the disease is sometimes preceded by a general uneasiness on the part of the patient, a sensation of fear, or a sense of impending mischief. Abernethy was of opinion that tetanus was usually ushered in by a disturbed state of the digestive organs, the stools being offensive, and indicative of much gastric irritation. When the disease sets in gradually, it may be somewhat difficult of recognition in its early stages ; if it come on suddenly, its nature is immediately evident. It is a remarkable fact that the cramps do not begin in the part injured ; but, wherever this may be situated, they are always first noticed in the muscles supplied by the *portio dura* of the seventh nerve ; and throughout, these and the muscles of respiration are principally affected. The first symptoms usually consist in the patient being unable to open his mouth widely, to take food or drink, the muscles about the temples, jaw, and neck, feeling stiff and rigid ; this condition has given to the disease the popular term of *lock-jaw*. As the affection advances, the countenance assumes a peculiar expression of pain and anguish, the features are fixed or convulsed from time to time, and the angles of the mouth drawn up, constituting the appearance called the *risus sardonicus*. When fairly set in, the disease is marked by spasms of the voluntary muscles of the most violent character, with much pain and partial remissions. The pain is of that kind that attends ordinary cramp in the muscles, as of the legs, and is usually very severe. The spasms are often of a jerking character, the patient being suddenly thrown up, or twisted on one side ; the breath is drawn with a loud sobbing catch from spasm of the diaphragm, and from the same cause there is usually violent pain experienced in the epigastric region, darting across to the spine. The muscles of the trunk are usually affected next in order of frequency to those of the head and neck, the body being bent backwards so as to form a complete arch

(*Opiethotonos*) ; more rarely it is drawn forwards (*Emprosthotonos*) ; and still less frequently to one side. In some cases the body becomes perfectly rigid, like a piece of wood, the belly being drawn in, and the chest expanded. It is said that in severe cases the spasms have been of so violent a character, that muscles have been ruptured, teeth broken, and the tongue lacerated. In the numerous cases of tetanus that I have unfortunately witnessed, it has never fallen to my lot to see any effects of this kind produced ; the spasms, indeed, being in general not of a very violent, though of a continuous and very painful character.

The intellectual faculties are not disturbed in these cases, and the mind continues clear to the last. In most instances there are great heat of surface, profuse sweats, and quickness of pulse ; not from any febrile disturbance, for this disease is unattended by symptoms of pyrexia, but apparently simply from the violence of the muscular contractions. The prolongation of life appears to depend greatly upon the intensity of the convulsive movements : the more severe these are, the sooner does death result. The fatal termination occurs not so much from any great physical lesion, or disturbance of important parts, as from exhaustion, consequent on the frequency of the tetanic spasms.

PATHOLOGY.—The morbid appearances found after death from tetanus throw but little light on the real nature of this affection,—so little, indeed, that it is frequently looked upon as a “functional disease.” But in saying that this or any other disease is functional, we but express our ignorance of its real cause. There is no function without an organ to perform it ; and there can be no derangement of a function without a corresponding and concomitant disorder of the organ that produces it. Every “functional” disease must, therefore, at last be referred to an organic lesion. The term “functional” is only employed when we are not acquainted with the true nature of the disease. As less is known of the real physiology and pathology of the brain and spinal cord than of other organs of the body, we have more “functional” diseases of the nervous system than of the circulatory or respiratory. But, as pathological anatomy becomes more studied, and as minute investigations into structure are entered upon, so the class of so-called “functional” diseases becomes narrower. We do not speak of “functional” coma, because we can appreciate the different conditions that occasion compression of the brain ; but we still speak of functional convulsive diseases and of functional amaurosis. The ophthalmoscope, however, has shown that functional amaurosis does not exist, but that the failure of visual power is always accompanied by and dependent on some corresponding change of structure in the interior of the eye ; and thus advances in pathology will doubtless show that other so-called functional diseases of the nervous system have no existence. It is true that as yet no specific or positive or invariable derangement of the nervous centres has been met with in tetanus—nothing beyond conditions that are common to many other nervous affections, such as congestion and softening of the brain and spinal cord, with possibly reddish serum in the ventricles and subarachnoid space. But there is one morbid condition that will, I think, invariably be found ; viz., a marked congestion and inflammation of a nerve connected with, and leading from, the wound that has occasioned the disease. This morbid state I have never found wanting. In all cases of fatal tetanus that I have seen in which a careful dissection has been made, the signs of inflammation of a nerve communicating with the wound have been found ; and the vascularity, which is often very intense, may be traced up the neurilemma, often to a considerable distance.

DISEASES OF THE ORGANS OF SUPPORT AND MOTION.

CHAPTER XLVI.

DISEASES OF BONE.

PERIOSTITIS.

Inflammation of the Periosteum is of common occurrence as a result of injury, as a consequence of syphilis and rheumatism, or as a natural process dependent on disease of the subjacent bone. It often affects the entire bone covering the shaft of a bone, and very commonly attacks the articular end, becoming associated with inflammation of the contiguous joint. When it is acute, the membrane becomes thickened, soft, and vascular, and loosens from the subjacent bone. When chronically inflamed, the periosteum becomes thickened by the deposit of plastic matter within and beneath it, and the subjacent bone usually participates in the changes, undergoing hypertrophy and induration, constituting a *node*. In some cases, but rarely, suppuration and death of the layer of bone immediately subjacent to the affected membrane take place.

SYMPTOMS.—The symptoms of periostitis consist of a hard elongated but somewhat puffy swelling—a *node*—not distinctly circumscribed, and attended by much pain in the part, especially at night, with tenderness on pressure.

TREATMENT.—In the treatment of the acute form of the affection, the free application of leeches, with hot fomentations, and the exhibition of calomel and opium, will arrest the disease, and give relief to the patient. In the more chronic form, the continued administration of iodide of potassium will take down the swelling, remove the nocturnal pains, and materially improve the local condition of the part. In those cases of periostitis which are of a syphilitic character, iodide of potassium may almost be looked upon as a specific. Added to this, the occasional application of leeches and repeated blistering will be of essential service. If there be much thickening, considerable relief will be afforded by the free division of the periosteum down to the bone, either through the skin or by means of a tenotome slid under it.

OSTEITIS.

Inflammation of Bone may arise from the same constitutional causes as the preceding disease, but most commonly occurs as the result of injury, either accidental, or inflicted by the surgeon in an operation. When a portion of bone is inflamed, the periosteum and medullary membrane participate in the morbid action, and, together with the affected osseous structure, become highly vascular; at the same time the inflamed bone becomes expanded and softened, partly in consequence of changes induced in its organic constituents, and partly in consequence of the cancellated structure becoming more cellular from interstitial absorption; the cells being filled with a sero-sanguineous fluid. The compact structure of inflamed bone undergoes a peculiar kind of

eight, or ten hours, the condition of the patient being looked to in the meanwhile. Sedative or antispasmodic agents are of no use in acute tetanus. I have seen many drugs of this kind employed without producing any effect in lessening the violence of the convulsions. In most cases, however, the inhalation of ether or chloroform materially lessens their severity, and gives the patient temporary ease.

In the *Subacute* or *Chronic* form of the disease recovery is much more likely to take place; and it is only in these cases that antispasmodics and sedatives, such as opium, camphor, conium, belladonna, and aconite, have been of use; and in these also, chloroform is far more beneficial than in the acute cases. There is a kind of trismus occurring in females, often of a hysterical nature, which is at once removed by the inhalation of chloroform. Professor Miller speaks highly of cannabis Indica pushed to narcotism; three grains of the extract, or thirty minims of the tincture, being given every half hour or hour; and the Rev. Dr. Houghton has employed nicotine in one-drop doses, administered every second hour, with complete success in severe cases of traumatic tetanus. In one case, at Dr. Garrod's suggestion, I tried atropine endermically on a blistered surface, and gave conium internally in large doses; and although the patient, an old man, eventually died exhausted, yet these agents appeared to exercise a marked influence in diminishing the violence of the spasms, and I should be induced to attach some importance to their administration. Dr. Elliotson has spoken highly of the preparations of iron, especially of the carbonate, in tetanus. At the same time that recourse is had to such measures as these, it must not be forgotten that the disease is one of great exhaustion, and that the patient will die worn out, unless he be supplied with plenty of nourishment. Beef-tea and wine should, therefore, be administered by the mouth, and nutritious enemata by the rectum; and in this way the powers of life may be supported until the violence of the disease expends itself. I am, however, disposed to think that even in these chronic cases much more may be done by simple than by specific treatment. Clearing out the bowels by turpentine enemata, the internal administration of calomel with opium, and keeping up the powers of the system till the disease wears itself out, appear most likely to be followed by a satisfactory result, when used in addition to the hygienic measures recommended in the acute form of the disease. It is certainly more rational to employ such measures as these, than to be constantly recurring to antispasmodics and sedatives, which repeated experience has proved to be useless as curative agents, in the vain hope of finding a specific for tetanus.

DISEASES OF THE ORGANS OF SUPPORT AND MOTION.

CHAPTER XLVI.

DISEASES OF BONE.

PERIOSTITIS.

Inflammation of the Periosteum is of common occurrence as a result of injuries, as a consequence of syphilis and rheumatism, or as a natural process dependent on disease of the subjacent bone. It often affects the membrane covering the shaft of a bone, and very commonly attacks the articular end, becoming associated with inflammation of the contiguous joint. When it is acute, the membrane becomes thickened, soft, and vascular, and loosens from the subjacent bone. When chronically inflamed, the periosteum becomes thickened by the deposit of plastic matter within and beneath it, and the subjacent bone usually participates in the changes, undergoing hypertrophy and induration, constituting a *node*. In some cases, but rarely, suppuration and death of the layer of bone immediately subjacent to the affected membrane take place.

SYMPTOMS.—The symptoms of periostitis consist of a hard elongated but somewhat puffy swelling—a *node*—not distinctly circumscribed, and attended by much pain in the part, especially at night, with tenderness on pressure.

TREATMENT.—In the treatment of the acute form of the affection, the free application of leeches, with hot fomentations, and the exhibition of calomel and opium, will arrest the disease, and give relief to the patient. In the more chronic form, the continued administration of iodide of potassium will take down the swelling, remove the nocturnal pains, and materially improve the local condition of the part. In those cases of periostitis which are of a syphilitic character, iodide of potassium may almost be looked upon as a specific. Added to this, the occasional application of leeches and repeated blistering will be of essential service. If there be much thickening, considerable relief will be afforded by the free division of the periosteum down to the bone, either through the skin or by means of a tenotome slid under it.

OSTEITIS.

Inflammation of Bone may arise from the same constitutional causes as the preceding disease, but most commonly occurs as the result of injury, either accidental, or inflicted by the surgeon in an operation. When a portion of bone is inflamed, the periosteum and medullary membrane participate in the morbid action, and, together with the affected osseous structure, become highly vascular; at the same time the inflamed bone becomes expanded and softened, partly in consequence of changes induced in its organic constituents, and partly in consequence of the cancellated structure becoming more cellular from interstitial absorption; the cells being filled with a sero-sanguineous fluid. The compact structure of inflamed bone undergoes a peculiar kind of

laminated expansion, so that a section of it presents an appearance of concentric parallel layers. When the inflammation is chronic, the bone is likewise expanded, but instead of becoming looser in its texture and softened, as in the acute form of the disease, it becomes very dense, indurated, and compact; looking and cutting more like ivory than ordinary bone. Sometimes considerable elongation without much or any thickening will take place. I have seen, as the result of chronic osteitis, the tibia from one and a half to two inches longer than its fellow.

SYMPTOMS.—The symptoms of osteitis consist of enlargement of the affected bone, with deeply seated pain and great tenderness in the limb; the pain, as in periostitis, is greatly increased at night, and when the disease is chronic, is much influenced by the state of the weather.

TREATMENT.—In the treatment of the *acute* cases, our principal reliance must be on local leeching, with calomel and opium. In the more *chronic* form of the affection, when the bone has become thickened and enlarged, nothing of a curative kind can be adopted; and the only remedy consists in the administration of iodide of potassium for the relief of the pain, with perhaps the occasional application of leeches. Should these means fail in giving relief, and the pain continue of an excessively distressing and persistent character, I have found that a cure may be effected by cutting down on the thickened osseous node, and then making a longitudinal section in the bone by means of a Hey's saw down to the medullary canal. In this way tension is taken off; and the pain, which appears to be dependent on the compression of the inflamed bone by its own condensed structure, is at once relieved. This means is especially applicable to osseous nodes on the tibia, and is a far less severe mode of treatment than trephining the bone, which has occasionally been adopted in such cases; while it is equally efficacious. After a time, when all morbid action ceases, the hypertrophied bone does not give rise to any very serious inconvenience, except such perhaps as may be occasioned by its bulk.

Osteitis is principally of importance to the surgeon from its connection with other more serious diseases of bones, in which it not unfrequently terminates. Those conditions are Suppuration of Bone, its Ulceration, Caries, and Necrosis.

SUPPURATION OF BONE.

Suppuration of Bone may present itself in two forms, the *Acute* and the *Chronic*.

ACUTE SUPPURATION: OSTEO-PYELITIS.—The acute form of suppuration is invariably of a diffused character. It usually arises as the result of injury inflicted on bones in compound fractures, gun-shot wounds, and operations; as, for instance, in amputations or in excision of joints. In it the medullary membrane is primarily affected, the inflammation rapidly extending through the whole of the medullary canal and adjoining cancellous structure, which speedily becomes filled with pus. Stanley observes that the medullary membrane in this disease becomes vascular like the conjunctiva in chemosis, and is often black and gangrenous (*Osteo-mycetitis*). This purulent infiltration of the interior of the bone is very apt to give rise to phlebitis and pyæmia, and hence becomes a most formidable affection, the pus finding its way into the veins of the bone, and thence into the general current of the circulation. Osteo-pyELITIS, phlebitis, and pyæmia, constitute a pathological sequence that is by no means an uncommon cause of death after operations implicating the medullary canal. When the diploe of the skull is affected, the sinuses and cerebral veins may be found after death highly inflamed and

filled with pus. In a case in which I excised the elbow-joint, the patient died of pyæmia; after death the interior of the humerus was found to be inflamed and filled with pus, and the axillary vein in a state of suppuration (Fig. 223).

The invasion of this disease, after an operation, is indicated by great and deeply seated pain, with much swelling, tension, cedema, and general redness of the limb or stump. The wound becomes sloughy, all discharge from it ceasing; rigors occur; and the symptoms of pyæmia speedily set in.

The Treatment consists in supporting the patient's constitutional powers by a tonic and stimulating regimen, and by scrupulous attention to hygienic rules.

So far as the affected bone is concerned, nothing can be done to it except its complete removal. Any operation performed upon the continuity of a bone affected with diffuse suppuration in its medullary canal is utterly inadmissible; the injury inflicted by the saw setting up great inflammatory action, and developing the disease in the part of the bone which is left. Hence, if secondary amputation of an injured limb should be rendered necessary, the bone being affected with osteo-mylitis, the operation should be performed at some joint above the injured and diseased bone. M. J. Roux has especially pointed attention to this important practical fact, and recommends as the result of his very extensive experience in the Italian war, that disarticulation of the injured bone should be performed in preference to amputation through its continuity. By the adoption of this practice he has successfully disarticulated the thigh at the hip-joint, in four cases of osteo-mylitis consequent on gunshot injuries of the lower end of the femur. Of 22 cases in which he performed secondary disarticulation of other joints for osteo-mylitis, all recovered; whereas every soldier died, whose limb was secondarily amputated through the continuity of the injured bone after the battles of Magenta, Montebello, Marignano, and Solferino.

CHRONIC SUPPURATION.—The more chronic form of suppuration of bone usually assumes a circumscribed character, and leads to the formation of abscess. The abscesses are usually met with in the cancellated structure, and occur with especial frequency in the head and lower end of the tibia. In some instances they are tolerably rapid in their formation, but in the majority of cases are excessively chronic. When of a more acute character, they are probably the result of the softening of tubercle previously deposited in the bone; and, forming in the cancellous structure, are very apt to undermine the contiguous cartilage of incrustation, and eventually to burst into the neighbouring joint (Fig. 224). When of a more chronic character, they are usually of very small size, and are deeply seated in the substance of the head, or in the medullary canal of the bone; the osseous substance covering them, having long been the seat of chronic inflammation, becomes greatly thickened and indurated. Most commonly the quantity of pus contained in these abscesses is extremely small, and it is often mixed

Fig. 223.—Diffuse Suppuration of Humerus.

Fig. 224.—Abscess in the Head of the Tibia.

with cheesy or tuberculous matter, or contains portions of necrosed bone intermingled with it. In some cases, however, Stanley has observed that abscesses of bone are large, containing a considerable quantity of fluid.

The *Symptoms* of chronic abscess of bone are usually of the following character. The patient, after the receipt of an injury, perhaps, has noticed that at one spot the affected bone has become swollen and painful; the skin covering it preserves its natural colour in the majority of cases, but in some instances becomes red, glazed, and cedematous; the pain, which is of a lancinating and aching character, is usually remittent, often ceasing for days, weeks, or months, and then returning, under the influence of very trivial causes, with its original severity. It is especially troublesome at night, and is always associated with a degree of tenderness of the part; and indeed, in the intervals of its accession, it will be found on careful examination that there is always one tender spot in the enlarged and indurated bone. The long persistence, for years perhaps, of these signs will usually point to the existence of a small circumscribed abscess under the thickened wall of the bone. But it must be borne in mind that the same local symptoms may be induced by three other conditions: 1, by the inclusion of a small portion of dead bone within a dense and impervious casing; 2, by the pressure of the osseous structures, greatly thickened and condensed by chronic inflammation; and, 3, by the expansion of the bone by an intracystic growth. For all practical purposes the diagnosis is of little consequence, as the treatment is the same, whether the pain and other symptoms arise from the confinement of a few drops of pus, from the inclusion of necrosed bone, from the pressure of hypertrophied osseous tissue, or from cystic disease.

Fig. 223.—Bone Trephine.

Treatment.—As a circumscribed abscess in bone cannot perforate the dense osseous structure overlying it by any process analogous to the pointing and discharge of an abscess in the soft parts, it becomes necessary for the surgeon to open up a vent for the pus. The proper way of doing this has been pointed out by Quasnay and Brodie. It consists in trephining the bone, so as to make an aperture for the exit of the pus, with an instrument having a small crown, of the size represented at *a*, Fig. 225. So soon as a vent has been given to the pus, which is often cheesy and occasionally very offensive in its character, the patient will experience great and permanent relief. In performing this operation, there are several points that deserve special attention. The bone must be exposed by a T- or V-shaped incision, made over the spot which has been found to be uniformly tender on pressure; and to this the trephine should be applied. The trephine should have a small and deep crown of the size and shape represented in Fig. 225; and it is well always to be provided with two instruments of the same shape and size that will exactly fit the same hole, lest one become disabled by the density and hardness of the osseous case, as I have seen happen. When the trephine has penetrated to a sufficient depth, the button of bone may be removed by means of an elevator; but care should be taken not to perforate the whole thickness of the bone. The diseased cavity will very commonly at once be opened in this way, a small quantity of pus escaping, which may, however, readily be overlooked, as it is carried away in streaks with the blood, which flows freely from the cut bone. Should no pus escape, perhaps a portion of dead

bone, or some dark gritty masses of disorganised osseous tissue, are exposed ; if so, they must be removed with a gouge. But if neither of these conditions be found, the surgeon must not be disappointed, but pierce the neighbouring osseous tissue in different directions by means of a perforator, when perhaps the abscess will be opened ; should it not be so, the patient will still in all probability be materially benefited by the removal of the circle of bone, and the consequent relief to the compression of the osseous tissue. After the operation, the cavity left must be dressed from the bottom with wet lint, and a poultice be afterwards applied ; it will gradually fill up with fibrous tissue, leaving the limb unimpaired in utility and strength.

CARIES.

By *Caries* some surgeons mean a kind of ulceration of bone ; others, a species of disintegration of the osseous tissue ; and Stanley includes under this term the various changes consequent on chronic suppuration of the cancellous structure. But caries, I think, properly means a disease of the bone, characterised by increased vascularity, softening, and ultimate disintegration of the osseous tissue. It appears to consist in a breaking down of the organised portion of the bone, in consequence of which the earthy matters become eliminated in a granular, molecular, and almost diffuent form in the pus formed by the inflammation of the surrounding more healthy structures.

STRUCTURE.—On examining a portion of carious bone, it will be found to be porous and fragile, of a gray, brown, or blackish colour ; partly broken down in softened masses, and partly hollowed out into cells, which contain a reddish brown and oily fluid. The process of wasting which goes on in the bone, appears to be partly the result of ulceration, and partly of disintegration of its tissue. In many cases, small masses of dead bone lie loose and detached in the carious cavity. Around this carious portion, the bone, as well as the medullary and periosteal membranes, are usually extremely vascular, and, in many cases, hardened compact masses of osseous tissue will be found deposited around the carious cavity, or even forming its exterior wall. These changes are most commonly met with in the cancellous structure, but the compact tissue may likewise be affected. As caries frequently occurs in the cancellated tissue, it is commonly met with in the heads of bones ; and here the disease is extremely dangerous, being apt to undermine and destroy the contiguous articular cartilage, and thus implicate the joint. This caries of the articular ends of bones is consequently a most serious affection, and is a very frequent cause of incurable joint-disease, such as suppuration and destruction of cartilage, followed perhaps by partial ankylosis. Any bone may be affected by caries, but it is perhaps more frequently met with in the short and cancellous bones.

CAUSES.—Caries usually occurs in constitutions that have been debilitated by struma or syphilis, often without any other apparent cause. Caries occurring in *strumous constitutions*, and affecting the short bones, as those of the tarsus, or the cancellated heads of the long bones, as the tibia, usually, if not always, commences in the centre of the bone, which becomes congested, softened, and disintegrated ; in many cases without any external cause, but apparently simply from the diminution of vitality in those parts of the osseous structure which are farthest from the periosteum, and which do not, like the deeper structures of a long bone, receive a supply of blood from an internal or medullary membrane. In these cases, the inflammation of the soft investing parts, and the destruction of the joint, which usually ensue, are consecutive to the disease in the bone.

In *sypilitic constitutions* caries is apt to affect the surface of the bone, disintegrating and eroding this in a remarkable manner. This condition has been described by Stanley as true *ulceration of bone*, and he regards it as distinct from caries, and analogous to ulcers of the soft parts. Here the disease does not penetrate deeply, but leaves the surface rough and porous, with a good deal of inflammation in the soft parts around the affected bone. He states that it only occurs in adults, and in males, and is very chronic in its character; it is met with primarily in the bones of the spine, but also occurs on the articular surfaces in advanced stages of joint-disease.

SYMPTOMS.—The symptoms indicative of the occurrence of caries are of a very equivocal character, and are not unfrequently, in the early stages, mistaken for those of ordinary phlegmonous abscess or rheumatism. They consist of pain in the bone, with a good deal of redness and swelling in the soft tissues covering it; abscess at last forms, often of considerable size, and, on letting out the pus, the character of the disease will be recognised, as the bare and rough bone may be felt with a probe, which sinks into depressions upon its surface, which, though rough, yields readily to the pressure of the instrument. The cavity of the abscess gradually contracts, leaving fistulous openings, which discharge a fetid pus, usually dark and sanious, intermixed with granules of bone, and containing a superabundance of the phosphates. The fistulous openings are generally surrounded or concealed by lugh spongy granulations, and the neighbouring skin is duskiy indamed.

TREATMENT.—The treatment of caries must be conducted in reference to the constitutional cause that occasions it, the removal of which is the first and most essential element in effecting a cure. If it arise from *sypilis*, this must be eradicated; if from struma, the general health must be improved. By the removal of causes such as these, the disease will often cease spontaneously, and even undergo cure, more especially in young subjects. Hence, it is well not to be in too great a hurry to interfere, by operative means, in the caries of the small bones of children. I have often seen cases, especially of caries of the bones of the hands and feet, in which an operation for the removal of carious bone was apparently indispensable, recover spontaneously on change of air, and attention to the general health of the child; the disintegrated particles of the diseased bone being eliminated piecemeal.

In the first stage of caries, which is inflammatory, measures should be taken, by means of appropriate local and constitutional antiphlogistics, to subdue the activity and limit the extension of the disease; and when this has fallen into a chronic stage, constitutional alteratives should be employed. Amongst these, cod liver oil, the iodulca, and change of air, more especially to the seaside, when the patient is young, should hold the first place.

Counter-irritation is of little avail in these cases in arresting the progress of morbid action. By means of blisters, iodine, and issues, thickening of the periosteum and of the soft structures covering the diseased patch of bone may be lessened, and pain subdued; but the real progress of osseous disease cannot, I think, be influenced by such means, when once it has passed the earliest stage of inflammatory congestion.

When the disease has fallen into a chronic condition, and nature seems unable to eliminate the carious bone, all reparative action having ceased, or being inefficient for the restoration of the integrity of the part, an operation becomes necessary. When the operative procedure has reference to the diseased part itself, it is impossible to be too careful in delaying it until the acute stage of the disease has passed, and the inflammation in the bone and surrounding tissues has subsided into a chronic state. Unless this be done, the excited action set up by the operation will unfaili-ly

give fresh impetus to the disease, which will make more rapid progress, and may perhaps terminate in diffuse suppuration of the bone.

OPERATIONS.—The operations practised upon carious bones are of four kinds; consisting either in simple Removal of the Diseased Portion of Bone; in Excision of the Carious Articular End; in Resection of the whole of the Bone affected; or in Amputation of the whole Limb.

The removal of the carious portion of bone is best effected by means of the gouge. This instrument is especially useful in those cases in which short, thick bones, or the articular ends of the long bones, are affected, without the neighbouring joints being implicated. In applying the gouge, the diseased portion of bone should be exposed by a crucial incision, and, if necessary, its cavity opened by a small trephine. The gouge, fixed in a short round handle, is then freely applied, and the diseased tissues are scooped and cut out. In order to do this efficiently, it is desirable to be furnished with instruments of different shapes and sizes, so that there may be no difficulty in hollowing or cutting away every portion of bone that is implicated. I have found the *gouge-forceps* (Fig. 232, p. 716), a very useful addition to the gouge in clearing away angular fragments and projections of bone, and thus removing the whole of the diseased structures. In some cases Marshall's *osteotrite* (Fig. 236) will be found a very serviceable instrument, clearing away the softened carious bone without risk to the surrounding healthy structures.

In removing the carious bone with these instruments, the surgeon may be sometimes at a loss to know when he has cut away enough. In this he may generally be guided by the difference of texture between the diseased and healthy bone; the former cutting soft and gritty, readily yielding before the instrument, whilst the latter is hard and resistant; so that, when all the disease is removed, the walls of the cavity left will be felt to be compact and smooth. In some cases, the healthy bone may have been softened by inflammation; should there be any doubt as to the condition of what has been gouged out, it may be solved by putting the *détritus* into water, when, if carious, it will either wash white or black: whereas, if healthy, but inflamed, it will preserve its red tint. In operating on young children especially, it is well not to have the gouge too sharp, lest the undrained, but otherwise healthy though somewhat softened bone, be cut away together with the disintegrated caries. The cavity that is left should be lightly dressed from the bottom, and allowed to heal by granulation, when it will gradually fill up by the deposition of fibrous material in it.

When caries affects the articular ends of the bones, as those that enter into the formation of the elbow or shoulder joints, it may be so situated as not to admit of removal in the way just indicated, but to require *excision* of the diseased articulation: this operation we shall consider in a subsequent chapter. When caries involves a bone so extensively that neither of the preceding plans can successfully be put into operation, it becomes necessary to perform either the *resection* of the whole of the bone, if it be of small size, or *amputation* of the limb, if of greater magnitude or if the neighbouring joints be extensively affected. Thus, for instance, resection of the os calcis may be required for caries of that bone; while, if the whole of the tarsus be affected, amputation is the only resource.

Fig. 236.—Marshall's Osteotrite.

NECROSIS.

The transition from Caries to *Necrosis* is easy. Caries may be regarded as the granular disintegration or molecular death of the osseous tissue, conjoined with suppuration of the surrounding healthy parts; whilst necrosis must be looked upon as the death of the osseous tissue as a whole—a condition, indeed, closely resembling that of gangrene of the soft parts. Whilst caries, however, chiefly affects the cancellous structure, necrosis is met with in the compact tissue of bone, and far more frequently occurs in the shafts than in the articular ends of the long bones. It is, however, occasionally found in the cancellous structure; thus in the head of the tibia, or in the os calcis, small masses of necrosed bone are not unfrequently found lying in the midst of carious or suppurating cavities. Different bones are affected by necrosis, with varying degrees of frequency. The tibia at its anterior part is most frequently diseased; the femur in its lower third is also very commonly affected. The lower end of the humerus is not so often necrosed; but not uncommonly the phalanges of the fingers from whitlow, the skull from syphilis, the lower jaw from the emanations evolved in the manufacture of phosphorus matches, and the clavicle and ulna from injury or constitutional causes, are found affected by necrosis.

CAUSES.—The causes of necrosis are of very various character. We have just seen that it is *Predisposed* to by the structure of particular parts of bone, and is more frequent in some bones than in others. Among the more constitutional causes, we may rank in the first line those cachectic conditions of the system that result from scrofula and syphilis, and those debilitated states of constitution that so frequently follow upon typhoid fever: in these various states, the bone may suddenly lose its vitality, more especially if the limb be subjected to slight accident, as concussion, or to exposure to some degree of cold. Sometimes the disease results from the vitality of the bone being destroyed by the extension of inflammation to it from the neighbouring tissues, as in some cases of whitlow, or by the bone becoming exposed by a neighbouring abscess.

Traumatic causes frequently give rise to necrosis. Thus the denudation of a bone by its periosteum being stripped off, may lead to its death; but, though the bone thus injured often loses its vitality, yet, if the membrane be replaced, its life may be preserved; even when it is exposed, adhesions may take place between it and the neighbouring soft parts, or granulations may be thrown out by its surface, which eventually form another periosteum. Necrosis frequently occurs as the result of the detachment and denudation of a portion of bone in cases of bad compound fracture, so also the application of certain irritants, as the fumes of phosphorus, may occasion this disease, and hence it has been found that, in lucifer-match manufactories, necrosis of the lower jaw is a frequent consequence of the acid fumes that are eliminated gaining access to the bone through carious teeth, or being applied to the exposed alveoli.

CHARACTERS.—In whatever way it originates, necrosis may affect the outer laminae only of the bone, when it may be called *peripheral*; or the innermost layers that surround the medullary canal may perish, and then it may be termed *central*; or the whole thickness of a shaft, or of the substance of a short bone, may lose its vitality. The necrosed portion of bone, called the *Sequestrum*, presents peculiar characters, by which its nature may at once be recognised. It is of a dirty yellowish-white colour, and has a dull opaque look, and, after exposure to the air, it gradually becomes of a deep brown or black tint; the margins are ragged, and more or less spiculated,

and the free surface is tolerably smooth, but its attached surface is very irregular, rough, and uneven, presenting an eroded or worm-eaten appearance. When the sequestrum forms in the cancellous structure, it is usually of a blackish-grey colour, irregular but somewhat ovoid in shape, as if the bony matter had been partially dissolved away, and here is frequently conjoined with caries of the surrounding bone.

SYMPTOMS.—The symptoms of necrosis are divisible into two distinct periods. In the first, the bone dies and undergoes separation, and an attempt is made by nature at the expulsion of that portion of it which has lost its vitality. In the second period, the reparative processes for the restoration of the proper length and shape of the shaft are carried on. The particular character of the symptoms depends, however, not only on the stage, but also in a great measure on the seat and extent of the necrosis. In all cases it is ushered in by symptoms of local inflammation of a more or less intense and painful character; the skin becomes glazed, cedematous, and of a purplish-red tint; abscess, often of large size, and discharging great quantities of fetid or bloody pus, forms in the limb, and burrows widely, in proportion to the extent of the necrosis, amongst its cellular planes. If the suppuration be not so extensive as to jeopardise life, as occasionally happens when the thigh is the seat of disease, the patient sinking into rapid hectic, the suppurating cavity will gradually contract, leaving fistulous and sinuous tracts, often of great length and extent, leading to rough and bare bone, discharging a fetid and ichorous pus, and having their orifices surrounded by protuberant and glazed granulations. All these symptoms of inflammation, abscess, and widely spread suppuration, have for their ultimate objects the separation and elimination of the dead bone, and the proper formation of new bone as a substitute for that which has died. They are in the first instance occasioned by, and are not the cause of, the death of the bone. When a bone or a portion of a bone necroses, it becomes to all intents a foreign body. The soft tissues around resent its presence, and endeavour to throw it off by an inflammatory action, just as they would if any extraneous substance, as a piece of wood, were thrust in amongst them. But the ultimate result of the action thus set up is not limited to the separation of the dead bone, but extends to the formation of material destined to repair the loss of substance occasioned by the separation and exclusion of the dead bone.

In *peripheral necrosis* of the shafts of the long bones, as of the femur or tibia, the inflammatory symptoms just indicated are well marked, and the disease usually runs a rapid course up to the period of the formation and discharge of the abscess. In the case of *central necrosis*, the pain is usually more severe than in the former case, and is peculiarly deep-seated and throbbing, being especially intense at night. The limb becomes very cedematous, red, and glazed; the bone enlarges greatly, and abscess at last forms, which spreads widely in the planes of cellular tissue, undermining the muscles, and producing general destruction of the limb, the tissues of which become rigid and condensed, having sinuses leading down through them. On introducing a probe into these channels, the instrument passes through apertures in the bony case, termed *Cloaca* (Fig. 227), at the bottom of which the dead bone will be felt rough and bare. Though this is the general condition that occurs in central necrosis, it occasionally but rarely happens that a small portion of some of the internal lamellae of the bone dies, and, being included in a greatly thickened case of new bone, gives rise to symptoms of osteitis, or closely resembling those of circumscribed abscess of bone, but not to those characterising necrosis.

When the whole thickness of a shaft dies, the symptoms are always of a

also, of the limb generally, if thick, as in the thigh, contribute to the formation of plastic matter, which gradually ossifies, and so tends to strengthen the new case; and, lastly, the articular ends of the old bone, still preserving their vitality, constitute most important agents in the reparative process, throwing out sufficient osseous matter to connect themselves firmly to the new shaft that is formed. Thus it will be seen that the new bone is formed by the vascular and healthy tissues generally that surround the seat of disease, though in this reparative action the periosteum and medullary membrane take the chief share. In acute necrosis there is no time for reparative action to take place; but the periosteum is found much thickened and vascular, separated from the dead bone and occasionally lined with scales of new osseous matter, the first step toward the reproduction of a new shaft.

The new bone deposited on those parts of the surface of the shaft from which scales of the old osseous tissue have been separated, or enveloping the sequestrum when the whole thickness of the shaft becomes necrosed, is at first rough, porous, cancellated, and very vascular; after a time it gradually becomes more compact and harder, at the same time that it assumes a bulk and shape to the bone whose place it takes. The case of new bone, which necessarily exceeds in circumference the old bone, as this is increased within it, gradually contracts both in texture and in size, becoming firmer and smaller after the removal of the sequestrum, and the cloaca closing so soon as all dead bone has been extruded, it eventually acquires the proper size and shape of the bone; the medullary canal even becoming lined with a proper membrane forming in it. In this way, regeneration of the whole of the shaft of many of the long bones, such as those of the arm, forearm, and leg, will take place, provided always the epiphyses have been untouched by disease. If one or other of these has been destroyed, all power of repair seems to be lost.

The new bone usually forms with a rapidity that keeps pace with the death and separation of the old bone. In acute cases of necrosis, in which amputation has been performed but a few weeks after the setting in of the disease, a thick layer of new bone will sometimes be found under the periosteum; but in some instances, when the whole of a shaft is necrosed, the new case is not completed, or has not become attached to the articular ends before these are separated from the shaft. In other cases, though complete, it has not sufficient strength to resist the contractions of the muscles of the limb; under these circumstances, it may spontaneously fracture—as happened in a case of necrosis of the thigh under my care in the Hospital—or become shortened or bent. In other instances, again, when the periosteum is deficient, new bone does not form (Fig. 228), but, as the sequestrum separates, the limb becomes shortened, loose, deformed, and useless.

Fig. 228.—Necrosis. Deficient formation of New Bone.

TREATMENT.—In the treatment of necrosis, the indications to be accomplished are sufficiently simple, though the mode in which they have to be carried out often requires much patience and skill on the part of the surgeon.

The first point to be attended to is to remove any constitutional cause.

cause that has occasioned or keeps up the disease ; unless this be done, it is clear that the whole of the rest of the treatment must be ineffectual. Thus, for instance, if the death of the bone appear to result from scrofula or syphilis, those conditions must be corrected. So, again, if it arise in the lower jaw from the fumes of phosphorus, the patient must necessarily be removed from their influence ; or, if it be threatened in consequence of accumulation of bone, the best mode of prevention will be to lay down the flap of integument, and so cover the exposed surface. Abscess should be opened as soon as it has fairly formed. The early and free opening of purulent collections is especially imperative when they are *sub-periosteal*. In these cases the constitutional irritation occasioned by the confined pus is often so intense, more particularly in children of feeble constitutions, that life is threatened, and can only be preserved by the evacuation of the pus from the midst of the tense structures between which it lies.

Removal of the Sequestrum.—After the cause has, in this way, been removed or counteracted, the separation of the sequestrum should be left as much as possible to the unaided efforts of nature. The less the surgeon interferes with this part of the process the better ; for, as has been justly observed by Wedemeyer, the boundaries of the necrosis are known to nature only, and the surgeon will most probably either not reach, or he will pass altogether beyond them. Here much patience will be required for many weeks or months ; and the utmost that the surgeon can do is to attend to the state of the patient's health, treating him carefully upon general principles, removing inflammatory mischief by appropriate antiphlogistic means, opening abscesses as they form in the limb, and at a later period, supporting the patient's strength by good diet, tonics, and general treatment, calculated to bear him up against the depressing and wasting influence of continued suppuration, and of the irritation induced by the disease.

So soon as a sequestrum has been detached from the adjacent or underlying bone, by the proper extension of the granulating line of separation, the surgeon must proceed to its removal. In most cases it is sufficiently easy, when the necrosis is superficial, to ascertain that this separation has taken place, as the flat end of a probe may be pushed under the edge of the detached lamina. When, however, the sequestrum is deeply seated, it is not always so easy to ascertain that the separation has occurred ; though, in the majority of cases, the introduction of a probe through one of the fistulous openings leading to the necrosed bone, and firm pressure exercised upon this, will enable the surgeon to detect that degree of mobility which is characteristic of looseness. In other cases, however, the sequestrum, though completely removed from all osseous connections, still continues to be fixed by the pressure of the surrounding granulations, and by the extension of its spicula into the corresponding cavities of the new osseous case. This especially happens when the sequestrum is central and invaginated, and the cloacæ leading to it of such small size that but a limited portion of it is exposed. Here a more careful examination will be required ; and its looseness may sometimes be determined by pressing upon it with a probe in a kind of jerking manner, or by introducing two probes through different cloacæ, at some distance from one another, and alternately bearing upon the exposed bone with one or other of them. Then, again, if the sound elicited by striking the end of the probe against the sequestrum be a peculiarly hollow one, the detachment of the bone may be suspected. The duration of the disease, also, will probably throw some light upon the probable state of things inside the new case.

The separation of the sequestrum having been ascertained, the surgeon

also, of the limb generally, if thick, as in the thigh, contribute to the formation of plastic matter, which gradually ossifies, and so tends to strengthen the new case; and, lastly, the articular ends of the old bone, still preserving their vitality, constitute most important agents in the reparative process, throwing out sufficient osseous matter to consolidate themselves firmly to the new shaft that is formed. Thus it will be seen that the new bone is formed by the vascular and healthy tissues generally that surround the seat of disease, though in this reparative action the periosteum and medullary membrane take the chief share. In acute necrosis there is no time for reparative action to take place; but the periosteum will be found much thickened and vascular, separated from the dead bone, and occasionally lined with scales of new osseous matter, the first step towards the reproduction of a new shaft.

The new bone deposited on those parts of the surface of the shaft from which scales of the old osseous tissue have been separated, or enveloping the sequestrum when the whole thickness of the shaft becomes necrosed, is at first rough, porous, cancellated, and very vascular; after a time it gradually becomes more compact and harder, at the same time that it assimilates in bulk and shape to the bone whose place it takes. The case of new bone, which necessarily exceeds in circumference the old bone, as this is included within it, gradually contracts both in texture and in size, becoming firmer

and smaller after the removal of the sequestrum; and, the cloacæ closing so soon as all dead bone has been extruded, it eventually acquires the proper size and shape of the bone; the medullary canal even becoming lined by a proper membrane forming in it. In this way, restoration of the whole of the shaft of many of the long bones, such as those of the arm, forearm, and leg, will take place, provided always the epiphyses have been left untouched by disease. If one or other of these have been destroyed, all power of repair seems to be lost.

The new bone usually forms with a rapidity that keeps pace with the death and separation of the old bone. In acute cases of necrosis, in which amputation has been performed but a few weeks after the setting in of the disease, a thick layer of new bone will sometimes be found under the periosteum; but in some instances, when the whole of a shaft is necrosed, the new case is not completed, or has not become attached to the articular ends before these are separated from the shaft. In other cases, though complete, it has not sufficient strength to resist the contractions of the muscles of the limb; under these circumstances, it may spontaneously fracture—as happened in a case of necrosis of the thigh under my care in the Hospital—or become shortened or bent. In other instances, again, when the periosteum is deficient, new bone does not form (Fig 328); but, as the sequestrum separates, the limb becomes shortened, loose, deformed, and useless.

Fig 328.—Necrosis Deficient Formation of New Bone.

TREATMENT.—In the treatment of necrosis, the indications to be accomplished are sufficiently simple, though the mode in which they have to be carried out often requires much patience and skill on the part of the surgeon.

The first point to be attended to is to remove any constitutional or local

ever, should be taken not to remove more of the new case than is absolutely necessary, as the aperture so made in it will not be filled up again by osseous matter, but will be closed by fibrous tissue, and thus the ultimate soundness of the limb might be endangered. For the extraction of the sequestrum, the most convenient instrument is a pair of strong necrosis-forceps, well roughened at their extremity, and straight or bent as the case may require (Fig. 234). Occasionally the sequestrum is so shaped and placed that it cannot be seized with this instrument; under these circumstances, it will be

Fig. 234.—Necrosis Forceps.

useful to drive a screw-probe (Fig. 57) into it, by which it may either be extracted, or so fixed as to admit of seizure and removal by the forceps. In some cases, additional and convenient purchase may be given to the dead bone, by fixing a bone forceps, such as is represented in Fig. 235, firmly into

Fig. 235.—Bone-Forceps.

it. If the sequestrum be too large to be removed entire through the cloaca, it may perhaps best be extracted piecemeal, having been previously divided by passing the points of narrow but strong cutting pliers into the interior of the bone.

After the removal of the sequestrum, a smooth hollow cavity will be left in the new case, from the bottom and sides of which blood usually wells up freely, issuing abundantly from the vascular bone, and from the granulating membrane lining its interior. Should this hemorrhage be at all troublesome, pressure will always sufficiently arrest it. Lint must then be lightly introduced into the bottom of the wound, and the part elevated; a good deal of inflammation is frequently set up after the operation, but that must be combated on general principles. If the sequestrum have been a long one, and have involved the greater part of the shaft of the bone, it may happen that the new case has not sufficient strength to maintain the limb of its proper length and shape, and that it will bend or break under the action of the forces and weight to which it is subjected. In order to prevent this accident, it will be necessary to put it up in light splints, or in a starched bandage. After the removal of the dead bone, the fistulae will speedily close, and the limb eventually regain its normal size and shape.

must adopt measures for its extraction. If the necrosis be *peripheral*, all that is necessary is to make an incision down to it through the soft parts, either by directly cutting upon it or by slitting up sinuses with a probe-pointed bistoury, and then to remove it with a pair of forceps, or to tilt it off the bed of granulations on which it is lying, by introducing the end of an elevator beneath its edge.

When the necrosis is *central*, the sequestrum being imbedded in the new case, or covered in by old bone, the operative procedures for its removal are of a more complicated character. The difficulties here consist in some cases in the depth from the surface, and in the obstacle offered by its passage through the soft parts; and in others, in the length and magnitude of the sequestrum in proportion to the small size of the cloaca, and in the manner in which it lies, in a parallel direction to these openings. In cutting down upon the bone, the surgeon must be guided by the direction and the course of the fistulous tracks that lead to the principal apertures in the new case, the incisions being carried in the axis of the limb, and carefully directed away from large blood-vessels and nerves. In many instances, however, the hemorrhage is somewhat abundant, in consequence of the injected state of the tissues furnishing a copious supply of blood, and their rigid condition preventing retraction of the vessels; this, however, may be arrested by a tourniquet or by the pressure of an assistant's fingers, and will soon gradually cease of itself. The bone having been freely exposed, it will sometimes be found that the cloacae are of sufficient size to allow the ready extraction of the sequestrum. But in the majority of cases, this cannot be done at once, and the apertures must be enlarged, either with the gouge or the trephine, according to the density of the new case, and amount of room required. Occasionally, when two cloacae are close to one another, the intervening bridge of bone may very conveniently be removed by means of cutting pliers, of different shapes (as in Figs. 229, 230, and 231), or by

Fig. 229.

Fig. 230.

Fig. 231.

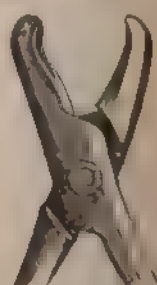

Fig. 232.—Gouge-forceps.

Cutting Pliers for removing Necrosed Bone.

means of a Hey's or a straight narrow saw (Fig. 233), and space thus given for the extraction of the sequestrum. Very convenient pliers for this purpose are those represented in Fig. 232. They are made by Mr. Coxeter,

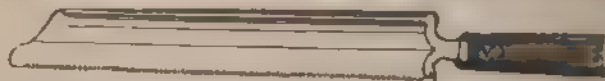

Fig. 233.—Straight Saw for removing Necrosed Bone.

with gouge ends, and hence may be termed *gouge-forceps*. I have found them extremely serviceable in many operations upon the bones. Case, how-

exposed for necrosis, as will be more fully mentioned when I come to speak of extension of the hip-joint. The tuber ischii, when affected, may readily be amputated.

NECROSIS OF THE CRANIAL BONES is of frequent occurrence as the result of struma or syphilis, or the two conditions conjoined. When met with in children, it is usually strumous, often occurring after measles or scarlet fever; in adults it is usually syphilitic, though by no means invariably so, being sometimes the result of blows in people of otherwise healthy constitutions. There are four situations in which necrosis of the cranial bones may occur, viz., in the vault of the skull, the frontal bone, the temporal bone, or in the sphenoid and ethmoid bones. When idiopathic necrosis affects the vault, it is usually syphilitic; when it occurs in the other situations, especially in the temporal bone, it is commonly strumous.

Two forms of necrosis affect the cranial bones. In one case the outer table is alone affected. this perishes, separates, and exfoliates; granulations then spring up from the outer surface of the inner table, and a process of repair is thus established. In the other form, the necrosis is hard, dry, rough, and pitted or worm-eaten, penetrating through the diploe to the inner table, separating very slowly, and lasting an indefinite period.

Results.—In necrosis of the cranial bones, there is always the special danger of extension of morbid action to the membranes of the brain, and the consequent occurrence of inflammatory effusion within the skull, leading to convulsions, coma, and death. This danger is greatest when the petrous portion of the temporal bone is affected, as the structure of this bone is homogeneous, and the dura mater is continuous with the lining of the cavities by which it is perforated. Cerebral complication is least likely to occur when the frontal bone is the seat of disease, more particularly the lower part of this bone, where, by the intervention of the frontal sinuses, the anterior wall is altogether carried away from the inner table, and from all dangerous proximity to the membranes of the brain.

The *Signs* of necrosis of the cranial bones are very obvious. When the vault or forehead is affected, there is tenderness, with some puffiness, and gradual elevation of the scalp into an abscess. When this is opened, the necrosed bone may be felt or seen lying, dry and dark, at the bottom of a sinus or unhealed ulcer. When the petrous portion of the temporal bone is the seat of disease, there will have been ear-ache, followed by profuse fetid discharge from the ear, with perforation of the tympanum, escape of the ossicula auditus, and deafness. When the sphenoid or the ethmoid is affected, deep pains in the head, persistent oedema of the eyelids, and fetid discharge from the nose, will reveal the nature and seat of the mischief.

The *Treatment* of necrosis of the cranial bones will vary according to the nature and the seat of the disease. In the dry pitted variety, exposing and scraping the diseased osseous surface will often bring about a healthy action, provided the disease have not penetrated too deeply. Should there be reason to think that the inner table has been perforated, it will probably be safer to leave the case to the reparative processes of nature than to trephine. If, however, the anterior wall of the frontal sinus be the seat of the disease, or if the supraorbital ridge be affected, the dry and rough bone may be safely removed, as I have on more than one occasion had to do, by the application of the trephine in the first instance, and of the gouge in the other case. When exfoliating necrosis of the outer table affects the vault of the skull, the loosened plate may readily be lifted off its granulating bed by means of the elevator or forceps, after it has been fairly exposed.

Necrosis of the petrous portion of the temporal is usually fatal from encephalitis. When the sphenoid or ethmoid are the seat of necrosis, little can usually be done by operative interference; though in the latter case portions of sequestrum may sometimes be extracted through the nostrils.

The PATELLA is rarely necrosed. I have, however, met with one instance of primary necrosis of this bone leading to disorganisation of the knee-joint, and necessitating amputation.

Ribs.—When the ribs are necrosed, abscesses and sinuses will often form to a considerable extent on the side of the chest. These must be laid open, and the diseased portion of bone scraped away by the gouge. In doing this, care must of course be taken that the adjacent intercostal space be not punctured by an unfortunate slip of the instrument—an accident that is best avoided by protecting the gouge well with the finger.

CHAPTER XLVII.

STRUCTURAL CHANGES IN BONE.

THE bones are liable to various structural changes, by which their size, shape, and consistence are modified, or in consequence of which they become the seat of tumours of various kinds.

HYPERTROPHY of bone usually results from inflammation of the osseous tissue, but in some cases it may occur apparently without having been preceded by any signs indicative of this condition; it then resembles in character some of the forms of exostosis that will presently be mentioned.

ATROPHY of bone occurs, as a natural result, in old age. In other cases it happens as a consequence of fracture; the nutritious artery of the bone having been torn across, and one of the fragments consequently receiving insufficient vascular supply. Atrophy of bone also commonly occurs from disuse, as is the case in old dislocations. In cases of hypertrophy, the bone is not only enlarged in circumference, and also perhaps in length, but is indurated, becoming specifically heavier. In atrophy, on the other hand, it is thinner, lighter, and more porous than usual, the compact structure disappearing, and the cancellous being expanded.

RICKETS, MOLLITIES OSSIUM, AND TUBERCLE.

RICKETS is a disease of early life, usually being met with in scrofulous children, and never occurring after the age of puberty. In it the structure of the bones is changed, the earthy matter being deficient, and the organic material in excess; so that the bone continues to be soft, flexible, and cartilaginous in structure, at an age when its tissue ought to have undergone proper consolidation. It appears to be atrophied, and the cancellous structure to be expanded into cells of varying magnitude, which contain a brownish-red serous fluid. In consequence of the change of structure and the loss of firmness in the bones in this disease, considerable distortion of the body takes place. The head early appears large and expanded, indeed, Kilian states that rickets always first appear in the head, the forehead being especially protuberant; according to Stanley, this arises not from enlargement of the cranial bones, but in consequence of the want of development of those of the face; the head thus appearing large from its dispro-

portion to the small face. The shape of the limbs is much changed and distorted, in consequence of their yielding to the pressure of the superincumbent weight; the pelvis becoming contracted, and the thighs and legs bent either forwards or outwards. The joints are usually swollen, the articular ends of the bones appearing enlarged. In early life the chest will be observed to be deformed in a peculiar manner, being narrowed above, where the upper ribs are contracted and pressed in, but expanded below, apparently from the weight of the abdominal viscera, which are often tumefied, and in these cases drag on the lower ribs. As puberty advances, lateral curvature of the spine commonly takes place. In rickety children there is a general delicacy of appearance, and often a strumous habit of body, though, according to Rokitsansky, they are not usually tuberculous; if they live, however, past the age of puberty, they may eventually become sufficiently powerful in frame.

The Treatment of rickets must be conducted on the same general principles that guide us in cases of scrofula; pure air, good food, and plenty of it, regular exercise, and the administration of tonics, especially the preparations of iron, with scrupulous attention to the general habits of life of the child, will generally improve his condition to the utmost limits compatible with the powers of his constitution, and will, by improving the nutrition of the system, tend to the more healthy deposition of osseous matter. In some cases, the administration of lime-water with milk seems to be of service in supplying those elements that are required by the system. It is of much importance in preventing deformity in these cases not to allow the child to walk or stand much, but to let it take exercise in doukey-panniers or hand-chairs, and to support those limbs that have a special tendency to become excurvated, with properly-constructed steel supports, which will be found of much use, provided they are not too heavy, or interfere with the action of the muscles. Methodical friction should also be employed, so as to stimulate the muscles; as these become more vigorous, their osseous attachments have a tendency to become stronger.

MOLLITIES AND FRAGILITAS OSSIUM—OSTEOMALACIA.—A very rare but most destructive and dangerous disease of the bones, characterised by softening and fragility of the osseous structure, is occasionally met with. This affection has of late years been studied with much attention by Curling, Solly, Stanley, MacIntyre, and Litzmann; and it is principally from their labours that we are acquainted with the principal facts relating to it.

In this disease the bones are bent, their epiphyses swollen, and their shafts broken in various parts of the body. Occasionally, though very rarely, only one is fractured; but in other cases, as in Tyrrell's, there may be as many as twenty-two fractures, or, as in Arnott's, thirty-one. These fractures are unattended by any attempt at the formation of callus. The body becomes angularly and distressingly distorted. On examining the bones after death they will be found to be light, soft, and somewhat gritty—ben ling, and at the same time readily snapping across; occasionally they are expanded and thickened. This happens especially with the skull, which becomes often considerably increased in substance. On cutting the bones, which are soft and yield something like cartilage, the knife usually encounters a kind of gritty sensation. On making a section of the bones they appear of a deep red lish-brown or maroon colour, and will be seen to contain cavities of various sizes, small or large, but always of a circular or oval shape, and generally filled with an oily, red, and grumous fluid, though sometimes they contain clear serum. On examining this red grumous matter under the microscope it shows a cell-development; hence Solly remarks that it is probably an adventitious

morbid product, and not simply fatty matter altered by the effusion of blood into it. Dalrymple has shown that this material is composed of granular matter, nucleated cells, and a few caudate corpuscles: he therefore believes it to be a disease essentially malignant in its nature, but differing from other malignant affections; for, "instead of progressively reproducing and developing themselves without limitation, the new and morbid formations which replace the original and sound structure seem to have been at an early stage of their existence removed by absorption and carried out of the system" (MacIntyre). The bone has been found by Solly, on microscopical examination, to have its laminated structure absorbed, the osseous corpuscles diminished in number, and the Haversian canals enormously distended.

In chemical composition, the diseased bone has been found by Dr. Leeson to be composed of 18.75 animal matter, 29.17 phosphate and carbonate of lime, and 52.08 of water in every hundred parts.

Cause—The cause of the complaint is obscure. It would appear that it is frequently connected with a rheumatic tendency; as, in every case recorded, the affection has been preceded or accompanied by severe pains, or distinct rheumatic attacks. In some instances the patients have been affected with syphilis. In a majority of the cases it appears to have a connection with the childbearing state. It most commonly, though not invariably, occurs in females, as pointed out by Kilian. Among 131 patients whose histories have been collected by Litzmann of Kiel, there were 85 females, in whom the disease either appeared during pregnancy and labour, or was modified in its course by these conditions. Of the remaining 46 patients, 35 were females and 11 males. It most generally attacks adults, having been observed in few cases under the age of 20; and it may occur even at very advanced age.

The *Seat of the Disease*, according to Litzmann, varies according as it occurs within the childbearing period, or independently of this. In 85 childbearing women, the whole skeleton was affected in 6 cases only, and all except the bones of the head in 2; while in 46 other cases, all parts of the skeleton were diseased in 21, and all the bones except those of the head in 6. The percentage of the occurrence of the disease in various parts is shown in the following table:—

	85 childbearing women	46 other cases
Pelvis	90	87
Spinal Column	54	87
Chest	31	80
Lower Limb	17	73
Upper Limb	12	62
Head	8	52

In childbearing women the disease appears to have a remarkable predilection for the pelvis, it is probable, however, that a careful examination of all the bones has not been made in all cases.

State of the Urine.—In all cases that have been recorded, the urine has been seen to contain large quantities of earthy matter. Solly pointed out that this is phosphate of lime, which has been absorbed from the bone, and thrown out by the kidneys in the urine; and sometimes the elimination of this matter is so abundant that it forms, as in one of the cases which he relates, a solid calculus clogging up the interior of the kidney. In Dr. MacIntyre's case, the earthy matters of the bone appear to have been, in the first instance, absorbed, and carried off from the kidneys by the urine; but afterwards an animal matter, of a peculiar and apparently previously undescribed character, was discharged in abundance.

Symptoms.—These are, in the early stages, extremely obscure and insidious. The patient complains, in the first instance, of wandering pains about the limbs and trunk; these assume usually a rheumatic character, though they have been observed to be of a much more severe, persistent, and intractable nature than in any form of rheumatism. The patient becomes debilitated, unfitted for exertion, and emaciated. Spontaneous fracture now occurs in some bones under the influence of the most trivial causes; others become bent, and the body consequently greatly misshapen and distorted. The urine presents some of the abnormal characters above described, and death eventually results from general exhaustion.

Diagnosis.—The diagnosis of this affection has to be made in the early stages from *rheumatism*. This is not always easy, and, indeed, is at first impossible; but after a time, when the peculiar phosphatic condition of the urine and the fragility or distortions of the osseous system manifest themselves, the true nature of the affection becomes apparent. From *rickets* the diagnosis may usually be pretty readily made, by observing that, whilst *rickets* is a disease of childhood, *osteomalacia* is peculiar to adult or advanced life. The severe pains and the great distortion, with the tendency to spontaneous fracture which is observed in this disease, are never noticed in rickety children.

Treatment.—With regard to treatment, but little can be done: the administration of tonics, and a general supporting plan of treatment, may arrest for a time the progress of this terrible affection; but when once it is declared, it usually progresses from bad to worse, and at last destroys the patient. Opiates may be employed to allay the pain, and in Dr. MacIntyre's case some temporary advantage appeared to result from the administration of alum; but no remedy has appeared to exercise any continuous advantage in this complaint, which there is reason to believe, with Solly, is truly malignant.

TUBERCLE OF BONE.—The deposit of tuberculous matter in bone plays an important part in many diseases of this tissue in children and young people of a scrofulous habit of body; being a common cause of some of the most intractable forms of chronic osteitis, circumscribed abscess, caries, and necrosis. As tubercle is almost invariably deposited in the cancellous structure, it is a frequent cause of those forms of inflammation of the articular extremities of long bones, that terminate in the destruction of the contiguous joint. In the short bones, as those of the tarsus, it commonly leads to caries and necrosis; and forming, as it often does, in the bodies of the vertebrae, it very frequently gives rise to some of the most destructive diseases of the spine, attended by the formation of large lumbar and iliac abscesses. When once tubercle has been deposited in a bone, it usually sets up a low form of inflammation in the surrounding osseous tissue, which rapidly runs into a carious condition, with the formation of curdy pus, in which masses of half-disintegrated tubercle may be seen. If this destructive action take place with great rapidity, portions of the bone will be found to necrose in small masses, which lie at the bottom of these tuberculous and carious cavities, as may commonly be observed in some forms of strumous caries of the os calcis and head of the tibia. These tuberculous vomica undermine the overlying articular cartilage, and thus opening up the interior, give rise to the most destructive suppurative disorganisation in it. Fig. 236 is a representation of one of these vomicae in the head of

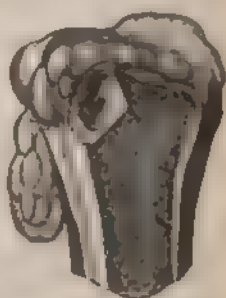

Fig. 236.—Tuberculous Vomica in Head of Tibia.

the tibia, their most common seat. When the tuberculous deposit has been very extensive, and is of a more acute character, it may cause inflammation and disintegration of the whole of the articular end of a long bone, with separation of the epiphysis. These destructive changes may take place with great rapidity; I have seen them happen in a lad, whose thigh I amputated for acute tuberculous infiltration of the lower end of the thigh-bone, in less than a month from the first occurrence of the complaint; the patient, at the time of the operation, being nearly exhausted by hectic, induced by the abundant discharge from the diseased bone, and from immense abscesses in his thigh.

When, on the contrary, the tuberculous matter is deposited in small quantity in an otherwise healthy bone, it may, as it undergoes softening, dispose to the occurrence of circumscribed abscess, at the same time that chronic thickening and condensation of the surrounding bone takes place. It is in consequence of this condensation of the peripheral portion of the bone by the deposit of fresh layers of osseous tissue under and by the inflamed periosteum, and the difficulty that the tuberculous abscess necessarily experiences in traversing the hypertrophied osseous structure, that it is so apt, when deposited in the vicinity of a joint, to work its way through the cartilages into the cavity of the articulation; as on this surface no fresh deposit nor condensation of osseous tissue can take place, and consequently no additional obstacle is offered to the onward progress of the tubercle, or rather of the curdy pus into which it has become transformed.

The presence of tubercle in osseous tissue thus not only gives rise to destructive changes in the bone and adjacent articulations, but will occasion inflammation and extensive suppuration in the neighbouring soft parts; indeed, some of the largest chronic abscesses that form in the body, those connected with diseased dorsal or lumbar vertebrae, owe their origin in the majority of cases to the deposition and disintegration of tubercle in the bones. When once tubercle in bone has given rise to caries and perforation of the osseous tissue covering it, together with plastic infiltration, and abscess and sinuses of the soft parts, these conditions will continue in a permanent manner; the fistulous tracks leading down to the bone, and the cavities in it, remaining open so long as any tuberculous matter is left at the bottom of them; and in this way the patient may eventually be exhausted by the copious and continuous discharge from the osseous vomicae. In some favourable cases as the result of natural processes, and in others by those operations that the surgeon practises for caries, the whole of the tuberculous matter may be disintegrated, and thus eventually eliminated, a true vomica being left in the bone, or scooped out by the gouge; and then the fistulous track, whether in the soft parts or in bone, having no longer this kind of foreign body lying on its bottom, will gradually close—not by the contraction of its osseous walls, which is of course impossible, but by the deposition of a fibrous tissue by which the cavity is occluded.

Pathology.—Nélaton has pointed special attention to the pathology of tubercle of bone, and to the important part that it plays in the diseases of the osseous structure. He describes two forms of tubercle in this situation; the first is the *encysted* variety, which occurs in the form of small masses, of an opaque white or yellowish colour, contained in a cyst, which is soft, vascular and spongy, apparently of a cellular structure. This variety is stated by Nélaton to be the most common. I have certainly not found it so, but have most frequently met with the infiltrated opaque tubercle. The other form in which tubercle occurs, according to Nélaton, is an *infiltration* into the cancellous structure of bones. This may be in the form of

semi-transparent granulations of a greyish or rosy tint, opalescent and slightly transparent, occasionally these granulations are firm, so as almost to resemble cartilaginous deposits in the interior of the bone. The osseous structure, in the midst of which this kind of tuberculous matter is deposited, does not appear at first to undergo any material alteration. Tubercle may also be infiltrated as opaque puriform matter of a pale yellow colour, soft, and without vascularity (Figs. 237, 238). The osseous tissue, under the

Fig. 237.—Tuberculous Head of Tibia.

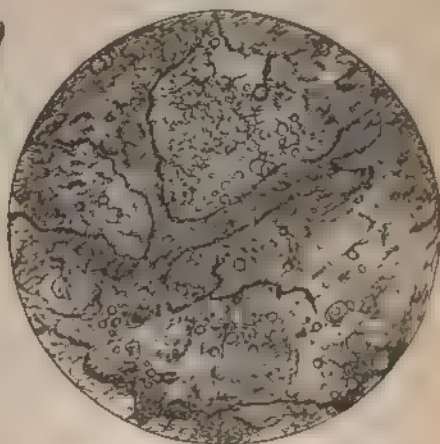

Fig. 238.—Tuberculous Bone magnified 2.0 Diameters.

influence of this disease, often becomes, as Nelaton observes, more condensed than natural, the cells being obliterated so as to resemble the compact substance of bone. In some cases it may continue thus chronically thickened and indurated; but in other instances the tuberculous inflammation will give rise to rapid and destructive inflammation of the surrounding osseous tissue, which becomes excessively vascular, and crumbles down into a crumbly state, with some necrosed masses intermixed. In other instances, as is not unfrequently observed in some of the forms of caries of the spine, or of white swelling, slow suppuration takes place in the interior of the bone; and on the sides or in the centre of the abscesses thus formed, hardened and white ivory-looking masses and knobs of osseous tissue may be seen to be deposited; these apparently consisting of tuberculous bone that has undergone some special modification of structure.

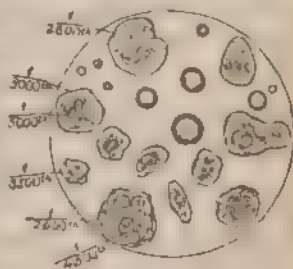

Fig. 239.—Cells of Osseous Tubercle

Treatment.—The treatment of tubercle of bone resolves itself into that of its effects. As its existence cannot be recognised except by the changes which it induces in the bone, the treatment must be directed exclusively to these. Thus, if it occasion circumscribed abscess, this must be opened; if caries, the diseased cavity and tissue must be scooped out, or removed in accordance with the principles already laid down; and if disease of the neigh-

bouring articulations result, it must be managed in the way that will hereafter be explained.

It is of importance, however, to recognise the dependence of these various affections on a tuberculous state of the bone; for, as this is always of a scrofulous character, it should necessarily occasion the constitutional measures that are employed to be specially directed to the removal of this cause. Thus good food, sea-air, the administration of iron, of the iodides, and cod-liver oil, will form most important elements in the treatment; and without these, indeed, it cannot be brought to a successful termination. The progress of these cases is generally excessively tedious. Stanley gives, indeed, two years as the time required for a strumous bone to recover itself; and in very many instances this period may even be exceeded. In this, as in all other of the chronic inflammatory affections of the bone, it is of considerable moment to continue the means of cure until the disease is fully recovered from; for relapse will occur with special readiness in the tubercular affections, if the patient be allowed to use the diseased limb or part too soon.

TUMOURS OF BONE.

Exostosis.—By exostosis is meant the growth of a bony tumour from some of the osseous structures of the body. The causes that immediately give rise to this disease are usually extremely obscure. There can be no doubt that, in some instances, it is predisposed to by syphilis, scrofula, or cancerous affections; and that in other cases, again, it is hereditary; but, in general, it occurs without any distinct or appreciable exciting cause. It chiefly occurs in the young, developing itself about the age of puberty. Exostosis appears to originate in two ways; being either primarily formed and deposited as true bone, or in other cases being the result of the ossification of an enchondroma.

Exostoses are of two kinds—the one hard and compact, the other softer and more spongy. The hard, or *Ivory Exostosis*, is a structure that differs both in appearance and composition from true bone. It is extremely compact and white, having a granular section closely resembling that of ivory, and presenting somewhat radiating fibres. In chemical composition, it is found to differ from healthy bone in containing more of the phosphate and less of the carbonate of lime, and also in the proportion of animal matters being smaller. This kind of exostosis principally grows from the flat bones, and, as it is generally of small size, seldom produces much inconvenience, unless it project into and compress important parts. Thus, Oloquet relates the case of a tumour of this kind growing from the pubic bone, and perforating the bladder; and it is occasionally found to project into the orbit, or from the inner table of the skull, upon the brain. When exostosis is left to itself, it becomes stationary after a time. In some instances it has been known to necrose, and to slough away, as it were, from the parts in which it has been situated. Of this termination Hilton and Boyer relate instances.

The *Spongy, Cancellous, or Cellular Exostoses* grow rapidly, often attain a considerable size, and are very commonly multiple. It is this form that is usually primarily enchondromatous. When numerous, they will often be found to be somewhat symmetrical in their arrangement. Not unfrequently they stretch across from one bone to another, bridging over joints, and thus giving rise to ankylosis; in shape they vary greatly, sometimes being globular, at others spinnous; in structure and chemical composition they are identical with cancellated bone.

The *Symptoms* of exostosis are simply those produced by a hard, thick,

and slowly growing tumour, connected with a bone and pushing forwards the soft parts covering it. In many cases, it produces serious inconvenience by its pressure, either upon neighbouring organs or mucous canals; or it may occasion ulceration of the skin lying above it.

Treatment.—If an exostosis be so situated as to occasion inconvenience or deformity, it will be necessary to remove it; and as it is a local disease, there is no fear of its return, provided this be fully done. If, however, the whole of it be not taken away, it may grow again; and Stanley accordingly recommends that if it be so situated, as upon the skull, that its base cannot be extirpated, potassa fusa or nitric acid should be applied to the part that is left, so as to produce exfoliation of it. The removal of these tumours is best effected by a Hey's or chain saw, or cutting pliers. In some situations, as when close upon joints, or springing from the cervical vertebrae, they cannot be interfered with; and in other cases, as occasionally happens in the neighbourhood of the orbit, their density and hardness may be such that the saw can scarcely work its way through them. There is one variety of exostosis which deserves special attention. It is that form of the disease which springs from the upper surface of the ungual phalanx of the great toe. It forms a small rounded mass, usually about half as large as a cherry, projecting under or beyond the nail, and giving rise to much pain and inconvenience in walking. Dupuytren, who first described this peculiar variety of the disease, has pointed out the treatment proper for it, which consists in exposing it by a double elliptical incision, and cutting it off with the scalpel, or a small pair of pliers, without amputating the toe.

There is a species of bony growth, called *Osteoma*, consisting of an uniform elongated mass of new bone, deposited on some of the osseous surfaces, somewhat resembling a node, and differing from ordinary exostosis in not being pedunculated. This does not admit of removal, and is not amenable to any treatment.

ENCHONDROMATOUS or OSTEO-CARTILAGINOUS TUMOURS are often met with. These have already been described when speaking of enchondroma and its pathology (p. 480), and need not, consequently, be more than adverted to here. They usually require resection or amputation of the affected bone, according to the attachments and size of the growth; but Stanley states that in some cases, where the cartilaginous tumour of bone is of small size, it may be influenced and eventually dispersed by the local application of iodine and mercury.

CYSTIC TUMOURS of bone of various kinds are commonly included under the terms *Osteo-sarcoma* and *Spina Ventosa*; which terms, having also been occasionally applied to various other solid growths, whether of a fatty, fibrous, gelatinous, or cartilaginous character, as well as to various kinds of malignant tumour springing from bones, have occasioned much confusion in the pathology of these affections.

Structure.—The cystic tumours of bone have been well described by Nélaton. They consist of cysts, having various kinds of fluid and solid contents. The cysts may be unilocular, and these are commonly filled with solid matter; or multilocular, and they then contain fluid. The solid masses are usually of a fibrous or fibro-cartilaginous character, filling up completely the cavity in which they are situated, and often attaining a very considerable size. They occur principally about the jaws and articular ends of long bones, especially the humerus, the femur, and the tibia. The cysts with fluid or semi-fluid contents attain a much larger size than the last, being often met with as large as a coconut or a fetal head. On a section being made of them, they are found to be composed of multilocular cysts, each cavity

having distinct walls, and often communicating with others. The fluid contained within these cysts is of various characters, thin and serous, sero-sanguinolent, viscid, or dark-coloured, often associated with masses of fibrous tumour, appearing as if it proceeded from the central softening of these large growths. The same situations are affected by the compound as by the single cysts, but they are also met with in the shafts of long bones. From whatever part they proceed, their walls are composed of expanded bone, not uniformly thinned, but thickened and nodulated at various parts, whilst it is perforated at others (Fig. 240).

These cystic tumours principally occur in adults, being rarely met with in children. They constitute smooth, round, or oval growths, increasing

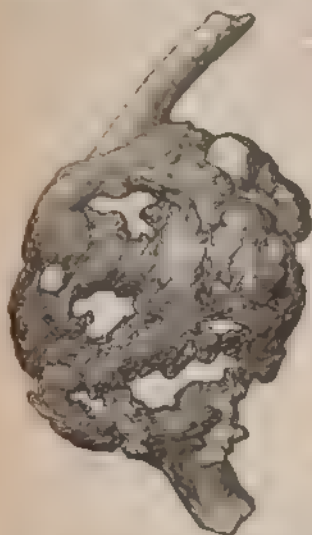

Fig. 240.—Cystic Tumour of Lower End of Long Bone.

slowly but steadily, with little or no pain; the skin covering them being of the normal colour, and the veins usually blue, enlarged, and tortuous. When a certain size has been attained, so that the shell of bone is expanded into a very thin lamella, and before it is perforated, pressure on the tumour occasions a peculiar cracking or rustling noise, like that produced by pressing together a broken egg-shell, or the cracking of tin-foil. Under this the elasticity or even semi-fluctuation of the tumour may be felt. This fluctuation is particularly marked after a time, when the osseous envelope has become still more expanded, or is partially or wholly absorbed.

Treatment.—When the contents of the tumour are solid, there is usually no means of ridding the patient of it but by the removal of the whole growth; by excision, if it be favourably situated for such procedure, as in the jaws; by amputation, if in the limbs. When the contents of the

tumour are fluid or semi-fluid, it must, if large, be treated in the same way as the solid growths are; but if it be small, or if of moderate size, so as not to have materially affected the integrity of the bone, it may suffice to remove one side of the wall of the cyst by the trephine or by excision, and then the cavity may be stuffed with lint, and allowed to granulate, and its walls to contract. This plan has proved especially successful in some of the cystic tumours of the lower jaw; and I have had occasion to practise it with success in a small cyst forming in the outer condyle of the humerus.

HYDATIDS.—Cavities are occasionally, but very rarely, found in bones, in which large numbers of hydatids are lodged; according to Stanley, both the acephalocyst and the cysticercus cellulose have been found in this tissue, but most frequently the first. In these cases a cyst forms in the bone, which becomes thin and expanded, resembling the ordinary fluid cystic tumour, but which, on examination, is found to contain the cutozoa. The treatment, as Stanley observes, must depend on the situation and extent of the disease; if it be a long bone that is affected, and it be much expanded, recourse must be had to amputation; if it be a flat bone, the cavity must be scooped out, and dressed from the bottom with stimulating applications, so that it may fill with healthy granulations.

CANCER.—*Malignant Osteoid, Osteo-cancer or Osteo-cephaloma*, are true malignant tumours of bone, constituting very serious but not very rare forms of cancer. Two distinct forms of cancer of bone are included in this disease. In one form the morbid growth is *central*, springing from the medullary canal, in the other it is *peripheral*, being attached to the compact osseous substance. Encephaloid of bone is harder and more fibrous-looking than the same affection elsewhere. The cancer-cell also is not so well marked, and minkow may be absent altogether.

In the *central* cancer of bone, the tumour is found to grow in the substance of, or to spring from, the interior of the medullary canal of the bone. It is usually situated at or about the articular ends, expanding the bone, which becomes completely enveloped and incorporated in the structure of the growth, either in the form of osseous rays diverging from the centre of the tumour, or more rarely as a thin shell of bone surrounding the mass, as in the more simple growths springing from this tissue. Under either circumstance it is important to bear in mind that this form of disease is never localised, but always invades the whole of the bone. The freedom of communication between the upper and lower ends of a long bone is so great, that, as has been shown by Richet, water injected at one end exudes in a few seconds at the other; hence the juices of a malignant structure might easily traverse the whole length of the bone, and we accordingly find, on examining the osseous tissue at a distance from the tumour, that there are red patches in it here and there indicative of its infiltration with the morbid structure.

In the *peripheral* form of cancer of bone, which is probably the most common variety, the osseous tissue is not so completely invaded; for, although the disease may be situated upon, or be in intimate contact with, the outer layers of the bone, which are incorporated in it, it does not extend into the cancellous tissue or the medullary canal. The tumour appears to spring from the periosteum; and, after removal and maceration, stalactitic projections and radiating fibres may be traced into it from the outer layers of the bone. In this form of osteo-cancer, the muscles that are attached to the affected portion of bone will often be found to be extensively infiltrated with cancer cells.

These tumours, whether central or peripheral, are chiefly of the encephaloid species of cancer, and are met with in all stages of development and of decay. Occasionally, some colloid, and more rarely melanotic matter is intermixed; but scirrhus, I believe, is never found in bone. They most frequently occur in the head of the tibia and the lower end of the thigh bone; occasionally in the humerus and in the jaws, more especially about the antrum. It is a remarkable fact, long ago pointed out by Petit, and more recently insisted on by Richet, and which I have often had occasion to verify, that although the epiphysis may have been completely converted into encephaloid matter, the cartilage of incrustation and of the neighbouring joint (Fig. 241) never becomes implicated; although the growth may eventually involve and include the whole of the rest of the articulation, by extension to the capsule and its soft parts. When internal organs become secondarily affected in these cases, the deposit will generally be found in the lungs.

Symptoms.—There is usually, with much lancinating pain, a rapidly growing enlargement of the bone, having a globular shape, feeling elastic, and sometimes semi-fluctuating. The skin covering it, at first pale, with numerous reticulated and blue tortuous veins, afterwards becomes discoloured, being eventually implicated in the morbid mass. In some cases fracture of

the bone takes place at the affected part (Fig. 242); the neighbouring tissues are speedily contaminated, the lymphatic glands become enlarged,

Fig. 242. Osteo-capsular of the Head of the Humerus, with Spinal Process Fracture of the Shaft in which I amputated successfully at the Shoulder joint.

Fig. 241.—Section of Osteo-capsular of Head of Humerus: Upper End and Head of Humerus destroyed, but cartilage of their station collected. Tumor divided by white vertical line—the Periosteum, inside which only were the Osseous Spicula found.

cancerous cachexy sets in, and the patient eventually sinks. In other cases, the disease being central, the progress, especially in the early stage of the disease, is less rapid, though it at last develops itself with fearful violence. So long as the disease is confined within the walls of the bone, it develops itself but slowly, and does not show much disposition to affect the constitution. Some years ago I had under my care a man whose thigh I amputated for cancer of the head of the tibia; the disease had existed for four years without contaminating the neighbouring parts. The patient's constitution appeared sound, and he made a good recovery. But when once the soft parts become engaged, the system is speedily contaminated. In some instances, pulsation of a thrilling kind, with or without a blowing murmur, is distinctly perceptible, especially in an advanced stage of the affection, when the vascularity of the tumour is greatly increased.

Diagnosis.—The diagnosis of osteo-cancer has to be made from other tumours of bone, and from aneurism. The malignant growths of bone may readily be confounded with those various forms of non-malignant disease that are commonly included under the term *spina ventosa*. In making the diagnosis, we may reasonably come to the conclusion that the growth is cancerous, if it occur in early life before puberty, or between this period and the early adult age; if it increase with great rapidity, and with much pain, especially of a lancinating character; if, to the touch, it present a somewhat diffused pulpiness, with much elasticity, great tension, and, at points, a semi-fluctuating feel; and more especially if the veins be greatly enlarged and tortuous, the neighbouring lymphatic glands involved, and if cachexy ultimately set in. These conditions, differing from the slow growth, the more circumscribed character, and more solid feel of the non-malignant

neighbouring structures, and which occur at later periods of life, usually enable us to make the diagnosis. There is one tumour, however, viz., *enchondroma*, which occasionally, in the rapidity of its growth, closely resembles malignant disease. Here the diagnosis is confessedly extremely difficult; though the more solid character, the less degree of elasticity, and the absence of lymphatic enlargement or implication of contiguous tissues, will often enable us to establish the true nature of a tumour before its removal.

The diagnosis of *aneurism* is necessarily unattended by any difficulty so long as its sac is pervious to fluid blood, and presents the characters that are met with in this condition. But if the sac have become consolidated by the deposit of stratified laminae, and thus have assumed the characters of a solid tumour, it may readily enough be mistaken for a tumour springing from the osseous structure, and amputation has occasionally been performed on this supposition. In these cases, however, the history of the progress of the disease will do more to elucidate its true nature than anything else, attention being more especially paid to the early symptoms of the tumour, when the aneurism was still filled with blood.

Treatment.—No means are of any avail in cases of osteo-cancer, except the removal of the diseased part by amputation or excision. These operations are, however, not very promising, as there are few forms of cancer in which the disease returns more rapidly in a secondary manner than in that of the bones. The rapidity of recurrence will, however, greatly depend upon the form of the disease, or the time when amputation is performed, and on the part where it is practised. Amputation should always, if possible, be performed in the earliest stage of the disease, before glandular or constitutional infection has set in. If the glands be enlarged, and cachexy have already occurred, little can be expected in the way of ultimate cure: yet I have known cases in which, even under these unfavourable circumstances, the patients have made a good recovery, life having been prolonged for months. I believe that return is much more speedy and certain after amputation in the peripheral than in the central form of osteo-cancer, provided that in the latter the whole of the bone has been removed; this is due to the more extensive contamination of the soft parts in the former than in the latter case.

The selection of the line at which amputation should be performed is of great importance, and the result will materially depend upon the judgment displayed in this. If the limb be removed in the continuity of the diseased bone, there must necessarily be a great probability of a very rapid return of the morbid action in the stump; and this probability amounts to a certainty in those cases in which the disease is central, and in which the whole of the medullary canal and cancellous structure are implicated, and infiltrated with cancer. In cases of peripheral osteo-cancer, this return in the same bone may not take place; indeed, I have seen one case of the kind in which the disease affected the lower end of the tibia, and that bone was amputated in its upper third; in this case, after a lapse of some months, fatal recurrence of the disease took place in the pelvic bones, but not in the stump. As, however, the peripheral is more rare than the central form of the disease, and as there are no means of ascertaining the precise kind before removal, the rule, I think, should be definite to amputate at or above the next joint—at the hip-joint, in cancer of the thigh-bone; in the thigh, for that of the bones of the leg, and at the shoulder, when the upper arm is affected. When the lower part of the thigh-bone, however, is involved, amputation through the trochanters may sometimes be substituted for disarticulation at the hip-joint, the latter operation being so formidable and so fatal that the surgeon

may think it advisable not to subject the patient to so serious a risk ; or the amputation might be performed through the trochanters, and then the head of the bone extirpated from the acetabulum. In this way the severity of the operation and the extent of incised surface would be lessened, whilst the whole of the diseased bone would be removed.

In the peripheral form of osteo-cancer, however, the muscles inserted into the affected bone often become speedily contaminated by the disease, and this contamination may spread widely through the substance of any particular muscle. Hence I think the rule in these cases should be to amputate not only above the diseased bone, but, if practicable, above the origins of the muscles in the neighbourhood of the disease. Thus, if there be a malignant tumour of the bones of the forearm, amputation should be done not only above the elbow-joint, but above the humeral attachments of the muscles of the forearm.

The propriety of *excision* of some bones, as of those of the face, in this disease, must depend on whether the morbid deposit is limited to the structures that can be excised. This operation can rarely be advantageously practised in malignant tumours, there being in general too great an implication of the soft structures in the neighbourhood to justify it.

SANGUINEOUS TUMOURS are occasionally met with in bones. According to Stanley, they appear under two forms :—1. As tumours composed of a vascular substance, having the general characters of erectile tissue, and bearing on section a close resemblance to certain naevi (Fig. 243) ; tumours of this

Fig. 243.—Aneurism by Anastomosis of one of the Parietal Bones.

kind may be removed without the liability to reproduction: 2. As cysts formed in the cancellous structure of a bone, and containing either fluid or coagulated blood. According to Stanley, these tumours expand the osseous walls, and will gradually cause ulceration of the skin and profuse hemorrhage.

The *Treatment* consists in the amputation of the limb, or the excision of the affected bone, as was successfully done by Travers, who removed a clavicle that was the seat of this disease.

OSTEO-ANEURISM.—Pulsating tumours of bone, or osteo-aneurisms, though of unfrequent occurrence, are of considerable importance to the practical surgeon, on account of the difficulty that often exists in establishing a diagnosis between them and ordinary aneurisms. It is only of late years that this kind of disease has been fully recognised ; and it is principally to the labours of Handyside, Nélaton, Stanley, and Roux that we owe an acquaintance with its characters.

Characters.—Tumours springing from bone, whether of a cartilaginous, fibrous, or cystic character, may have pulsation communicated to them from a neighbouring artery ; but the true pulsating tumours of bone owe their pulsations to some inherent peculiarity of structure, which appears to consist either in the development of a vascular tissue of abnormal character, or else

in the simple enlargement and dilatation of the vessels of the bone. In the first and most frequent class of cases, those in which a new tissue is developed in the osseous structure, we usually find the tumour to partake of an encephaloid character; a creamy, curdy or brain-like, soft, and very vascular mass is formed as an essential and principal constituent of it. This might consequently with propriety be termed an *encephalo-osteo-aneurism*. This abnormal mass will be found to present every shade of transition from true encephaloid cancer to a purely vascular tissue of an erectile character. In the second and more rare form of the disease, there is developed in the bone a structure, which originally, and in many cases throughout, is a *vascular erectile growth*, closely resembling capillary naevus in its structure, composed of an infinity of bloodvessels, interlacing in every possible way, so as to form a soft reddish-yellow tumour. In a third form, a hollow cavity is formed in the bone, scooped out of the cancellous structure and filled with blood, partly liquid and partly coagulated, and having arterial branches freely opening into it. The shell of bone surrounding this cavity is very thin and expanded, being usually absorbed at one point, where it often becomes at last perforated. This constitutes the *true aneurism of bone*.

Situation.—These various kinds of pulsatory tumour of bone have been met with in almost all parts of the body; most commonly the cancellous articular ends of the long bones, more particularly of the tibia, the radius, the humerus, and the femur, have been found affected. The pelvic bones are also not unfrequently the seats of these growths; and they have been encountered in the skull and in the ribs.

Symptoms.—In its early symptoms an osteo-aneurism closely resembles the ordinary forms of spina ventosa, being oval in shape, uniform, and elastic to the touch, growing slowly, without enlargement of the veins or discoloration of the skin; these characters it possesses in common with most other tumours of bone. The special signs by which it is individualised, however, are its pulsation and bruit: the pulsation is very distinct, superficial, and commonly of a thrilling character; in other cases it is directly impulsive, and distinctly expansive; the bruit is most usually soft and blowing, but not unfrequently harsh, loud, and whizzing. In some cases the bruit is absent, though the pulsation continue distinct, this, according to Nélaton, is most frequently the case in true osteo-aneurism. In the pulsating encephaloid form of the disease, I have heard the bruit peculiarly loud, rough, and superficial. On compressing the main artery leading to the part of the limb in which the tumour is situated, all movement and bruit commonly cease in it, and it lessens in size. By pressing upon the tumour when it is thus diminished, it will commonly be found to have a bony margin, with a central depression, more especially in those cases in which there is no encephaloid entering into its composition, the growth being apparently composed of erectile and expanded osseous tissue, filled with fluid blood. In some cases, however, the tumour is fed by several arterial branches, which may be felt distinctly pulsating under the skin. This is more particularly the case when it occurs upon the bones of the pelvis and the scapula, and then the bruit and pulsation cannot be made to cease in it. All these signs are commonly somewhat intermittent, appearing perhaps in the earlier stages of the disease, and disappearing as it advances; or the reverse may occur, the pulsation and bruit becoming distinct as the disease increases in size, and meets with more resistance in its outward growth.

Prognosis.—It is of considerable importance in many cases to diagnose the different forms of pulsating tumour of bone from one another; some being of a truly cancerous character, whilst others appear to consist of simple

expansion of the vascular element of the bone, with atrophy of its osseous substance; and consequently the prognosis also in the two conditions is very different. The true osteo-aneurism has so many signs in common with the *pulsating encephaloid tumour* of bone, that in many cases it is almost impossible to effect the diagnosis; yet it is well to bear in mind that the malignant form of the disease is not unfrequently multiple, occurring, with pulsation and bruit, in more situations than one: thus I have seen growths of this kind, with their signs well marked, springing both from the pelvis and from the ribs. The true osteo-aneurism is only met with in the articular ends of long bones; whereas the malignant disease, though commonly occurring in these situations, is also frequently found in other parts of the body. Besides these, there are two conditions which, in many cases, will enable the surgeon to determine that the pulsating tumour is an osseous aneurism: viz., the absence of all bruit, though the pulsation be distinct, and the detection by firm pressure, after the tumour has been diminished by compressing the artery leading to it, of an osseous margin around its depressed centre.

From *ordinary aneurism* the diagnosis of osteo-aneurism is, in many cases, attended by almost insuperable difficulties. So great are these, that there are many cases on record in which the most experienced surgeons of the day have ligatured arteries for tumours that were supposed to be aneurismal, but which have turned out to be pulsating growths connected with bone. A principal point to be attended to in effecting the diagnosis is the situation of the tumour, which may occur away from the ordinary sites of aneurism, in parts of the body where there is no vessel large enough to give rise to such a disease—as, for instance, about the head of the fibula or the side of the pelvis. Then, again, its incorporation with the subjacent bone, the want of a distinctly limited and circumscribed outline, and the existence in many cases of plates of bone in the wall of the tumour—giving rise perhaps, on pressure, to the peculiar rustling or crackling sound characteristic of expansive bony growths—will enable the surgeon to come to a conclusion as to the true nature of the tumour. In this he will be further assisted by its giving on compression a soft, doughy, or spongy feel, or appearing as a depression surrounded by an osseous margin. In many cases, also, the less impulsive character of the beat of the tumour, the peculiar shrill and tremulous whiz in the pulsation and bruit, will throw much light on the nature of the disease. But it cannot be doubted that, when tumours of this kind occur in some of the ordinary situations of aneurism, as about the brim of the pelvis, and in the popliteal space, the diagnosis is surrounded with difficulties which no amount of surgical skill or tact may be able to overcome.

From *ordinary tumours of bone*, the existence of pulsation and bruit will always suffice to distinguish the growths under consideration.

Treatment.—Incision into a pulsating tumour of bone, or any attempt to remove it without its osseous connections, is clearly contrary to the rules of good surgery; and when it has been practised, the hemorrhage has been of the most alarming and dangerous character. *Resection* has been had recourse to in some instances, as when the disease has been seated on the cranial bones, but without success. Liston, in a tumour of this kind growing from the scapula, which he called “an ossified aneurismal tumour of the sub-scapular artery,” excised the greater portion of the bone from which it sprang; but fungous growths reappeared in the wound, by which the patient was at last exhausted. When the disease has proceeded to such an extent as to produce extensive alteration in, and destruction of, the tissue of the bone affected, *amputation* of the limb is the only resource left to the surgeon. This operation is also called for in those cases in which the disease returns

After other means, such as the *ligature of the artery*, have been practised. In these cases, if the disease partake at all of the encephaloid character, the limb must be removed at a point above the affected bone.

The result of *ligature of the main artery* leading to the tumour depends greatly upon the nature of the growth. When it is partly composed of encephaloid or other solid tissue, but little good can result from this proceeding—the tumour continuing to increase by an inherent growth, which will continue as long as the vitality of the limb is maintained; and we accordingly find that, in all such cases in which this operation has been practised, the progress of the tumour has either not been retarded, or, if the pulsations have been stopped, and its size lessened for a time, the activity of the symptoms has speedily returned, and amputation has been rendered necessary. When, however, the tumour has partaken more of the characters of true *arterio-aneurism*, then a more favourable result has followed the *ligature of the main artery of the limb*. In a case of this kind seated in the radius, in which Roux ligatured the brachial artery, a complete cure resulted. The same also occurred to Lallemand; and in a patient of Dupuytren's, there was no return of the disease for six years, when it recurred, and amputation became necessary. These results are sufficiently satisfactory to justify the surgeon in having recourse to the *ligature*, or perhaps the *compression*, of the main artery of the limb, in those cases in which the tumour could be ascertained not to partake of the nature of encephaloid.

CHAPTER XLVIII.

DISEASES OF JOINTS.

THE various joints of the body may become the seat of *Inflammatory Affections* of an acute or chronic character; of *Strumous Disease*; or of various other morbid conditions, such as more or less permanent rigidity, or *Anchylösis*, the formation of *Foreign Bodies* within their cavities, or their *Malignant Degeneration*, and *Neuralgia*. In studying these various articular affections, it must be borne in mind that a joint is composed of a number of different tissues; of *synovial membrane*, *cartilage*, *ligament*, *bone*, and *capsule*, or investing fibrous expansion. In any one of these structures the disease may primarily begin, though eventually the morbid action often spreads to other tissues besides that which was originally involved. The merit of having been the first to point out the true mode of studying these affections in reference to the different structures in which they have originated, and to have set aside that coarse pathology which, under the general terms of "*arthritis*" and of "*white swelling*," confounded together these various diseases, is certainly due to Sir B. Brodie.

SYNOVITIS.

Inflammation of the Synovial Membrane, the most common perhaps of all the articular affections, may be acute, subacute, or chronic.

Cases.—Whatever form it assumes, *synovitis* usually results from exposure to cold, especially in rheumatic or syphilitic constitutions. In these cases it commonly happens that more joints than one are implicated at the same time; and the affected articulations are most frequently those that are most exposed by having the thinnest covering of soft parts, and by being

especially subjected to transitions of temperature, such as the knees and ankles. Injuries of joints, as blows, bruises, wounds, or sprains, will also frequently occasion this inflammation; but when arising from such causes, it is usually associated with inflammation of the other textures of the articulation.

PATHOLOGY.—As uncomplicated acute synovitis is never fatal, we seldom have an opportunity of studying its pathology. It would however appear, from the examination of joints in cases of synovitis from injury, as well as from the experiments of Richet, Bonnet, and others, who have induced traumatic synovitis in animals, that there is in the first instance an inflammatory congestion and vascularity of the membrane, with loss of its peculiar satiny polish. The synovia is then increased in quantity, and becomes thin and serous, and after a time intermixed with plastic matters which are poured out with it. If the disease progress favourably, these products are more or less completely absorbed. In more rare cases, the vascularity and swelling of the synovial membrane increase, until at last it becomes so turgid and distended with blood and effused fluids, that a kind of chemosis of it results; a thin, purulent-looking fluid, composed of granular corpuscles floating in a serous liquid, is poured out, and disintegration, with thinning and erosion of the cartilage, and probably complete destruction of the joint, ensues. In other cases, granulations are thrown out on the looser portions of the membrane, and, becoming injected with bloodvessels, constitute fringed and villous membranous expansions, lying upon the subjacent disintegrated and eroded cartilage.

SYMPTOMS.—*Acute Synovitis.*—The symptoms of synovitis consist of pain and heat of the joint, with distension and fluctuation of it. If it be large and exposed, the pain is severe, especially at night, being greatly increased by moving or pressing upon the articulation; it is usually sharp but, when the disease occurs in rheumatic or gouty constitutions, of a gnawing character. In purulent synovitis from pyæmia, it is usually very superficial, indeed almost cutaneous. On laying the hand on the joint, this will be felt to be hot.

The swelling of the affected joint is considerable, and evidently depends on accumulation of fluid within the synovial sac, the extreme outline of which is rendered apparent by the tension to which it is subjected. Thus in the knee it rises up high in the thigh under the tendon of the quadriceps extensor, to the extent of three or four inches above the upper border of the patella, and in the elbow under that of the triceps. There is but little if any effusion into the surrounding tissues; and hence the outline of the joint can be distinctly felt, and undulation perceived in it. The limb is usually semiflexed, as giving the patient most ease, and the joint cannot be moved. The constitutional febrile disturbance is tolerably severe, especially if the affection occur in a rheumatic constitution.

Chronic Synovitis.—The disease, at first acute, may terminate in a subacute or chronic form; or, subacute at its commencement, it may fall into a chronic condition. Chronic synovitis is characterised by all the symptoms of the acute variety of the disease, but in a less severe degree. The swelling and weakness of the joint are the most conspicuous local conditions. In some cases, the swelling from accumulated serous fluid is so considerable as to constitute a true dropsy of the joint—*Hydrarthrosis*. This accumulation of fluid, partaking in various degrees of the characters of serum and synovia, is usually preceded or accompanied by evidence of synovial inflammation; but, though this generally happens, it is not invariably the case. Richet, in particular, has recorded instances from which it would appear that inflammation is not a necessary or invariable accompaniment of the affection, the synovial membrane being indeed preternaturally white, and looking as

If it had been washed or soddened; and though these cases are rare, those that commonly present themselves to the surgeon being of a decidedly inflammatory character, yet their occasional occurrence is sufficient to establish the existence of a passive, as well as of an inflammatory form of the disease.

The presence of an abnormal quantity of fluid in the joint is always easily perceived by its *fluctuation* and *undulation*, and by the *peculiar steps* that it communicates to the part. Thus in the knee, which is the most common seat of this affection, the patella will be felt to float, as it were, on the subjacent liquid; and the capsule of the joint projects distinctly in three situations, viz., on each side of the ligamentum patellæ, and above that bone. In the elbow, there is a soft and fluctuating swelling on each side of the olecranon, and under the tendon of the triceps; and in the shoulder there is a general roundness and distension of the articulation. It is said that, in some cases, the distension of the joint has been so great that the synovial membrane has been ruptured, and the fluid poured forth into the surrounding cellular tissue. In these cases, however, it is probable that some destructive change in the synovial membrane preceded its rupture.

In some cases of chronic synovitis distinct *crackling* will be felt in the interior of the joint, on laying the hand over the articulation whilst it is freely moved. This appears to me to be due to the existence of plastic bands or deposits in the interior of the joint, through which the fluid is pressed by the articular movements, and thus occasions the sensation which is met with under other but similar circumstances in enlargements of the tumour, and in fluid effusions in the sheaths of tendons.

TERMINATIONS.—The termination of synovitis will depend mainly on its cause. When of a simple uncomplicated character, arising as the result, perhaps, of rheumatic influences, it will in most cases terminate in complete resolution. In other instances, however, plastic matter may be thrown out, which either assumes the form of warty vegetations or concretions within the joint, or of bands stretching across its interior or incorporated with its capsule, occasioning more or less permanent stiffness. When synovitis arises from wound, it usually goes on to suppuration within the joint, with superficial erosion or disintegration of the cartilage, and eventually, if the limb be not removed, to complete disorganisation of the interior of the articulation, and to more or less complete ankylosis. The same happens in the puerperal and pyæmic inflammations of joints; in which cases the morbid action commencing on the synovial membrane extends downwards to the cartilages, eventually destroying them.

The chronic or subacute synovitis and hydrarthrosis usually terminate favourably; but occasionally, more particularly in strumous constitutions, the disease runs on to suppurative destruction of the joint. This, however, is rare; yet its occurrence, in some instances, should make the surgeon careful not to confound the fluctuation of serous accumulation with that of purulent collection. In the latter instances the symptoms of inflammation will always have preceded.

TREATMENT.—The treatment of synovitis depends partly on the severity of the symptoms, and partly on the cause of the disease. If the inflammation be acute and arise from injury, it requires to be actively treated by venesection, if the patient be young and strong; but in all instances by the free and repeated application of leeches to the inflamed articulation, followed by fomentations and accompanied by perfect rest of the part on a splint, or on pillows properly arranged. In some instances, cold irrigation will be found to be of essential service. At the same time, saline purgatives with antimony must be given, and the patient kept on a low diet.

If the disease be of a *rheumatic* character, leeches must be applied, followed by hot fomentations, and rest of the part in the elevated position; at the same time colchicum, with salines, if there be much febrile disturbance, and in combination with Dover's powder, if there be much pain at night, should be administered. In some instances, where colchicum disagrees, great benefit will result from the administration of Dover's powder and calomel, in small but frequent doses. When the disease is of *syphilitic* origin, leeches are not often required; but the application of blisters, followed by calomel and opium, will be attended with marked success.

When the synovitis is *subacute* or *chronic*, the same principles of treatment must be adopted, modified according to the intensity of the affection. In these forms of the disease, rest is perhaps the most important element in the treatment, everything else proving nugatory unless this be attended to; the limb is usually best fixed by leather splints, buckled on so that they may be removed in order to make the necessary applications to it. In these cases, repeated blisterings over the whole of the joint constitute perhaps the most useful local means that we possess; in a more advanced stage, counter-irritation by means of stimulating embrocations, together with douches, either of warm sea-water or of some of the sulphureous springs, such as those of Harrowgate, Aix, or Barèges, will prove most useful; and when all inflammatory action has been subdued, and weakness of the joint merely is left, the joint should be properly strapped with soap-plaster, spread upon leather. Amongst the internal remedies likely to be of most service, may be mentioned the iodide of potassium, either alone, or in some bitter infusion.

In *hydrarthrosis*, rest and repeated blistering will usually promote the removal of the fluid. In addition to this, the employment of pressure and friction, with absorbent remedies, as the iodine or mercurial ointment, conjoined with the internal administration of the iodide of potassium or a mild mercurial course, will often procure the absorption of the fluid. If these means fail, we have a very powerful method of cure at our command in the injection of the joint with tincture of iodine. This plan, a sufficiently bold one, has been much employed by Jobert, Velpeau, and Bonnet. These surgeons use the tincture diluted with two or three parts of water. A small trochar is introduced into the joint, a moderate quantity of the serous fluid is let out, but not all, and then a corresponding quantity of the iodine solution is thrown in; and after being left for a few minutes, is allowed to escape. Inflammation of the joint, which is a necessary result of this procedure, comes on. This is then treated by ordinary antiphlogistic means, and, according to the statements of the French surgeons, has in no case been followed by any serious consequences, but in several instances by a complete cure without ankylosis; a new and healthy action having been imprinted on the synovial membrane. This mode of treatment does not appear as yet to have met with much support in this country; yet it certainly deserves a trial, though recourse should not lightly be had to it, as it is evident that the induced inflammation might exceed the expected limits. In one case of hydrarthrosis of the knee, in an old man, in which I employed it, about six ounces of thin synovia were drawn off, and a drachm of strong tincture of iodine was injected into the joint. But slight inflammation ensued; and the disease, which was of two years' standing, was completely cured. The chief points that appear to require attention are that no inflammation be going on at the time, there being no tenderness or pain in moving the joint, the effusion being quite passive, and of a very chronic character; and, above all, that no air be allowed to enter with the injected fluid. After dropsy of the joint has been removed, the articulation is usually

left weak for some length of time, in consequence of the stretching to which its ligaments have been subjected : here cold douches and an elastic bandage will constitute the best mode of treatment.

ARTHRITIS.

SIMPLE ACUTE AND CHRONIC ARTHRITIS.—By *Arthritis*, in its simple form, is meant inflammatory disease of an acute or chronic kind of the whole or greater part of the structures that enter into the formation of a joint. This affection may commence in the *synovial membranes*, and then spread to the other articular tissues ; or it may begin in the *cartilages* or *bones*.

Diseased action is very seldom primarily set up in the *ligaments* of the joint ; though these structures commonly become elongated, softened, and destroyed, as a consequence of other forms of articular disease. But, though primary inflammation of the ligaments is so rare an affection as to have been denied by many, yet it certainly does occasionally occur. This is especially seen in the hip-joint, where the inflammatory affection may commence in the round ligament ; illustrative of which there is a very beautiful model in the University College Museum.

Inflammation may commence in the *fibrous capsule* of the joint : this we find more particularly to be the case when the affection is of a rheumatic character ; in these cases inflammation, running into suppuration and slough of this structure, will commonly spread to the internal parts. In some instances, this form of disease gives rise to the deposition of masses and layers of bone in the cellular structures outside the articulation.

Causes.—In some instances, *acute necrosis* of the *shaft* of one of the long bones, as of the tibia, will run on to destructive action in the terminal articulations, the cartilages becoming undermined, softened, and perforated. It not unfrequently happens that the arthritic disease is the result of a *morbid condition* of the *articular ends* of the long bones, or of those short bones that enter into the formation of the joint ; this we especially see in diseases of the foot, of the elbow, of the knee, and hip ; but it is a condition which, I believe, may occur in any joint. The bones usually become, in the first instance, the seat of tuberculous infiltration ; this runs into unhealthy suppuration, which gives rise to caries and limited necrosis (Fig. 244 *a*) ; as the diseased action approaches the articular surface, the incrusting cartilage becomes loosened and detached, and at the same time gradually disintegrates, and becomes perforated (Fig. 244 *b*), nutrition in it being arrested or modified by the morbid state of the subjacent bone. When once the cartilage becomes affected, the whole of the interior of the joint speedily suppurates, and is destroyed. In other cases, inflammatory congestion, but without the formation of tuberculous matter, takes place in the articular ends, which become somewhat expanded ; and then, without any suppuration occurring in the osseous structure, the cartilage gradually separates or peels off, and becomes softened and necrosed. This condition is often met with in disease of the tarsal articulations.

Fig 244.—Chisel of Head of Tibia Perforation of Cartilage.

Arthritis commonly results from *wounds of joints, or injuries*, such as sprains and fractures occurring in their vicinity, more particularly in young people, and in those of a lymphatic constitution. It also occurs as a not unfrequent accompaniment of *pyæmia* (pp 463, 464), and of some of the morbid conditions of the *puerperal state*. The puerperal inflammation of joints is of a very destructive character, most generally speedily terminating in suppurative disorganisation. One or several joints may be affected, and the knee is the one that I have seen most frequently and seriously involved. Puerperal arthritis probably depends upon a purulent infection of the blood, the result of uterine phlebitis. Arthritis not unfrequently occurs as a consequence of *scarlatina*; and I have especially seen the knee-joint affected in a destructive manner after this disease. In some forms of *albuminuria* there is also a great tendency to inflammation of the joints; and, indeed, I have so frequently seen that form of renal dropsy which follows scarlet fever accompanied by serious inflammation of some joint, as almost to look upon one condition as the sequence of the other.

Symptoms.—The symptoms of arthritis that are most marked are the pain, heat, swelling, and peculiar position of the joint. The pain is often severe, tense, and throbbing: so acute is it sometimes, that the patient screams with agony; he cannot bear the bed to be touched, the room to be shaken, or the slightest movement communicated to the limb, any attempt at examination of the joint in such cases being attended with insupportable agony. There are usually nocturnal exacerbations, and the pain is commonly referred with especial severity to one particular spot in the joint; thus it is generally felt at the inner or under side of the knee-joint, and at the outer aspect of the hip. The heat of the diseased joint is considerable, and is often accompanied with more or less superficial redness. The swelling is uniform, involving the whole of the articulation, and not projecting at certain parts of it, as when the synovial membrane alone is affected; it is generally not very considerable, and has a soft and doughy, rather than a fluctuating feel. As the disease advances, however, the swelling generally increases suddenly, and to a considerable extent, either in consequence of the irritation of the synovial membrane, or of the accumulation of pus within or around the joint. In many cases the synovial membrane gives way, and the pus from the interior of the joint becomes widely diffused through the muscular interspaces of the limb, forming enormous abscesses and long sinuous tracts. The position of the affected limb is peculiar, and that attitude is insensibly adopted in which the patient will have the greatest amount of ease; thus the knee is semi-flexed and turned outwards, the thigh is adducted, and the elbow is bent. *Spasms or startings* of the limb, often of a very sharp and painful character, come on at times, more particularly at night. The constitutional disturbance is very severe, and of an actively febrile type.

As the disease progresses, *suppuration* takes place within the joint, which becomes hot and red, with a good deal of throbbing pain, and at last fluctuation is perceived where the coverings are thinned. In some cases the suppuration occurs with very great rapidity, and luxation of the head of the bone takes place. In other cases an abscess forms externally to the articulation, and extensive purulent collections become diffused through the limb. As the joint becomes loosened by the destruction of its ligaments, the bones become mobile, and grate against one another where the incrusting cartilage has been removed, thus giving rise to very severe suffering. The cartilages may, however, in some cases be very extensively destroyed, and yet no grating takes place; this is owing either to the destructive action being limited to the edge of the incrusting cartilage, the opposed surfaces being sound, or else

the interior of the articulation being filled up with plastic matter after the removal of the cartilages. But though abscesses, either within the joint or external to it, usually forms when the bones grate and the cartilage disintegrates, yet it occasionally happens that these conditions take place—these symptoms that are indicative of the erosion of the cartilage, such as painful startings of the limb, grating, and preternatural mobility of the joint—and yet no abscess forms; all the symptoms subsiding under proper treatment, and the joint recovering, though perhaps with a certain degree of ankylosis. If suppuration take place, the constitutional disturbance usually partakes of the irritative type, the patient suffering severe pain, and being worn out by want of rest. Hætic may occur, and death from exhaustion and irritation, unless the diseased part be removed; in other cases it falls into a state of chronic thickening, perhaps with fistulous openings leading down to the diseased structures; and in some of the more favourable instances the patient may recover, with a permanently rigid joint.

Diagnosis.—Abscess may form externally to, but close upon, the capsule of a joint, and closely simulate disease of the articulation. In these cases the absence of serious constitutional disturbance, the irregularity of the swelling, greater on one side than the other, its extension over bony points, as the patella or olecranon, the superficial character of the fluctuation, the absence of all rigidity about the joint, and of other severe local symptoms, such as pain, starting, looseness, or grating, will enable the surgeon to effect a correct diagnosis.

Pathology.—In arthritis, the principal changes are undoubtedly found to take place in the cartilages; at the same time, it must not be supposed that all morbid appearances that are found in these structures are the result of inflammation, as erosion and absorption of their tissue may take place independently of any diseased action. The long-continued disuse of a joint, as in the treatment of fractures, may occasion this; and in old people it is very common to meet with a porcellaneous or ivory-like deposit on the articular ends of the bones, which, however, does not prevent the joints from being used, though it may occasion stiffness and pain in them. According to Quakett, this porcellaneous deposit is of two kinds, one consisting of unorganised earthy matter, the other of true bone having the Haversian canals filled with phosphate of lime.

In acute arthritis, the cartilages are usually found ulcerated and eroded in patches of varying size, exposing bone, which is rough and vascular. The remains of the cartilage are softened, inelastic, opaque, and thickened, and separate easily from the subjacent bone, which can be felt rough and grating. The synovial membrane is usually much thickened and very vascular; the vascularity being most distinct about those parts where the erosions and grooves in the cartilage are deepest, and often assuming a dentated or fringed appearance. In other parts, especially

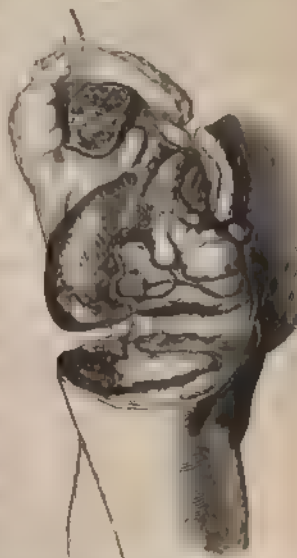

Fig 345.—Interior of Knee Unorganised by Inflammation.

about the circumference of the joint, masses of plastic matter are deposited underneath and upon the syno-

vial membrane ; these are smooth and semi-transparent, having a somewhat fatty look ; the ligaments are relaxed, vascular, and softened, and the interior of the joint is filled with thin, flaky, and light-coloured pus. The capsule and the cellular tissue around are thickened, and either infiltrated with pus or clogged with the same kind of plastic matter that is seen in the interior of the joint. The articular end of the bone is enlarged, soft, and vascular ; and in strumous cases may be the seat of tuberculous infiltration (Fig. 245).

Nature of the Changes in Cartilage.—The changes that take place in the cartilage in this disease have excited much attention amongst surgeons, and a good deal of difference of opinion exists as to the mode in which they are induced. Many surgeons hold the doctrine that, cartilage being extra-vascular, the changes that take place in it are accomplished through the medium of the contiguous synovial membrane or bone, and consequently are secondary to disease of these tissues. We may, I think, conclude that this disease of cartilage may arise in three ways: 1, through the medium of the Synovial Membrane; 2, through the medium of the subjacent Bone; and, 3, by means of changes taking place in the Cartilage itself.

1. The destruction of cartilage, as the result of *Synovial Disease*, may best be studied in cases of wound of a joint. In these cases it will be found, if the joint be examined before complete disorganisation of it has occurred, that the diseased action spreads from the synovial membrane, where it is most intense, downwards into the substance of the cartilage, which, superficially diseased, appears more healthy the deeper the examination of it is carried. Immediately under the swollen, gelatinous-looking, brightly injected synovial membrane, the cartilage will be found to be reddened, roughened, and softened. On examining a thin slice of this, it will be found to be composed of granular matter and nuclei of cells whose walls have disappeared. At a little greater depth than this it will present an opaque matrix, with cells, some perfect, others imperfect or disintegrating ; and below this level we come to healthy white cartilage, with clear matrix, and well formed cells.

The disorganisation of the cartilage will eventually go on to its complete removal, and to the exposure of bare and roughened bone. It is in this way that destruction of joints, as the result of punctured wounds, pyæmia, or puerperal inflammation, results.

Aston Key advocated the doctrine that a peculiar disease was set up in the synovial membrane, so as to form a fimbriated or fringed vascular network or tissue, by means of which the cartilage was absorbed ; and that, as this membrane extended, so did the removal of the cartilage go on. That an appearance of this kind in inflamed joints is of common occurrence is doubtless the case ; but Goodsir has shown that Key erred in attributing the disintegration of the cartilage to this membrane ; for he states that a fibrous tissue forms in a diseased joint as the result of the disintegration of the cartilage, and that this, which is connected with either the synovial or the osseous surfaces, speedily becomes vascular. So far, therefore, from being the organ by which the cartilage is removed, it is the result of prior disease in this structure. At the same time it cannot, I think, be doubted that a villous injected state of the synovial membrane will modify the nutrition of the subjacent cartilage in such a way that disintegration, erosion, and apparent ulceration of it, will ensue.

2. Disease of cartilage primarily dependent on *Morbid Action in the Subjacent Bone* is, I believe, one of the most frequent modes of disorganisation of joints in strumous subjects, and most certainly leads to those

rapidly destructive affections of joints, in which amputation or excision is required. In these cases, either as the result of violence, or from constitutional causes, the articular ends of a bone, or the whole of a bone if it be one of the tarsal, becomes congested, inflamed, carious, or necrosed, sometimes infiltrated with tubercle. In consequence of this disorganisation of the osseous tissues, the incrusting cartilage becomes detached, its under or attached surface softened, and at last perforation takes place, as in a preceding cut (Fig. 244 b, p. 739), taken from the tibia of a boy whose limb I amputated for acute disorganisation of the knee-joint, following carious disease of the head of the tibia. This process of disintegration, and at last perforation and erosion of the cartilage, takes place in a direction from below upwards. So soon as perforation occurs, the whole of the interior of the joint becomes acutely inflamed, and suppuration is set up in it, the ligaments loosen, and complete disorganisation ensues (Fig. 244). On examining the diseased patch of cartilage in cases of this kind, it will be found to correspond to the carious or tuberculous bone, from which it is separated by some bloody fluid; it will also be seen that the under edges of the erosion or perforation in the cartilage are separated to some extent from the subjacent bone, from which they readily peel off, and that they are bevelled off towards the aperture.

3. That cartilage is susceptible of *Primary Change of the Nature of Inflammation or Ulceration*, induced by the action of its own vessels, is the opinion of Brodie, Mayo, and Liston, all of whom have observed true vascularisation of cartilage. This condition, however, is extremely rare, and is certainly not one of the more common forms of joint-disease, seldom occurring except in the more chronic stages of arthritis.

These, however, are not the sole changes that take place in the cartilage in arthritis; the observations of Goodsir, of Rainey, and of Redfern, all point to the fact that cartilage, like other extravascular tissues, is subject to other transformations, independent of the prolongation of vessels into it. The changes that ensue are, according to Redfern, of the following kind. The cartilage-cells enlarge, become rounded, and granular-looking; and, instead of their containing two or three nuclei, a considerable number are enclosed in the cell-wall, eventually these corpuscles break up, and are disintegrated. The matrix of the cartilage now softens, and, according to Redfern, splits up into fibres or bands which become nucleated. A species of fatty degeneration also, as pointed out by Rainey, takes place, and helps to soften and break down the structure of the cartilage. In the more advanced stages of disease of cartilage, masses of porcellaneous deposit are found attached to the ends of the bones in plates and layers, taking the place of the eroded cartilage.

In other cases, a soft, pulpy, and vascular fibro-plastic deposit of a greyish, sahy, or reddish brown colour, with whitish streaks of a firmer material running through it in various directions, takes the place of the cartilage that has been removed, or that has undergone fibro-cellular degeneration. On examination under the microscope, this will be found to be composed of plastic material, with cartilage-corpuscles intermixed, and with the subjacent bone in a state of disintegration and softening. This condition of joints I believe to be analogous to the "pulpy degeneration of the synovial membrane" of Brodie. It would appear, from the microscopical examinations that I have in various cases made of this material, to which my attention was first directed by Dr. Quain, as occurring in a patient of his whose elbow-joint I excised, that it is either fibro-cellular degeneration of the cartilage, or an imperfect attempt at repair set up in the articulation, after the

removal of the cartilage by previous disintegration and disease. On making a vertical section of the surface of the diseased articulation in the case alluded to, it was found that the pulpy and villous substance covered the bone to the thickness of a line and more in some parts. The bone was found to have its cells filled with oil-globules, but surrounded by tolerably healthy osseous tissue, showing the usual laminae and bone-corpuscles. Nearer the diseased surface the laminae and corpuscles became less distinct; and, still nearer, the cells of the bony tissue appeared to be surrounded merely by a layer of fibrous texture, in which irregular particles of bone were observed. These particles, which were elongated, irregular in form, and rounded off at the angles, were very aptly compared, by Dr. Quain, to crystals in a state of solution. At the diseased surface, the place of the cartilage and synovial membrane was occupied by a fibrous texture abounding in cells, larger than pus-cells, nucleated and spherical, containing numerous granular particles. Irregular masses of cartilage, undergoing the same process of softening as the bony particles already mentioned, appeared in this fibrous texture. The morbid appearances found in this case were so characteristic that they may be taken as the type of this peculiar morbid condition, which I have since repeatedly met with in other articulations besides the elbow, more particularly those of the fingers and the knee, and which always, I believe, constitutes an incurable form of disease. I have met with this condition in instances only in which the articular affection has been of very old standing, and has fallen into a truly chronic state.

Repair.—When repair takes place in a joint, the cartilages of which have been eroded or destroyed, it is by the articular ends of the bones becoming connected, and the surface from which the cartilage has been removed filled up by fibro-cellular tissue, forming a kind of cicatricial material that leaves the joint permanently stiffened. In other cases, porcellaneous deposit takes the place of the eroded cartilage; and, in some instances, the exposed osseous surfaces may grow or become soldered together, forming a permanently ankylosed and immovable state of the articulation. Under no circumstances does cartilage, when once destroyed, become regenerated.

Treatment.—In the treatment of *acute* arthritis, perfect rest of the articulation is of the first moment. Unless this be secured, no after-treatment can be of any avail. The limb should be comfortably supported on pillows, or laid upon a well-made and softly padded leather-splint; at the same time blood should be freely taken away by cupping or leeching the affected part, and this local depletion must be followed by assiduous fomentations. In the acute stage of the disease, the internal remedy from which the most essential service may be derived is the calomel and opium pill (gr. $\frac{1}{2}$ and gr. $\frac{1}{4}$) every fourth or sixth hour, at the same time that a strict antiphlogistic regimen is persevered in. After the violence of the symptoms has been subdued, and the disease has assumed a *chronic subacute* form, the joint may be repeatedly blistered; but in many instances most benefit will be derived by the application of the actual cautery. This agent, when properly applied, yields much more certain and successful results than any other form of counter-irritation with which I am acquainted. The patient having been anaesthetised, a cauterising iron heated to a black-red heat should be rapidly drawn over the diseased articulation in a series of parallel lines, across which an equal number of cross-bars are again drawn, so as to char, but not destroy, the true skin. A good deal of inflammatory action is thus set up, followed by slight suppuration. When this has subsided,

the application of the hot iron may, if necessary, be repeated; in this way the deep gnawing pain will usually be readily removed, and suppuration of the joint may be averted. For counter-irritants to be of any use, they must be employed before suppuration has set in; I believe that it is only torturing the patient unnecessarily to have recourse to these agents when once pus has formed in the articulation. In order that full benefit should be derived from this plan of treatment, it must be persevered in steadily for a considerable length of time, and should be conjoined with a moderately antiphlogistic and alterative treatment. With this view, the bichloride of mercury, in doses of from one-eighth to one-twelfth of a grain, may be advantageously given with the compound decoction of sarsaparilla, or, if there be much debility, with the compound tincture of bark; nourishment, and even stimulants, being conjoined with it, in proportion to the advance of the debility. When suppuration has taken place in the joint, more particularly if the skin covering it be reddened at any one part, the abscess should be freely opened by one or two lateral incisions, extending fairly into the joint, so as to afford a free exit for the pus.

In some cases, even when abscess has formed, the joint being perfectly loose and grating, by perseverance in proper treatment, both local and constitutional, a good and useful limb may be left; and although there be mobility and grating, provided there be no sign of abscess, the surgeon should never despair of obtaining a satisfactory result.

The practice of making free incisions into a suppurating joint, as advocated by Mr. Gay, is a great improvement on the former method of merely puncturing it. If a small aperture only be made, air is admixed with the pus, which becomes offensive and irritating, and, being unable to escape freely, sinks to the bottom of the articulation with *débris* of the disintegrated cartilages, &c., giving rise not only to much local mischief, but to proportionate constitutional disturbance. By freely laying the joint open, all this is prevented; exit is given to the pus through one or two incisions that extend the whole length of the articulation; no constitutional disturbance can occur from pent-up and putrid matter, and the joint has a better chance of healthily granulating.

After the formation of abscess the prognosis is more unfavourable, when large joints such as the knee or hip are affected; or when those are implicated which are important to life, such as the articulations of the vertebrae; so, likewise, when the articular ends of the long bones are affected, it is seldom that the joint can recover itself, as caries or necrosis are complicating its disease and keeping it up. When the articulation is very sinuous, as in the carpus, or when a number of small joints communicate with one another, if not directly by synovial membrane, at all events indirectly through the medium of ligament and of fibrous tissue, as in the tarsus, a cure can scarcely be anticipated. In all these cases, hectic and great constitutional irritation usually come on; or, the joint becoming useless or cumbersome, its removal must be practised either by excision or amputation.

The result will at last in a great measure depend upon the state of the bones that enter into the conformation of the joint. If these be sound, or not primarily affected, and the patient's constitution have got over the effect of the occurrence of suppuration in the joint, ankylosis more or less complete may be confidently looked for. But if the articular ends of the bones be primarily or deeply implicated, then excision or amputation will be the only alleviation.

When an inflamed joint appears to be disposed to unrepair by ankylosis must be facilitated by keeping it in

This disease most frequently occurs amongst the poorer classes, and is almost invariably met with in males. It usually occurs about the age of fifty, though sometimes earlier. I have seen two instances of it in individuals little more than thirty years of age, one of whom was a female. It is an incurable affection, and, as it is commonly attended by much suffering, constitutes a source of great discomfort to the patient.

Diagnosis.—It occasionally happens that individuals labouring under this affection, meeting with a fall or contusion on the hip, present signs of fracture of the neck of the thigh-bone, such as shortening, eversion, with some crepitation perhaps, and inability to move the limb. The diagnosis may in general readily be effected by attention to the history of the case, and by eliciting the fact, that the symptoms have existed to some degree before the accident, although the pain and immobility may have been increased by it.

In the *Treatment* of this affection, little can be done. Rest and the habitual application of warm or stimulating plasters will afford relief, and, in many instances, the administration of the iodide of potassium with sarsaparilla will lessen the nocturnal pain. Dr. Smith recommends an electuary composed of guaiacum, sulphur, the bitartrate and carbonate of potash, and ginger, with a small quantity of rhubarb; and I have certainly seen benefit result from the administration of this remedy in some cases. When the disease is once fairly established, and has assumed a very chronic character, nothing can be done except to mitigate the pain by some such means as those recommended, conjoined with rest and careful attention to the general health.

Dry Chronic Rheumatic Arthritis of the Lower Jaw.—Chronic rheumatic arthritis has also been described by Dr. Smith as occasionally affecting the temporo-maxillary articulation in individuals of rather advanced life. This disease is mostly symmetrical, and gives rise to an enlargement of the condyle of the jaw, which can be felt under the zygoma, attended with much pain in opening the mouth, a sensation of cracking or grating in the joint, and some enlargement of the lymphatic glands by the side of the neck. The pain is generally increased at night, and influenced by the state of the weather. The face becomes distorted, the affected side of the jaw projecting and being pushed towards the opposite side; but when both joints are affected the chin projects, the entire jaw being drawn forwards. This distortion is chiefly owing to the destruction of the articular eminence; for when this takes place, the external pterygoid muscle draws the jaw forwards and to the opposite side; but when both articulations are equally affected, those muscles displace it directly forwards: the glenoid cavity becomes enlarged, the fibro-cartilage disappears, and the condyle is sometimes greatly thickened and flattened, and always rough, being devoid of cartilage. In such cases there is but little to be done by medicines; but the treatment must be conducted on the same principles as in the same affection attacking the hip.

Dry Chronic Rheumatic Arthritis of the Shoulder.—When it affects the shoulder, chronic rheumatic arthritis gives rise to a considerable enlargement of the head of the humerus, wasting and rigidity of the deltoid, and inability to move the elbow upwards, except by the rotation of the scapula on the trunk. In fact, the scapulo-humeral articulation being fixed, all movements of the shoulder are effected through the medium of the scapula, which becomes more mobile than natural. The articulation is the seat of much pain, lancinating at times, but generally gnawing and intermittent, being dependent on the state of the weather, and greatly increased in cold

and wet seasons. The whole of the arm becomes wasted, and weakened in power. In two instances I have seen this disease in young and otherwise robust and healthy men, between twenty and thirty years of age, coming on without any apparent cause. In both cases the joint continued permanently rigid, though the pain was relieved by the use of the iodides and by local counter-irritation.

CHRONIC STRUMOUS ARTHRITIS: WHITE SWELLING.—By *White Swelling* is meant a very chronic form of arthritis occurring in scrofulous subjects.

This condition has not in many cases any definitive starting-point, but appears slowly to supervene upon some slight injury, as a twist, or blow, or strain; at other times it commences with a subacute synovitis, assuming its peculiar characters by occurring in a strumous constitution, and is especially liable to happen in children and females.

Symptoms.—The disease presents peculiar characters. The affected joint is enlarged and rounded, the bony prominences being effaced by an uniform, doughy, semi elastic, or pulpy swelling, occupying the interstices of the articulation. The integuments covering it preserve their white colour; there is usually but little pain felt except in moving the limb; and the position is always that in which the patient has most ease, the joint being generally semiflexed. There is a degree of stiffness and rigidity in the joint; and, in consequence of the wasting of the limb from disuse, the affected articulation appears more swollen than it really is. The general health does not appear at first to suffer much; but, as the disease advances, symptoms of irritation and hectic declare themselves. This affection is always characterised by a special tendency to run on to suppuration, and in the majority of cases at last passes into this condition, although the tendency may be checked by proper treatment. The joint suffers from exacerbations of intercurrent attacks of inflammation, the limb swells and becomes cedematous, and abscess finally forms in and around the joint; often around, before it takes place within. When this is opened the constitutional symptoms become more severe, hectic speedily sets in, and strumous deposit takes place in other organs, such as the lungs, which at last carries off the patient.

Pathological Changes.—In this affection the tissues immediately external to the joint, as the fibrous capsule and the investing cellular membrane, are always much thickened and infiltrated with fatty and plastic matter; and the great tendency of this gelatinous infiltration to run into unhealthy suppuration greatly adds to the mischief that ensues. In the interior of the joint, we find much the same kind of changes that have been described as characterising acute arthritis; the cartilages have lost their polish, their elasticity, and their firm hard section, being softened, eroded, and disintegrated; the synovial membrane is removed in parts, and is here and there vascularised; in others it is replaced, together with the cartilages, either by large quantities of the semi-transparent gelatinous-looking fatty deposit, or by the pulpy grey or brownish fibro-cellular material, that are met with in arthritis. The ligaments are inflamed, softened, and destroyed, being converted into somewhat amular materials; and the interior of the joint is filled with a purulent-looking synovial fluid, thin and yellow, usually containing a large quantity of fatty matter. The bones undergo important changes in this disease, the articular ends becoming expanded and enlarged; and, though this was denied by Crowther, Russell, and others, it is affirmed by more modern surgeons, and I have had repeated opportunities of determining the fact. In all the cases that I have examined, the osseous tissue has undergone important changes, the compact structure having become thin and expanded, and the cells

of the cancellated portion filled with a bloody and fatty serous fluid. The bone is softened, often cutting readily with the knife; and, owing to the deposit of fat, presents a more homogeneous section than healthy bone. In many cases, tuberculous matter is deposited in it. From this it would appear that the principal changes that take place in a joint affected with white swelling consist in a kind of fatty degeneration of the tissues that enter into the formation of the articulation, associated with an unhealthy strumous inflammation of the parts, and in the consequent deposition of considerable quantities of semi-transparent and lowly organised plastic matter which, in its turn, has a tendency to undergo the same structural change, or to run into unhealthy suppuration.

Treatment.—In the treatment of white swelling, we must bear in mind that we have to manage a truly scrofulous inflammation and its effects. Our first object should be to prevent, if possible, the occurrence of suppuration. In the early stage, when the affection has come on insidiously, without any very active symptoms, we must trust to general antisthmous treatment, to the influence of good diet and sea-air, and to the administration of tonics, cod-liver oil, and iodine.

In the local treatment there are three great principles to be carried out. 1. *Rest, with perfect immobility* of the joint, is by far the most important element in the treatment, without which all the efforts of the surgeon to prevent suppuration and disorganisation of the joint will be futile. 2. *Compression*, by means of bandages, strapping, or splints, will aid in the absorption of the plastic effusion in and around the joint. 3. *Counter-irritation* by means of issues, blisters, or the actual cautery, must be employed. These means, to be of real service, should be used before suppuration has occurred; after this, I believe they are of no use. The limb should be put into a position which is not only most easy to the patient, but will leave it most useful should a stiff joint result. If it be one of the joints of the lower extremity that is affected, especial care must be taken that the patient do not bear his weight on it. If the symptoms be of rather an acutely inflammatory kind, a few leeches may be applied: these, however, must be used as sparingly as possible, being confined either to the earlier stages of the disease, or to the subdual of any more active intercurrent inflammation. Rest is best secured by well padded leather or gutta percha splints in the earlier stages; and, at a later period, by the application of the starched bandage, well lined with cotton wadding, to the limb. This kind of application will be found to give the most efficient support, and will keep the whole of the limb perfectly motionless, so that the patient can take open air exercise, and walk with the aid of crutches, without the risk of injuring the diseased joint. In this respect the starched bandage presents great advantages over the short leather splints generally used. It may readily be cut open opposite the diseased joint, so as to admit of the application of proper dressings to it. The actual cautery is extremely beneficial in these cases, applied as directed (p. 744); or caustic issues may be put in, at a little distance from the articulation, so that there may be no risk of the inflammatory action penetrating to it.

After all inflammation has, in this way, been removed, and nothing but thickening and stiffness of the joint are left, measures must be adopted for removing these conditions, and restoring the flexibility of the articulation by friction with somewhat stimulating and counter-irritant embrocations, and eventually its strength by douches of sea-water. The swelling and pulsations that are left, together with the debility dependent on relaxation of the ligaments, are perhaps best remedied by the use of Scott's strapping, but

pressure should not be applied so long as there is evidence of active inflammation going on in the articulation, which it would certainly increase.

If abscess form, it must be freely opened by an incision of a proper length, the joint poulticed, and the patient's general health attended to, so as to promote the evolution of granulations, and prevent hectic. In these cases, if the limb can be preserved, its subsequent utility, and the patient's comfort, will mainly depend upon the position in which it is allowed to become ankylosed.

ANCHYLOSIS, OR STIFF JOINT.

Anchylisis is invariably the result of the destruction of a joint by inflammation, being one of the modes by which nature effects its repair. It consists in the more or less complete consolidation of the parts around and within the articulation. It is of two kinds: the *Incomplete*, or *Fibro-cellular*; and the *Complete*, or *Oseous*.

In the *Incomplete*, or *Fibro-cellular Anchylisis*, the stiffness of the joint may be dependent on thickening and induration of its fibrous capsule, or on the formation of fibroid bands as the result of inflammation within the joint, or in consequence of the cartilages and synovial membrane being in part or wholly removed, and their place supplied by a fibroid or fibro-cellular tissue, by which the articular ends are tied together. The stiffness may be materially increased by the shortened and contracted state of the muscles around the joint. The incomplete, or fibrous anchylisis, is the most favorable termination that can usually be expected in chronic scrofulous affections of joints. In some cases it arises simply from disuse: the limb becoming stiffened in the position in which it has been too long detained.

Complete or Oseous Anchylisis is of two kinds. In one, all the soft parts within the joint are destroyed, and the osseous surfaces have conformed, or are fused together by direct bony union; this is most commonly seen in the hip, knee, and elbow (Fig. 248).

In the other kind there has been fibro-cellular deposit, or degeneration within the joint; and the bones, united partly by this, are also tied together by arches or bridges of osseous matter, thrown out externally to the articulation, and stretching across from one side to the other. It has been supposed that these masses proceed from the ossification of the ligaments, or even the muscles; but, from the inequality of their appearance, it is evident that they are new and accidental formations.

The true or osseous anchylisis does not occur as a consequence of scrofulous articular inflammation, but is usually the result of traumatic inflammation in persons of a healthy constitution. In the incomplete anchylisis there is always some degree of mobility, however slight, and, indeed, perhaps only perceptible on deep and close examination. In the complete form of stiff joint, the articulation is perfectly rigid and immovable. It not unfrequently happens, in old standing cases of diseased joint, that more or less complete anchylisis is taking place at one part of the articulation, whilst caries or necrosis of the bones is going

Fig. 248.—Complete Anchylisis of Hip.

on at others. Under such circumstances, excision or amputation will, probably, be the course to be pursued.

TREATMENT.—The *treatment* of ankylosis is, in the first instance, of a precautionary nature; that is to say, when the surgeon finds that the establishment of ankylosis is, as it were, the natural means of cure adopted by nature in a deeply diseased joint, his efforts should be directed to seeing that the joint becomes ankylosed in such a position as will leave the most useful limb to the patient. Thus, if it be the hip or knee, the ankylosed joint should be in the straight position; if it be the elbow, it should be placed at a right angle.

When once ankylosis has occurred, the treatment to be adopted will depend partly on the degree of stiffness, whether it be fibrous or osseous; and partly on the object to be attained, whether this be merely the restoration of mobility in a part ankylosed in a good position, or the remedying of the deformity occasioned by faulty ankylosis.

1. In attempting to restore the mobility of a joint ankylosed in a good position, as of a straight but stiff knee, the surgeon may usually succeed if the ankylosis be only fibrous, (when some degree of movement will always be perceptible in the part,) by the employment of passive motion, frictions, and douches, more particularly with warm salt water or the mineral sulphureous springs. In the more obstinate cases, and where the immobility appears to depend, in some degree at least, on fibrous bands stretching across the limb, an attempt might be made to divide these subcutaneously. In doing this no mischief can result; for, the synovial structure of the joint having been destroyed, no dangerous amount of inflammation can be set up in it.

2. When fibrous ankylosis has taken place in a faulty position—if, for instance, the knee be bent, or the elbow straight—the first thing to be done is to place the limb in such a position that it will be useful. This may most readily be done by putting the patient under the influence of chloroform, and then forcibly flexing or extending the limb as the case may require, when with loud snaps and cracks it will usually come into proper position. Should any of the tendons near the joint appear to be particularly tense, they may be divided subcutaneously. Either some days before the extension is attempted, or else if it have been carried as far as the rigid state of the tendons will permit, tenotomy may be practised, and, an interval of a few days having been allowed to elapse, extension may be completed. The inflammatory action that follows this forcible extension or flexion of the limb is usually but very trivial; an evaporating lotion and rest will speedily subdue it. Indeed, it is surprising what an amount of violence may be inflicted on an ankylosed joint without any bad consequences ensuing. After the limb has been restored to its proper position, passive motion and frictions may tend to increase its mobility.

3. When osseous ankylosis has taken place, and the position of the limb is a good one, it will generally be wiser for the surgeon not to interfere; except in the case of the elbow-joint, which, under these circumstances, may be excised with advantage, so as to substitute a movable for an immovable articulation. If the position be faulty, the osseous union may be divided, or a wedge-shaped piece of the bones may be taken out, and the position of the limb thus rectified.

4. Amputation may be required in cases of faulty ankylosis with so much atrophy of the limb as to render it useless, or in cases in which there is necrosed or carious bone co-existing with ankylosis and rigid atrophy of the muscles of the limb.

LOOSE CARTILAGES IN JOINTS.

It sometimes happens that in the instance of a joint the synovial membrane assumes a warty condition, as the result of chronic irritation of the articulation. This warty state of the membrane usually consists of flattened fibroid deposits upon its surface. In other cases these may become pedunculated, and pendant into its interior. For this condition, which gives rise to occasional uneasiness and puffiness about the joint, with a crackling or creaking sensation when it is moved, but little can be done beyond the application of discutient plasters and the use of elastic bandages.

Loose Cartilages, as they are termed, are not unfrequently met with in the different articulations. In many cases they are not truly cartilaginous, but appear to be composed of masses of condensed and indurated fibroid tissue, not very dissimilar in structure from the warty synovial membrane just referred to, and from which they appear to be detached. In fact, the flattened and tuberculated fibroid deposits forming warty growths, the pedunculated fibroid masses, and the same detached or lying loose in the interior of the joint, appear to be successive stages or conditions of the same pathological formation. Though commonly fibroid, it is probable that in some cases these bodies may be truly cartilaginous.

CHARACTERS.—These bodies vary in size from a barley-corn to a chestnut. When small, they are round; when large, they are somewhat flattened or depressed on the surface. They are smooth, shining, and usually of a yellowish or greyish white colour. They are most frequently met with in the knee; but not uncommonly occur in the elbow or the joint of the lower jaw, and occasionally in the shoulder. Most commonly only one is found; but their number may range from this up to fifty or sixty.

SYMPTOMS.—The severity of the symptoms will to a great extent depend upon the mobility of the loose cartilage, and its consequent greater or less liability to be nipped between the opposite articular surfaces in the movements of the joint. When these bodies are tolerably firmly attached to the synovial membrane, they may merely occasion weakness of the joint, with occasional synovial effusion. When loose, they usually give rise to a very distinct train of symptoms. The most marked of these is the very severe pain which occurs in particular movements of the limb. This comes on suddenly, prevents the patient from either straightening or flexing the joint completely, and is often so intense as to cause faintness or sickness. It is usually followed by a degree of synovial inflammation, and by relaxation of the ligaments. These attacks of pain and of sudden irritability of the part come on at varying intervals, as the result of movements of it: they commonly happen in the knee whilst the patient is walking. It is difficult to say to what this severe pain is due. Richet thinks it may be owing to the synovial membrane being pinched between the foreign body and one of the articular surfaces. I think that it is most probably due to the foreign body being drawn in between the opposite surfaces of the joint, when these are separated anteriorly in the act of flexion of the knee, and then, when the limb is extended, acting as a wedge between these, tending to keep them separate and interfering with the complete straightening of the limb. In consequence of this wedge-like action of the loose cartilage the ligaments are violently stretched, and the sickening pain consequent on this act is experienced, followed, as happens in a violent sprain, by rapid synovial effusion. The sensibility of the ligaments of a joint is of that peculiar nature that it is only called into action when an attempt is made to stretch them, and thus forcibly to counteract or destroy their natural use. Ligaments may be cut without any suffering, but they

cannot be stretched, either by accident or disease, without the most severe pain. In some cases the loose cartilage can be felt by carrying the finger over the joint, when it may be detected under the capsule, slipping back when pressure is exercised upon it, and often possessing great mobility, gliding from one side of the joint to the other, so as to be extremely difficult to be fixed.

TREATMENT.—The treatment consists in supporting the joint with an elastic bandage or knee-cap, so as to limit its movements, and thus prevent the liability to the recurrence of the attacks of pain; and in this way the fixing or absorption of the cartilage may sometimes be obtained. Any inflammatory action that has been excited requires to be subdued by proper antiphlogistic treatment.

If the cartilage occasion great and frequent suffering, so as to interfere seriously with the utility of the limb, and if it appear to be of large size, and to be loose and single, means may be taken for its extraction. But it must be borne in mind that, whilst the loose cartilage is at most an inconvenience, though perhaps a serious one, any operation for its removal by which the joint is opened, becomes a source of actual danger to limb and even to life. It is far less dangerous, in fact, to leave the foreign body than to perform the operation necessary for its extraction. Hence an operation should not be lightly proposed or undertaken, without warning the patient of the possible consequences that might follow. No operation should be undertaken so long as the joint is in an irritated state, as the result of a recent attack of pain; this must be first subdued, and then the operation may be proceeded with. The extraction used to be effected by directing the patient in the first instance to make those movements by which he usually gets the cartilage fixed in the joint. So soon as the surgeon feels it (as this operation is commonly required in the knee), he should push it to one side of the patella, where he must fix it firmly with his forefinger and thumb, he then draws the skin covering it to one side, so as to make it tense, and cuts directly down upon the cartilage by a sufficiently free incision to allow of its escape. The wound which, when the skin is relaxed, will be somewhat valvular, is then closed by a strip of plaster, and the limb is kept at rest for a few days until it has united. Severe inflammation of the joint less frequently follows this coarse operation than might have been expected, the synovial membrane having probably undergone some modification of action that renders it little liable to this process. It has, however, happened that acute synovitis has set in, and this has terminated in suppuration of the joint, causing the patient's death, requiring amputation, or leading to ankylosis.

It has been proposed by Goyrand, in order to obviate the dangers of direct and open wound into the joint, to remove the loose cartilage by subcutaneous section; this he proposes to accomplish in a way that I have seen practised by Liston, and have often done myself, viz., by passing a tenotome obliquely under the skin after fixing the foreign body in the way that has already been described, dividing the synovial membrane freely, and then squeezing the cartilage into the cellular tissue outside the joint, where it may be allowed to remain until removed by a fresh incision after that in the synovial membrane has healed, or, better still, may be left to be eventually taken up by the absorbents of the part.

A most useful modification of this method has been practised by Mr. Square of Plymouth; it consists in fixing the loose cartilage, dividing the capsule subcutaneously over it, and then pressing the foreign body into the opening thus made, retaining it there by a compress and plasters. Adhesion speedily ensues, and the loose cartilage is eventually absorbed. In operating by this method on the knee, the cartilage should be fixed below and to the

inner side of the patella, between it and the head of the tibia; a long narrow tenotome is then introduced obliquely under the skin from a distance of about two inches below the loose cartilage; the capsule of the joint is divided, the subcutaneous cellular tissue freed by a slight sweep of the blade, and the loose cartilage then pressed into the cavity thus made to receive it, where it may become absorbed. By the adoption of these subcutaneous methods there will be but very little danger of inducing undue inflammation in the joint, the entrance of air being prevented, which, and not the mere section of the capsule and synovial membrane, constitutes the chief risk. Should there be more than one loose cartilage, the operation must be repeated, but not until the inflammation induced by the former one has been subdued. In this way I have successfully removed in succession five loose cartilages from one knee.

NEURALGIA OF JOINTS.

Pain of a severe character is often experienced in or around a joint, closely simulating, but not dependent upon, inflammation or other structural disease. This pain, which is purely neuralgic, may either have its origin in some local irritation of a nerve leading to the sensitive part, or it may be dependent on constitutional disorder of an hysterical character. It is this class of cases, occurring in young women who are either the subjects of hysteria, or are of a highly nervous temperament, that should especially be considered as *Neuralgia of the Joints*, to which the attention of the profession has principally been directed by the labours of Sir B. Brodie.

In these cases it is generally found that the hip, knee, ankle, or shoulder is the joint affected—the hip and the knee more especially. The neuralgia is usually localised in a particular joint by some slight injury that the part has sustained. But it is important to observe that in these cases the pain often does not develop itself for some days, or even weeks, after the injury that is the alleged cause of it. Severe pain is complained of in the joint; and it is rendered comparatively useless, often with a good deal of distortion or contraction. On examination, it will be found that the pain, which is commonly very severe, is superficial and cutaneous, not existing in the interior of the articulation, nor increased by pressure of the articular surfaces against one another; and that it is not strictly confined to the joint, but radiates for some distance around it. This pain is often intermittent in its character, and is frequently associated with neuralgia elsewhere, as in the spine; and not unfrequently with uterine irritation or disease. At the same time, it will be observed that all the signs that ought to accompany a severe attack of inflammation in a joint, such as would be attended by a corresponding amount of pain, are absent; there being no painful startings of the limb at night, no heat, redness, or swelling of it, nor constitutional fever and irritation; and the suffering being increased by causes, such as mental and emotional disturbance, that do not influence organic disease. Attention to these various circumstances will usually enable the surgeon to diagnose the nature of the attack without much difficulty; the only cases in which he will really experience any, being those in which the tissues around the joint have been thickened, indurated, and altered in their characters by the application of issues, moxæ, &c.; or by some slight articular disease having at some time existed, but been cured.

TREATMENT.—The treatment must be of a constitutional character, directed especially to re-establish a healthy condition of the uterine organs. If there be amenorrhœa and anæmia, alopecia and the preparations of iron must be given; if uterine irritation or ulceration exist, this must be

proper local means, and the general health attended to. General nervous antispasmodics and tonics, such as valerian and bark, or assafoetida and quinine in full doses, should be freely administered. The most efficient treatment that can be directed to the affected joint, is, I think, the application of cold douches and the employment of electro-magnetism, which I have found to cure cases in which all other means had failed; the application of atropine and aconite may be of service to allay the pain when especially severe. If contraction or other distortion of the limb exist, the patient should be put under chloroform, and extension or rectification of faulty position then made, care being taken to keep the limb on splints in a proper position for some time after the operation.

CHAPTER XLIX.

EXCISION OF JOINTS AND BONES.

To the surgeons of this country is undoubtedly due the merit of originating and carrying out the practice of excising diseased joints and bones with the view of saving a limb, by the removal of those morbid structures that would otherwise have necessitated amputation. Although the older surgeons, dreading amputation on account of the difficulty they experienced in arresting the hemorrhage from a stump, had recourse to various gouging, scooping, and scraping operations in cases of diseased bone, yet they never attempted the excision of a joint, nor indeed the resection of a whole bone. The articulated ends of bones were first excised in a compound dislocation of the elbow as far back as 1758, by Wainman of Shampton, and afterwards by White, Bent, and Orred in cases of compound dislocation of the humerus. In 1762, Filkin of Northwich excised the knee for disease; and in 1773, Justamond cut out the olecranon and two inches of the ulna for diseased elbow-joint. The first distinct publication on the subject was by Mr. Park, in the year 1782; his object was to show that, in some of those affections of the knee and elbow for which amputation had hitherto been considered indispensable, surgery possessed another resource "in the *total extirpation of the articulation*, or the entire removal of all the bones which form the joint, with as much as possible of the capsular ligament." In the same year Moreau excised the ankle-joint, and some years subsequently the head of the humerus and the knee-joint. The new practice made few converts, however; and in 1805, Mr. Park in another publication expresses his mortification that it had not met with the success in this country that it deserved; and observes that, if it had not been for the Moreaus in France, it would have fallen into complete oblivion. Although excisions continued to be occasionally performed, it was not until a quarter of a century later that they were again prominently brought before the profession; and the second revival was due to the Edinburgh surgeons, chiefly to Liston and to Syme. Since then, they have continued to gain in favour, and now constitute that department of surgery which has been termed the *conservative*, or more correctly the *preservative*.

Before proceeding to discuss the different resections in detail, we must endeavour to lay down some general rules for their performance in those cases in which they are alone admissible.

INDICATIONS FOR EXCISION.—The excision of an articulation may be practised for the following reasons:—

1. As a substitute for amputation in cases in which the joint is so extensively diseased, that the patient will be worn out by the discharge or pain, unless it be removed. Here an useful limb may be secured by the sacrifice of the diseased part.

2. In some cases of articular disease in which amputation would not be practicable, excision may be done in order to hasten the cure, and thus to save years of suffering to the patient.

3. Excision may be done in cases in which amputation is not practicable; as in disease of the hip-joint or of the temporo-maxillary articulation.

4. As a substitute for other and less efficient treatment, in order to restore the utility of a limb or joint; as in osseous ankylosis of the elbow, or in osseous ankylosis of the knee.

5. Excision may be required in bad compound dislocations and fractures of joints, especially in gun-shot injuries; more particularly in those of the head of the humerus, and of the elbow.

As a general rule, resections are more required for diseases of the articular ends of bones than for simple disorganisation of joints. If only the soft structures of a joint be involved, it usually happens that, without the necessity of resection or operation of any kind, an useful limb will result; in the upper extremity, with fair mobility of the articulation; in the lower, with more or less complete ankylosis, sufficient for a fair basis of support. But when the constitution is very strumous, or the bones are primarily or extensively affected, we can scarcely expect that the limb will recover to such an extent as to become useful.

CONDITIONS OF SUCCESS.—For resection to succeed, the following conditions appear to me to be necessary.

1. The disease should not be too extensive, so that its removal would entail such an amount of mutilation of the limb, as to render it less useful to the patient than an artificial member would be. This is especially important in the lower extremity. If the bones be so extensively affected as to require to be shortened by a considerable extent—for several inches—a limb would be left, which, instead of serving as a proper basis of support to the patient, would only be an useless incumbrance. In the upper extremity, length and strength are of less consequence than in the lower; the preservation of the hand is the chief thing to aim at, and if this be effected the bones may be encroached on to a greater extent than is proper in the lower limb.

2. The disease for which resection is practised should be allowed to become chronic before any operation is undertaken: for this there are two reasons. First, in the acute stage of disorganisation of a joint, it is not always possible to say, however unpromising the case may appear, whether ankylosis may not result, so that as useful a limb would be left as could be obtained by resection. And, secondly, if the joint be excised whilst acute and active disease is going on, inflammation and diffuse suppuration of the medullary canal are apt to set in—a condition very apt to be followed by phlebitis and pyæmia. In the only fatal instances of resection of the elbow-joint that I have witnessed, death resulted from this cause; the operation having been performed whilst the articular affection was acute.

3. The soft parts about the joint must be in a sufficiently healthy state. There are two morbid conditions connected with the soft parts that may interfere with the success of resection. First, they may be so thinned and perforated by sinuses, and so adherent to the bones, that an insufficient covering would be left. Or, secondly, the long-continued existence of strumous disease in joints and bones may give rise to a great deposit of slowly organised plastic matter around the articulation. This material

becomes insusceptible of healthy organisation, and slowly suppurates. Sinuses form in it, the integuments covering it become blue and doughy, and the soft parts around the seat of operation fall into a state of strumous disorganisation that prevents alike the formation of a false joint, of osseous ankylosis, or of the healing of the wound, and thus leads inevitably to the ultimate amputation of the limb. Even though this exudation-matter do not exist in large quantity, if the joint be peculiarly loose, owing to softening and disorganisation of ligamentous and tendinous structures, excision is not very likely to succeed, especially if it be the ankle or knee that is removed.

4. *The state of the patient's constitution* must necessarily influence the surgeon materially in his determination whether to resect, or to amputate. If the constitution be tolerably sound, or if the general health have given way, provided that it has done so as the simple consequence of pain, irritation, and continued discharge, resection will have a fair prospect of success. In fact, when the patient is hectic in consequence of continued suppurative action, the removal of the joint or bone that maintains such action may be advantageously practised. But if there be a state of irritative fever in consequence of continuance and spreading of morbid action, the operation is likely to occasion erysipelas, phlebitis, or pyæmia, and is not a safe measure. So also, if the constitution appear to be very much broken down, the patient being anæmic, wasted, and cachectic, with some irritative fever, but with no open abscess in connexion with the joint to account for the cachectic condition, excision of the larger joints, as of the knee and hip, is not a desirable operation. If the patient be very highly strumous, or decidedly phthisical, there will be little prospect of his being able to bear up through the long convalescence that follows resection. A slight degree of pulmonary disease, however, which appears to be rather the result of the long-continued irritation of the local affection, than of any constitutional taint, need not be a bar to these operations. In such cases, I have several times had occasion to observe that the general health improved rapidly after the removal of the local disease.

5. *The extremes of life are unfavourable to resections.* In very early childhood, these operations are seldom necessary; the natural processes usually sufficing, with very little assistance, to eliminate diseased bone, and the disorganised joints admitting readily enough of ankylosis. If the disease be too severe for this, it will usually be found to be associated with so strumous a constitution as to interfere with healthy reparative action of any kind. Another serious objection to these operations in young children is, that should the epiphysis be removed, the development of the limb will be arrested to a great extent, if not entirely. At advanced periods of life, destructive joint disease is not very common, and when it does happen, it is generally in constitutions not fitted to stand up against the prolonged drain consequent on these operations. It is at the early adult age when the diseases most frequently occur that render resections necessary, that these operations are best borne.

REPAIR AFTER EXCISION.—The mode of repair after resection differs according to the circumstances of the operation.

When a bone, as the os calcis, has been entirely removed, it is never, of course, regenerated, but its place is occupied by a firm fibrous cicatrix.

When partial excision of a bone is practised, the result varies according to the tissue that is removed. If a portion of the compact tissue have been cut away, callus is thrown out. If it be the cancellous structure that is scooped out, the cavity left is filled up by a dense fibrous mass which may eventually ossify.

When a joint has been excised, either osseous or ligamentous ankylosis may take place; and the surgeon should endeavour to secure osseous union in some cases, fibrous in others. Thus, when the knee has been excised, as a sound and firm limb is desirable, osseous ankylosis should, if possible, be brought about; whilst in the upper extremity, where mobility is of more use than strength, ligamentous union is most desirable. In these cases the ends of the bones become rounded, and are united by a dense mass of fibrous tissues which envelopes them, and to which the insertions of those muscles that are naturally connected with the articular ends that have been removed become attached.

The question as to the arrest of the development of the bone, and consequently of the whole limb on which an operation of excision has been performed, is one of great practical moment. It is well known to physiologists that the longitudinal growth of a bone is chiefly carried on through the medium of the layer of cartilage by which the epiphysis is attached to the shaft, and which does not become ossified until the bone has attained its full length. It has further been pointed out by Dr. Humphry, that the two epiphyses of the long bones of the limbs do not take an equal share in this development, but that one is a more active organ of growth than the other. Thus the upper epiphysis in the humerus and tibia, the lower epiphysis in the radius and femur, are the most important in this respect. If, therefore, in an excruciating operation practised on a growing child, in whom osseous development has not fully taken place, the whole of the epiphysis be removed, the subsequent growth of the bone, and necessarily of the whole limb, will be arrested proportionately to the share that the epiphysis which is so removed takes in the development of the bone. And if that epiphysis on which the length of the bone is chiefly dependent, be removed—as, for instance, the upper epiphysis of the tibia and humerus, or the lower epiphysis of the thigh-bone—the limb will continue undeveloped and useless for the rest of life.

In the adult, after ossification is completed, the epiphysis loses its importance as an organ of growth; and may be removed, if necessary, without interfering with the subsequent length of the limb, except to the extent of its removal.

INSTRUMENTS.—The instruments required for resection are of a somewhat varied character; strong scalpels and bistouries, straight and sharp-pointed. In addition to these I have found a strong-backed, probe-pointed bistoury with a limited cutting edge, of great utility in clearing the bones. The pliers should be of various sizes and shapes (Figs. 229 to 232), and gouges will be found useful for scooping out suspicious patches on the cut osseous surfaces. For ordinary purposes, a small amputating saw will, I think, be

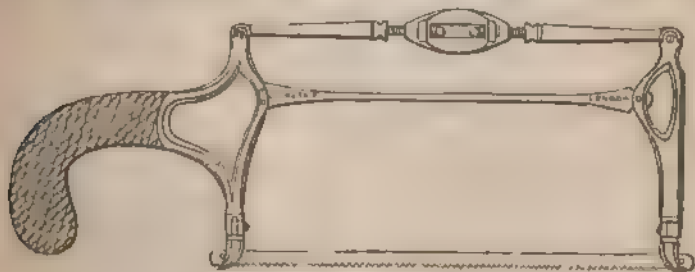

Fig. 240—Butcher's Saw.

found the most convenient instrument for dividing the bones; but in some cases a narrow keyhole saw, or that introduced by Butcher (Fig. 240),

will answer best. The last instrument is especially useful when it is intended to cut the bone obliquely, or when the space is limited; for, as the blade is narrow and its angle can be changed at pleasure, any required direction can be communicated to the cut. I invariably use it in preference to all others in resections. The chain-saw is perhaps not used so frequently as it might be.

OPERATION.—The steps of the operation must of course vary with the different resections; but there are some general rules that may be laid down as applicable to all cases.

1. The incisions through the soft parts should be sufficiently free to expose thoroughly the bones to be removed. By making them, as far as practicable, parallel to tendons, blood-vessels, and nerves, parts of importance may readily be avoided.

2. As little of the bone as possible should be removed. The gouge may be applied to any carious or tuberculous cavities or patches that appear upon the surface of the freshly cut bone; and, in this way, shortening of the bone by the saw may be materially avoided.

3. In young children the epiphysis should never be entirely removed, as it is on the growth of this portion of bone, or rather on that of the epiphysal cartilaginous layer adjoining the shaft, that the development of the bone in length is mainly dependent.

4. In adults in whom the bone has attained its maximum longitudinal development, the epiphysis may be more freely removed, if necessary. But the shaft should not be encroached upon if it can possibly be avoided, and especial care should be taken not to open the medullary canal.

5. It is of great importance not to confound bone softened by inflammation, but otherwise healthy, or roughened deposits of new osseous matter, with that which is carious or necrosed.

6. Skin, however redundant, should seldom if ever be cut away. The flaps, at first too large, soon shrink down to a proper size, and, if trimmed, are very apt to become too scanty.

7. After the operation, light dressings only should be used. As healing always takes place by granulation, no accurate closing of the wound is necessary, but it is sufficient to lay the limb on a pillow, or well padded splint, and to apply water-dressing. When it begins to granulate, more accurate attention to position is required.

8. The constitutional after-treatment should be of a nourishing or stimulating character. As there will be a great drain on the system, and a prolonged confinement to bed, the strength must be kept up under it by good diet. These operations are always of a serious character; in many cases fully as much so as the amputation of a corresponding part, or even more so, owing to the large wound that is often inflicted in the more extensive division of the bones; to the necessity of making the incisions in the midst of diseased or injured structures; and to the more prolonged character of the after-treatment. Hence it is of especial importance that the general health should be carefully maintained after these operations.

9. Should caries or necrosis return after the operation, *secondary reaction* may be required. This I have done successfully at the hip, shoulder, and elbow-joints. In the elbow, in one case I performed a third resection with perfect success; the two previous operations, which had been performed by other and different surgeons, having failed. The success of these secondary resections will necessarily be greatly dependent on the possibility of establishing an improved state of the patient's constitution.

EXCISION OF SPECIAL JOINTS AND BONES.

SHOULDER-JOINT.—Excision of the shoulder-joint may be required for two conditions: 1. Disease, and 2. Compound and Comminuted Fracture of the articulation.

1. *Excision for Disease.*—For disease, excision is not so commonly required as in any other articulation; disease of this joint not being of very frequent occurrence, and, when it happens, often terminating in false ankylosis, without suppuration taking place. When abscess and necrosed bone are met with about the shoulder, it will frequently be found that the coracoid or acromion processes, or the scapular spine, are at fault rather than the joint itself, and extraction of the sequestra formed there may prevent excision of the articulation. In some cases a small sequestrum lying in a carious cavity in the head of the humerus may be removed by sitting up sinuses, without the necessity of excising the head of the bone. When excision has been practised for disease of the shoulder joint, it has usually been for strumous disease, commencing in the head of the humerus, especially in children and young people.

Operation.—The articulation may most readily be exposed by making a semilunar flap about three inches in length, commencing at the posterior part of the acromion, cutting across the line of insertion of the deltoid, and carried up to the inner side of the coracoid process. Or the surgeon may adopt T, J, or Π-shaped incisions. I think, however, that the elliptical, or U-shaped is preferable, as less muscular fibre is sacrificed by it. By a few touches of the scalpel, a large flap composed of the deltoid muscle may be raised, and the diseased articulation fully exposed. As the capsule and the ligaments are destroyed by the morbid action that has taken place in them, the head of the bone may readily be turned out of the glenoid cavity; and, being freed by a few touches of the knife, and isolated by passing a spatula behind it, may be removed with a narrow saw (Fig. 250). In doing this, the shaft of the humerus should be encroached upon as little as possible, not only that the bone may not be shortened more than is necessary, but in order that wound of the circumflex arteries may be prevented, which will certainly happen if the incision be carried too low down. After the removal of the head of the bone, the glenoid cavity must be examined; if this be carious, it may be removed most conveniently by means of gouge-forceps and the gouge, care being taken that all diseased bone is thoroughly scooped away. After the operation, the flap must be laid down, and retained in position by two points of suture, and the arm well supported in a sling, the elbow especially being raised.

Fig. 250.—Excision of Shoulder joint

Result.—The wound unites by granulation, and, though the deltoid muscle does not recover its full utility, a very excellent limb and most useful forearm and hand are left to the patient. The accompanying drawing (Fig. 251) has been taken from a man whose shoulder-joint I removed some years ago. I last saw this patient about seven years after the operation had been performed, and then found that the upper end of the humerus had been drawn up underneath and between the acromion and coracoid processes,

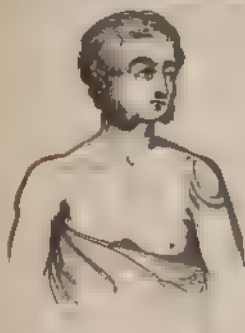

Fig. 251.—Result of Excision of Shoulder-joint.

where a false joint had formed. The arm was extremely useful, and all the parts below the elbow were well developed. The upper arm was two and a half inches shorter than the other. Excision of the shoulder-joint is on the whole a very successful operation. It is true that Velpeau has recorded thirteen deaths after its performance, but even this number would probably give but a small percentage on the number of cases in which it has been done; and an improved acquaintance with the principles of conservative surgery has doubtless still further very materially lessened the mortality.

2. *Excision for Compound and Comminuted*

Fracture.—When excision of the shoulder-joint is required for compound and comminuted fracture from gun-shot injury, the operation is of a less formal character. The bullet-holes must be laid freely open, or the deltoid cut across at its superior attachment, all loose splinters removed, and the ragged and spiculated ends of bone cut off with pliers or saw; especial care being taken in manipulating towards the inner and under sides of the joint, in the vicinity of the plexuses of nerves and large vessels. This operation has been attended by the most satisfactory results; Baudens relates 14 cases occurring in the Crimea, with only 1 death; and in the British army, of 14 cases, 12 recovered.

SCAPULA.—The scapula has occasionally been excised in part, or entirely, for gun-shot injury or disease. Most commonly the operation has been practised after the arm has been removed at the shoulder joint, the state of the scapula requiring its ablation at a later period; this I saw admirably done several years ago by Mr. Fergusson. Occasionally, however, the scapula has been excised without previous amputation of the arm. Thus Liston removed three-fourths of the bone for a vascular tumour springing from it. South excised the whole of the body of the scapula by sawing through its neck; and Jones of Jersey and Syme have taken away the bone with its processes entire. Operations such as these are rarely required, and when called for can scarcely be performed in accordance with any positive rule, the operator varying the extent and arrangement of his incisions according to the extent of the disease, the situation of sinuses, &c. In whatever way they are practised, there is one rule, however, which should be attended to; viz., that the axillary border of the bone should be the last to be interfered with, on account of the hemorrhage that may be expected from this situation.

CLAVICLE.—The clavicle has been partially or wholly excised by Travers, Mott, and others. In caries or necrosis of this bone, portions of it may be gouged away or extracted without much difficulty; but when, in consequence of the growth of tumours, the removal of the whole or greater part

If the bone is required, the operation is one of the most hazardous in surgery, as a glance at the anatomy of the parts lying beneath the bone, and approached upon by the morbid growth, will indicate. In Mott's case, forty ligatures were applied. In this operation, the bone requires to be exposed by a free incision along its whole length: it is then sawn across or disarticulated at its acromial articulation, and carefully dissected out in a direction from without inwards, the sternal end being forcibly twisted outwards, and its ligamentous connections carefully divided. The sternal end only of the clavicle has been excised by Davie of Bungay in a case in which dislocation backwards had resulted from deformity of the spine, and the luxated end, gradually pressing upon the oesophagus, threatened the life of the patient. The bone was cut through by means of a Hey's saw about an inch from its sternal end, and the sterno-clavicular ligaments having been divided, the portion of bone was forcibly elevated, and at last extracted.

ELBOW JOINT.—Excision of the elbow-joint has been more frequently practised than that of any other of the articulations, and the result has upon the whole been far more satisfactory. This operation may be required, 1, for Chronic Disease of the Joint; 2, for Osseous Anchylosis; and 3, for Compound Fractures and Dislocations.

1. In cases in which the elbow-joint requires to be excised for *strumous disease* in young persons it will generally be found that, after morbid action has existed for a considerable time in the joint, the limb will have become useless, and the soft parts around the joint swollen, spongy, and perforated by fistulous openings. When disease of this joint occurs in the middle aged adult, the mischief will usually be found to be principally seated in the bones, the articular structures being only secondarily involved. In these cases there will often be very little external evidence of mischief, merely one or two fistulous apertures leading down to carious or necrosed bone in the condyles or the olecranon, the joint being permanently flexed and swollen, and the arm so useless that it cannot support the weight of the hand. On exposing the articulation, perhaps caries, with complete destruction of the cartilage, with or without necrosis of the articular ends, and with loose pieces of dead bone lying in the cavity of the olecranon, or in one of the condyles, may be found. Most commonly the radius is the last bone that is affected, the ulna and the articular end of the humerus being generally first diseased.

2. If *osseous anchylosis* have occurred, whether in the straight or with bent position, excision or simple division of a portion of the consolidated bone may advantageously be practised. When the elbow is anchylosed in the straight position, the arm is quite useless; and any operation by which flexion of the limb can be obtained, even without mobility of the joint, will add most materially to the patient's comfort, rendering the hand available for most purposes of life. In cases of *angular osseous anchylosis* of the elbow, the bony union should be sawn across or a wedge-shaped piece removed, so that a useful and moveable articulation may be substituted for one that is rigid and fixed.

3. In cases of *compound fracture or dislocation* of the elbow-joint, more or less complete resection of the protruding, and possibly splintered fragments, may be required (pp. 260 and 310).

Operation. Excision of the elbow-joint may be performed by three different procedures, viz., the H, the T-shaped, or the simple longitudinal incision. Each method has its advocates. The H-shaped operation consists in making an incision parallel to, and a little to the radial side of, the ulnar

nerve, another along the outer side of the joint, and uniting the two by a cross cut, dissecting up and down two square flaps, and clearing the bones laterally. It was soon found by surgeons that by this method a very unnecessary amount of incision was practised; and accordingly the vertical cut along the outer side was dispensed with, and the \neg -shaped operation necessarily adopted. This consists in making the longitudinal incision parallel to, and a little to the radial side of the ulnar nerve, and the cross cut over the olecranon to the outer side of the joint. More recently still, it has been found that this incision may be still further simplified, and that the cross cut may be entirely done away with, and the operation reduced to a single longitudinal incision carried nearly over the centre of this joint in the middle line from above downwards. In comparing these different methods of operating, I decidedly give the preference to the single longitudinal incision, as being quite sufficient in all ordinary cases for the complete and easy removal of the articulation. Should the soft structures towards the outer side of the joint not yield sufficiently, a cross cut can at once be made, so as to liberate these, and give the surgeon more room, by turning up the two triangular flaps that will thus be formed.

The following is a detail of the successive steps of the operation as practised by the \neg -shaped or the single longitudinal incision. The patient having been laid prone, the perpendicular cut should be made parallel to, and a line or two to the other side of, the ulnar nerve; being commenced at least two inches above the point of the olecranon, and carried down to about three inches below it. The transverse incision may then, if necessary, be

Fig. 252.—Excision of Elbow joint \neg -shaped Incision.

made directly across the end of the olecranon, to the outer side of the joint, and extended as far as the extremity of the outer condyle (Fig. 252). The two triangular flaps thus made must be dissected up, the knife being carried close to the bones. Or the transverse incision may be dispensed with, and the bones readily exposed and turned out by the third method, that of the

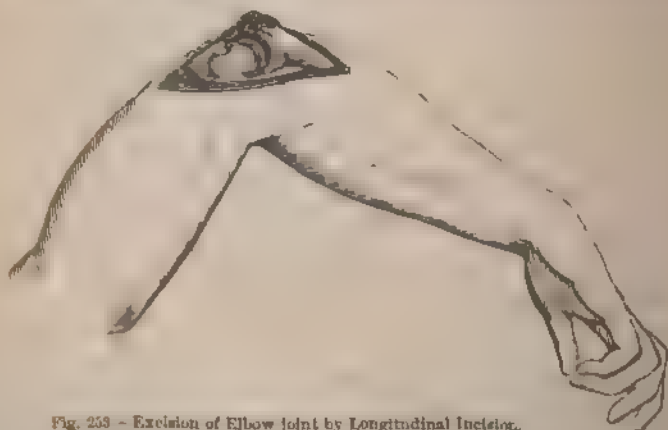

Fig. 253.—Excision of Elbow joint by Longitudinal Incision.

single perpendicular incision (Fig. 253). This must be of sufficient length to allow of the sides being held well apart, and then it constitutes the

simplest plan of excising the elbow that can well be devised, bones have been fairly exposed, they must be cleared to the inner joint in carrying the incision in this direction, the edge of the knife should always be kept against the bones, and their sinuosities closely followed, so that the ulnar nerve, being dissected out from behind the inner condyle, may escape injury. If the incision be properly planned, and the knife kept in contact with the bone, the nerve ought not to be exposed during the operation, more particularly as it is usually imbedded in a quantity of plastic tissue. When the posterior part of the joint has been laid bare in this way, the knife should be carried round the tip of the olecranon, and this process removed with cutting pliers. By forcibly bending the joint, pushing the forearm upwards, and lightly touching the ligaments with the point of the knife, the interior of the articulation will be fully exposed. By means of a small narrow saw, the articular end of the humerus is separated from the rest of the bone; the upper end of the ulna and the head of the radius may either be removed in the same way, or by means of cutting pliers. There is never any necessity to place a spatula before the bones, as the parts of importance anterior to the joint could not easily be wounded, being completely protected by the brachialis anticus. The ulnar nerve will occasionally, however, be in some danger, and it must be guarded or drawn on one side by a bent copper spatula. In this operation it is of great consequence, so far as the after-utility of the arm is concerned, not to remove more of the bones lengthwise than is absolutely necessary; the shaft of the humerus, for instance, should never be encroached upon, but it will be quite sufficient to limit the excision to the articular surface; should any carious portions of bone extend beyond this, I think it is better to scoop them out with the gouge than to remove them in any other way. The excision of the ulna and radius should not be carried so low as to divide the insertions of the brachialis anticus and biceps. After opening the articulation, a practical question of considerable importance often arises; viz., to what extent the resection of the articular ends should be carried. If they be all diseased, there can of course be no doubt as to the propriety of removing the ends of the three bones. So, also, if the humerus and ulna be diseased, the head of the radius should be cut off on a level with the section of the ulna. But the important point is, whether, in the event of only one bone being implicated, by disease or injury, the surgeon should limit himself to the excision of this alone, or should remove the other two. Formerly, in accordance with the principle of conservative surgery, that diseased or injured parts alone should be sacrificed, I have advocated leaving the healthy articular ends, and only removing that which was diseased; but increasing experience has convinced me that this practice is erroneous, and that, if the joint be only partially excised, ankylosis is more apt to ensue than when the whole of the three articular ends are extirpated. I would therefore advise that, in cases of caries involving the elbow-joint, the whole of the articulation be removed, as well as in those cases in which operation is required in consequence of comminuted and compound fracture of only one of the bones; as, for instance, when the lower epiphysis of the humerus, or the upper end of the ulna only, is the seat of such injury.

In some instances no vessels require ligature, though there may be free general oozing, but most commonly one or two must be tied. In several cases, it is said the bleeding has proved extremely troublesome. This, however, I have never seen. After the operation, the limb should be laid upon pillows, nearly in the extended position, so that the cut portions of bones are in close approximation with one another. If the excision have been

Though a single straight incision, there will be but little if any wound, the flaps falling closely together. If any transverse incision be practised, the edges cannot so readily be brought into apposition. At the end of a week or ten days, when granulations have sprung up, may be put on a slightly bent leather splint, and, as the healing goes on, this may gradually be flexed, until at last it is brought to a right angle. The fibrous union that takes place between the bones will be a more compact and useful false joint will form, than if the articular surfaces be too widely separated in the first instance, and be allowed to unite by a lengthened ligamentous tissue. Until the contraction of the articular surface has fully taken place, and the neighbouring tissues are quite firm, the joint should be supported by one lateral leather splint on the inner side of the arm. The splint should then be removed, the arm put in a sling, and passive motion had recourse to, in order to prevent osseous ankylosis. Should there appear to be, as sometimes happens in children, a special tendency to this, the limb may be laid, before cicatrization has taken place, upon a splint jointed opposite the elbow. Much of the success in the result of excision of this, as of other joints, will depend upon the care and attention bestowed on the after-treatment of the case. The position of the parts and the relation of the bones to one another should be scrupulously attended to, bagging of matter prevented, and exuberant granulations repressed. At the same time, the patient's strength must be kept up by constant attention to diet, fresh air, &c. In this way good ligamentous union will take place. In two cases which I have had the opportunity of dissecting, one sixteen months and the other two years and a half after the

Fig. 254.—Arm after Excision of Elbow Joint.

operation, it was found that the ends of the bones were rounded and firmly united by a dense fibroid or ligamentous structure. In this way a most excellent and useful limb will result, having the four movements of flexion, extension, pronation, and supination nearly perfect, with but little deformity, as may be seen

by the accompanying cut (Fig. 254), which was taken nearly two years after operation from a patient of mine. A coachman, whose elbow-joint I excised, was able to drive, to lift a pail of water, and to do all the duties of his employment, nearly as well as if the arm had been left in its normal condition.

Should recurrence of disease take place, resection may be again resorted to with success. In one case, indeed, which had been unsuccessfully operated on twice by other surgeons, I excised the bones about the elbow for the third time with complete success, removing a considerable portion, nearly three inches, of the necrosed shaft of the humerus and the carious upper ends of the radius and ulna. In this case, which was that of a boy about fourteen years of age, complete recovery took place. He had a most useful arm, regaining the four movements of the joint, pronation, supination, flexion, and extension, and this notwithstanding his being of a most strumous habit of body. Six months after the excision he was obliged to have one thigh amputated for disease of the bone, and he eventually died at the end of two and a half years, of caries of the spine.

Results.—Excision of the elbow-joint, so far as life is concerned, is a very successful operation. I have only lost one patient out of eighteen cases in

which I have done it. The principal danger after this operation arises from diffuse suppuration of the medullary canal of the humerus. I have seen this happen in two fatal cases in the practice of others, phlebitis and pyæmia developing themselves in a secondary manner in both instances; and in a third, in which the patient lost his life, it is probable that death, which was attributed to pneumonia, remotely occurred from the same cause.

The result, so far as utility of limb is concerned, is equally satisfactory. If proper care be paid to the after-treatment, a strong arm, useful for all the purposes of life, with a moveable articulation, will be left, admitting of the four normal movements of the joint, viz., flexion, extension, pronation, and supination. If the whole of the articular ends be excised, and if passive motion be employed, or the limb be kept suspended in a sling merely without splints after a few weeks have elapsed, anchylosis will but very rarely take place. Should there be danger of this occurrence, the patient should be put under chloroform, and forcible flexion and extension employed, or the limb pinned on a splint with a hinge joint and ratchet apparatus, which will shut off its being moved daily by the surgeon; care being taken that it be kept flexed rather than extended. Undue mobility is of but rare occurrence; I have never seen it follow excision for disease, but have met with it in our case—that of a young woman, the lower end of whose humerus was completely disorganised by a fall, and the elbow joint opened. In this case the lower epiphysis of the humerus was excised, together with the articular ends of the ulna and radius. A good recovery took place; but although every care was taken to support the limb on splints, a very moveable joint was left. This I attributed to the whole of the lower epiphysis of the humerus having been extirpated, and the union taking place between its shaft and the bones of the forearm in an imperfect manner.

ULNA OR RADIUS.—One or other of the bones of the forearm has occasionally been excised with advantage, leaving a sufficiently useful limb with good power in the hand. Carnochan of New York and Jones of Jersey have successfully excised the whole ulna. Dr. Butts of Virginia has removed the whole radius. In a woman who was under my care about eight years ago, I also resected successfully the whole radius, with the exception of its articular head, which was sound (Fig. 256); and an useful arm, of which the annexed figure is a good representation, was left (Fig. 255). After a time the hand

gradually inclines towards the radial side of the arm; but, although the articulation between it and the fore-arm is but a slender one, through the medium of the ulna, a very useful member will be left. These operations

do not require any specific rules for their performance; the bone is exposed by a long incision in the direction of, and made by slitting up, the sinuses that burrow amongst the muscles, and is then carefully dissected out from the parts amongst which it lies, especial care being taken to preserve the periosteum and any new bony deposits that may already have been formed. In one case in which the

Fig. 255.—Arm from which Radius has been removed

Fig. 256.—The Radius after removal.

elbow-joint was involved, and the radius diseased, instead of amputating the limb I obtained an excellent result by the excision of the articulation as well as of the affected bone. The patient, a builder about thirty years of age, is able now—four years after the operation—to use his hand not only in all the ordinary purposes of life, but also in his trade.

WRIST.—Excision of the wrist is not an operation that has found much favour with surgeons. Most commonly, when the carpus is diseased, the morbid action rapidly extends, with great constitutional irritation, to all the small bones that enter into its formation; and although in some cases a few of these may have been successfully taken away, yet methodical excision of the whole of the joint has not been followed by very satisfactory results, having either been attended by persistence of the disease in the soft parts, or followed by a stiff and useless hand and arm. A great objection to excision of the wrist consists in the superficial character of the articulation, and its close connection with the flexor and extensor tendons; hence, when the wound cicatrises, consolidation of these and of their sheaths is apt to result, and loss of that utility of hand, the preservation of which should be the great object in the performance of the operation, is entailed. I have lately had a case, however, in the person of a middle aged man, in whom the whole of the carpus and a portion of the bases of the metacarpal bones were removed, and who has recovered with a very useful hand, with some power of flexing and extending the wrist, and with very considerable mobility of the fingers. This case is, however, an exception to the general rule, as in the majority of the few instances in which the operation has been done of late years, either an useless hand has been left, or secondary amputation has been required.

Operation.—The operative procedure varies according to the amount of disease. When only a few of the carpal bones are diseased, they may readily enough be removed, through an extension of any fistulous opening that exist over them. But when the lower articular ends of the radius and ulna are implicated, a more formal operation is required; and its performance is attended by some difficulty, on account of the necessity of saving the extensor tendons of the fingers and thumb. Those tendons, however, that are inserted into the metacarpus, such as the supinators, and the radial and ulnar extensors, may be divided; for as ankylosis will, under the most favourable circumstances, result, their preservation can be attended by no useful object; but the extensor tendons of the fingers and thumb should be carefully protected from injury.

The surgeon has the choice of two modes of exposing the radio-carpal articulation. A horse-shoe flap, with its convexity downwards, may be made on the dorsal aspect of the joint, and then dissected up without dividing the extensor tendons of the fingers; the articulation is thus freely exposed; the carpal bones may be removed, and the lower ends of the radius and ulna clipped off. Or a longitudinal incision may be made on either side of the joint, the lower ends of the radius and ulna removed, and the carpal bones that are diseased, extracted. Of the two operations, I prefer the former, as it gives more room; but even by it, the removal of the bones without cutting across the extensor tendons is a troublesome procedure.

HAND.—In the removal of diseased or injured portions of the hand, it is, as a general rule, of the greatest consequence to sacrifice as little as possible of the healthy or uninjured structures. In all operations on the hand, indeed, we must have two great principles in view,—the preservation of the utility of the member, and the maintenance, so far as practicable, of its symmetry. Utility is necessarily the primary consideration; but if a part be not useful,

it may, as in the case of the head of the middle metacarpal bone in amputation of the corresponding finger, be sacrificed for the purpose of preserving the symmetry of the maimed limb. The hand is the organ of *prehension* and of *touch*; and in all operations applied to it we should endeavour, as far as practicable, to maintain its efficiency in both these respects. It is also of importance to bear in mind that two great classes of actions can be carried out by the hand—those that require force, and those that require delicacy of manipulation rather than strength. By a surgical operation we may sometimes succeed in preserving one, though we are compelled to sacrifice the other; and in this respect, our procedure should be a good deal influenced by the occupation of the patient. Thus, by partial excision, we may leave a hand that would enable a clerk to hold his pen, but which would be almost useless to a labourer or blacksmith.

In looking at the hand from a surgical point of view, we may consider it as being composed of two constituents—the hand proper, and the *Thumb*; the thumb being an accessory hand, an opponent to the rest of the member, through the medium of which the movements of ab- and adduction are chiefly performed, and without which the member is susceptible of a comparatively limited utility, being capable of little beyond flexion and extension. Hence the thumb is of equal importance to the rest of the hand: and the preservation of its three bones is as much to be considered as that of the remaining sixteen that enter into the conformation of the metacarpus and fingers. In all cases of injury or disease implicating the thumb, every effort ought to be made for its preservation. Even if it be left stiffened and incapable of flexion, it will be a most useful opponent to the rest of the hand. Should it be found necessary to shorten it, care must be taken that as little curtailment as possible be practised: a portion of a phalanx, or its metacarpal bone even, is of essential utility in giving strength and breadth of grasp to the hand. In cases of disease, a very useful member may be left by the removal of a portion or the whole of the ungual phalanx, of the metacarpo-phalangeal articulation, or even by the excision of the metacarpal bone, the phalanges being left. These various operations are easy of performance; an incision through the diseased and disorganised soft parts will expose the necrosed bone or carious joint, which must be removed by cutting-pliers or a narrow saw.

When the thumb has been forced back or badly lacerated by powder-flask or gun-barrel explosions, it may often be saved by being replaced and maintained in position on a splint, with light watdressing over it; and should amputation be required, it must be done in accordance with the rule just mentioned, of saving as much as possible of the injured part.

In the conservative surgery of the *Fingers*, the preservation of flexion and extension in the part left is the main thing to be aimed at; a rigid stump is always in the way. The preservation of these movements becomes more important in proportion as the palm is approached. It is of more consequence that the proximal phalanx, which carries the rest with it, should be capable of being bent into the palm, than that the distal can be flexed on the second. If the proximal phalanx can be bent down, a very small degree of movement in the distal one will be sufficient to furnish pliability enough in the finger to make it a useful member; but if the proximal one be stiffened, no amount of mobility in the distal phalanx can make it useful.

In preserving these movements, it is necessary to be particularly careful of the sheaths of the tendons. If they be in any way opened or injured, it will generally be found either that the tendon sloughs, or that it becomes con-

solidated, and matted to its sheath in such a way that all movement is lost, or at least greatly impaired.

The only phalanx that can be excised with advantage is the distal one. It often happens, in the destructive disorganisation which results from whitlow, that this necroses ; when, instead of amputating the end of the finger, it may be removed by an incision on its palmar aspect. Disease of the phalangeal articulations usually leads to amputation of the affected finger. The rules for performing these various operations have already been laid down at pp. 33 *et seq.*, to which I must refer the reader.

Resection of the *Metacarpal Bone*, either of the thumb or index-finger, without the removal of the corresponding digit, is occasionally required, more particularly in cases of injury ; it may readily be done by making a longitudinal incision over the dorsal aspect of the bone to be removed, carefully detaching it from surrounding parts by keeping the edge of the knife close against the bone, avoiding the tendons, and then either disarticulating, or (what is preferable) cutting across the neck of the carpal end of the bone, turning it out, and separating it from any distal attachments which it may retain. After the removal of the metacarpal bone of the index-finger in this way, but very little deformity results, and a very useful hand will be left, more particularly in children, on whom I have more than once had occasion to practise this partial resection with success.

CONSERVATIVE SURGERY OF THE LOWER EXTREMITY.—In all conservative operations that are practised on the lower extremity, it is of essential importance that a good basis of support, of sufficient length and sturdiness, be left to the body. These operations differ thus in some important respects from those that are practised on the upper extremity. In the latter, the preservation of the hand, even though in a mutilated condition, is the thing that the surgeon aims at ; and, provided this be attained, it matters comparatively little how much the arm may be shortened or impaired in power. In the lower extremity, however, strength, length, and solidity are essential to the patient's comfort ; and unless these can be secured, his interests are better considered by the removal of the limb, and the adaptation of some artificial contrivance, than by his being left with a shortened, wasted, and crippled member, which is unequal to support the weight of the body.

HIP-JOINT.—Excision of the head of the thigh-bone has of late years been a good deal practised in some cases of hip-joint disease. This operation may, however, most conveniently be considered in connection with that affection (p. 818).

KNEE.—Excision of the knee-joint may be required either as a substitute for amputation in cases of extensive disease and disorganisation of the articulation, or may be practised in some rare cases of faulty ankylosis resulting from old disease or injury, by which the limb has been rendered useless. This operation, originally practised at the close of last century by Park, Filkin, and the Moreaus, fell into disrepute until it was revived in 1850 by Fergusson, since which time it has been extensively practised.

Operation.—Excision of the knee-joint may be performed by making a horseshoe incision with the convexity downwards, from the side of one condyle of the femur across the tuberosity of the tibia to a corresponding point on the opposite condyle (Fig. 257). By this incision the ligamentum patellæ is divided, and that bone turned up in the elliptical flap, the crucial ligaments, if not already disorganised, are then to be cut across, any remaining lateral attachments divided, and the bones cleared for the saw. In doing this the limb must be forcibly flexed, and the knife carefully applied to the

posterior part of the head of the tibia; for this purpose a blunt-pointed resection-knife is the best. The articular surfaces must now be sawn off. This may best be done by Butcher's saw. The lower end of the thigh-bone should first be removed, and then a slice taken off the tibia by cutting from behind forwards, the blade of the saw being turned horizontally; care should be taken not to remove more bone than is absolutely necessary, lest the limb be too much shortened. It not unfrequently happens that carious cavities are found, extending below the level of the section that has been made (Fig. 258): when this is the case, it is better to apply the gouge to them than to saw the bone below their level. It is usually sufficient to remove from one-third to three-fourths of an inch of the tibia, and about one inch or an inch and a half of the thigh-bone (Figs. 259 and 260). Should,

Fig. 257.—Incision in Excision of the Knee joint

Fig. 260.—Upper End of Tibia, excised.

however, the operation be required for disease of the limb, consequent upon the deformity resulting from badly reduced fractures or dislocations about the knee, as has been done successfully by Dr. Humphry of Cambridge, it may be necessary, in order to bring the limb into good position, to remove a wedge-shaped piece from one of the bones.

If the patella be much diseased, it must be removed; if it be only slightly carious, it may be scraped or gouged out; and if healthy, in accordance

with that principle of conservative surgery by which no sound part is removed, it should be left, becoming consolidated with and strengthening the joint. The anterior articular surface of the thigh bone, which extends some way up its forepart, may advantageously be sliced off, so as to leave an osseous surface, instead of a cartilaginous one, for the patella to attach itself to.

In some cases no ligatures will be required, but usually two or three of the articular arteries furnish sufficient hemorrhage to require restraint. The patella flap when laid down will often appear inconveniently long and thick; but it is better not to curtail it, unless the bones have been shortened more than usual, as it will contract and eventually fit in well.

I have always found the operation, as it has just been described, easy of performance and good in its results; but various modifications are adopted by different surgeons. Thus, some make one straight transverse incision; others two parallel incisions, one on each side of the patella, or an H-shaped incision, and thus open the articulation from the side. The late Mr. Jones of Jersey, who had great experience in this operation, advised that the skin be dissected up by means of a semilunar incision, and then that the ligamentum patellæ be preserved by being pushed with the patella and the quadriceps extensor tendon to one side, the joint then opened, and the bones sawn. Others advise that the patella be removed; and Holt has recommended that, after the excision, the soft parts of the ham be perforated to allow the discharges to drain through.

The result of the operation will mainly depend on the care taken in the after-treatment. After the operation, the limb should be at once put up securely in a Liston's splint, and well supported. Subsequently, when granulations spring up, it may most conveniently be placed in a long leather trough, extending from beyond the foot to the pelvis, and well padded; particular attention being paid to the position of the limb, and especially to the prevention of any bowing outwards which is apt to take place. In order to prevent displacement, it has been proposed to divide the hamstring tendons; this, however, I have never found necessary, nor does it seem to me to be advisable to complicate the operation by such an addition to it. The protuberance of the flap, if at all excessive, may be diminished by the pressure of a many-tailed bandage. In this way osseous ankylosis will ensue, and a good and useful straight limb result. In two cases I have succeeded in getting a good limb with a partially moveable joint: both these cases were in children; and I am disposed to think that in young patients this result may often be satisfactorily attained. In adults, however, osseous ankylosis should always be aimed at.

Results.—In determining the propriety of performing this operation, there are two points to be considered:—1. The Danger attending it; and 2. The nature of the Result.

1. In estimating the *Danger* of excision of the knee-joint, we must compare the results of this operation with those of amputation of the thigh, as a substitute for which it is performed. No surgeon would think of excising a knee-joint that could be saved by ordinary medical treatment, but would only have recourse to the removal of the diseased articulation in those cases in which its condition did not admit of cure, and would consequently necessitate operation. It is, therefore, useless to institute a comparison between the results of excision of the knee-joint and those of treatment for curable affections of that articulation; but we must compare them with those of amputation of the thigh for incurable disorganisation of the joint.

In 1837, according to Butcher, excision of the knee-joint had been per-

performed 182 times since its revival in 1850. Of these cases 15 proved fatal, and in 4 amputation of the thigh was required, of which 1 case had a fatal issue. In some instances there is reason to believe that the unsuccessful result was owing to want of due attention to the after-treatment of the case. Mr. Price has collected the particulars of 160 cases of excision of the knee performed up to December, 1858: of these, 32 were fatal—8 from pyæmia; and to these must be added 60 cases collected by Mr. Clarke of Bristol, of which 6 died—1 from pyæmia: in all 220 cases with 38 deaths.

The mortality after amputation of the thigh has been given at pp. 30-32. In comparing this with the result of excision of the knee-joint, it will be found that there is no very material difference in the rate of mortality after the two operations.

2 The second point that has to be determined, is as to the *Utility of the Limb* after the operation.

On this point, the result of recorded cases is in favour of the operation. In one of Park's cases, operated on in 1783, that surgeon states that the patient (a sailor), seven years after the operation, "was able to go aloft with considerable agility, and to perform all the duties of a seaman." In some of the later cases the result has been equally good. One of Jones's patients (a boy) "could run and walk quickly without any aid of a stick, could stand on the limb alone, and pirouetted and hopped two or three yards without putting the sound limb to the ground." In several of my own cases an excellent strong and straight limb has been left, useful for all ordinary purposes. In a case which I have lately examined, seven years after the operation, the limb is well nourished, straight, firmly ankylosed, and but very little shortened. The patient, a lad of twenty, can walk eight or ten miles, and even jump and stand on the operated limb without the least pain, sign of weakness, or difficulty. In very young children the result of the operation is not satisfactory, the leg continuing shortened and wasted, not developing with the rest of the body. This is apparently due to and dependent upon the removal of the epiphysis of the tibia, on the integrity of which the growth of the limb is dependent.

After the operation, osseous ankylosis takes place with a firm cicatrix; the limb is shortened from one to three inches, according to the amount of bone removed, but by means of a high-heeled shoe this inconvenience is greatly remedied. It has been urged against excision of the knee-joint that convalescence is tedious and prolonged; but this argument can with justice have but little weight. If an useful limb can be preserved to the patient, it can matter but little if a few additional weeks be devoted to the procedure by which it is obtained; and, indeed, it is a question whether in many cases the patient may not be able to walk just as soon after the excision of the knee-joint as after amputation of the thigh: for, as has been very properly remarked, though the amputation-wound may be healed in three or four weeks, it may be as many months before an artificial limb can be worn.

BONES OF THE LEG.—The *Tibia* is very frequently the seat of caries in the upper and lower epiphyses, and of necrosis in the shaft, requiring partial operation for the removal of the diseased portions. Occasionally a very considerable extent of the shaft, indeed the whole of it, may be removed in a state of necrosis; as a loosened sequestrum, from the interior of the periosteum, more or less consolidated and strengthened by the deposit of new bone. Such operations present nothing special, and the result is usually very satisfactory, the limb that is left being strong, useful, and sound.

The *Fibula* is less frequently the seat of operation, but it, like the tibia,

may require partial removal. In one case, that of a child six years of age, I successfully removed the whole of the necrosed fibula. This operation is

Fig. 261.—Limb with Necrosis of Fibula.

Fig. 262.—Limb after removal of Fibula.

readily done by slitting up the sinuses in a direction so as to expose the sequestrum, which may be then drawn out without difficulty (Figs. 261, and 262). After the operation an inner splint must be applied, in order to obviate the tendency to varus which will ensue. In the case from which the annexed drawings are taken, very considerable reparative action was set up in the periosteum and soft tissues along the line of bone that had been removed, new osseous matter apparently being deposited; and the child, when examined two years after the operation, had an excellent, well-nourished, and useful limb. The foot, however, had a tendency to be drawn inwards, apparently owing to the flexors having overcome the antagonism of the peroneal extensors. This deviation inwards was counteracted by the patient wearing a properly constructed boot, with which walking was perfectly easy.

FOOT.—In looking at the division of the foot into its three great component parts—toes, metatarsus, and tarsus,—we shall perceive that firmness of gait is given by the foot resting on the heel behind, and on the ball in front formed by the projection of the broad line of the metatarso-phalangeal articulations, more particularly that of the great toe; whilst elasticity is communicated to the tread by the play of the toes and metatarsal bones. The elasticity of the foot may be lost without any very serious inconvenience to the patient; but the preservation of stability and firmness of gait are of essential importance; and as these are secured by the heel, the ball of the great toe, and the breadth of the anterior part of the foot, these are the most important parts to preserve in all resections of this part of the body.

In no region of the body have the good effects of modern conservative surgery been more distinctly shown than in the tarsus. In the “good old times” of surgery, if a person had a white swelling of the bones of the foot, or a diseased tarsus, he was at once condemned to amputation of the limb. No distinction was made between disease of the different parts of the foot, nor any attempt to save the sound by the sacrifice of the diseased part.

Until a comparatively recent period, indeed, “diseased tarsus” was described as a whole. Surgeons did not endeavour to make out the exact

extent and amount of the disease, and any case described as "diseased tarsus" was looked upon as requiring amputation of the leg. The rule of practice then observed was, amongst the wealthier classes—those who could afford the expense of a "cork leg"—to amputate a little above the ankle; but amongst the poorer classes, to remove the leg about a couple of inches above the knee, so as to give the patient a stump which, when bent, would fit into the socket of a wooden pin. Thus, in the latter case especially, not only was the leg, itself perfectly sound, sacrificed, but the patient was exposed to great additional danger; for if there be one point more than another which has been indisputably proved by surgical statistics, it is, that the mortality after amputation increases, *ceteris paribus*, in exact proportion as we approach the trunk—every additional inch which we remove augments the danger to the patient. This practice continued to prevail until Chopart drew some distinctions between the treatment to be pursued, according as the disease affected the anterior or the posterior tarsal bones and articulations. He showed, that when the anterior articulations only were affected, amputation at the junction of the astragalus and calcaneum with the scaphoid and cuboid—an operation which goes by the name of "Chopart's amputation"—ought to be performed; thus removing the whole of the disease, and allowing the patient to recover with a shortened foot, with the heel preserved—one on which he could bear the weight of his body, and which would be highly useful to him.

The next step in the conservative surgery of the lower extremity, in cases of diseased foot, was the operation introduced by Syme—that of disarticulation at the ankle-joint. This was certainly a great advance; for, the flap being taken from the heel, the patient has a stump on which he can bear. The operation is also a very safe one. According to Dr. O. Weber, 17 deaths only have occurred in 101 cases of this operation. I have performed it nine times without a death, and this, in the lower extremity, is extremely satisfactory.

Since the introduction of anæsthetic agents, conservative surgery has taken great strides; and I think conservatism in surgery may be regarded as the necessary result of anæsthesia. For, although operations of this kind were performed years ago by Park, the Moreaus, and others, and their utility demonstrated, yet the operations of gouging, scraping, and partial resection were so horribly painful to the patient, and occupied so much time in their performance, that surgeons dreaded to undertake them. Of late years surgeons have learned to discriminate disease of one part of the tarsus from that of another, and to apply appropriate treatment to each.

Looking at the subject in a diagnostic point of view—and the treatment is most intimately connected with the diagnosis—we find that the pathology of diseases of the tarsus is closely connected with its healthy anatomy. Composed, as it is, of seven bones, it presents four distinct articulations. By the term "articulation," applied to the tarsus, I do not mean merely the connection of contiguous bones with each other, but distinct synovial sacs shut off from communication with other synovial sacs in the foot. There are well represented in the diagram on next page (Fig. 243). The posterior calcaneo-astragaloid is the first of them; next comes the (a) anterior calcaneo-astragaloid, the synovial membrane here serving also for the astragalus-scaphoid; the calcaneo-cuboid (b) is the third, and the anterior tarsal synovial membrane (c) is the fourth and largest of all, and the most important in a surgical aspect. It extends between the scaphoid and the three cuneiform and the cuboid bones, between the cuneiform bones themselves, between the two outer cuneiforms and the bases of the second and third meta-

tarsal bones, and also between the external cuneiform and the cuboid. The

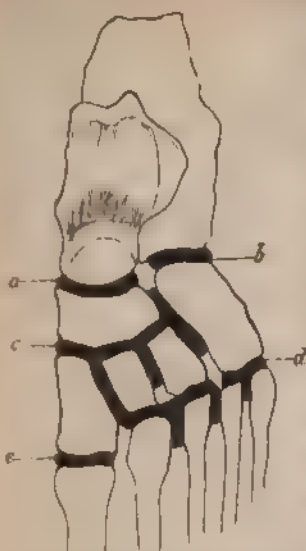

Fig. 263.—Articulations of the Foot

articulation between the cuboid and last two metatarsal bones is shown at *d*; and *e* is that between the internal cuneiform and the first metatarsal bones. These two (*d* and *e*) are not, strictly speaking, tarsal joints.

In the vast majority of cases, so far as my experience goes, it is the osseous structures, and not the articulations, which are primarily diseased. The bones, being cancellous, far removed from the centre of circulation, and exposed to alternations of temperature, readily become the seat of congestion and caries, rarely, however, of necrosis; and in strumous subjects not unfrequently fall into a tuberculous condition. Caries, whether simple or tuberculous, once set up in bones, speedily implicates the articulations secondarily.

Now it is easily understood, on casting an eye on the arrangement of the tarsal synovial membranes, that the extent of disease will, in a great measure, depend upon its seat. Thus, a person may have disease in the os calcis, extending even to the cuboid, with very little likelihood of its proceeding further for a length of time. Such disease will be limited to the outer part of the foot, does not involve its integrity, and readily admits of removal by operation. But let him have disease springing up in the scaphoid, or in one of the cuneiform bones, or in the bases of the second or third metatarsal bones, and the morbid action will rapidly spread through the whole of the anterior and inner part of the tarsus, and, in all probability, no operation of resection can be advantageously employed. Hence the seat of disease influences materially its amount and extent, and the kind of operation required for its removal.

The foot is frequently the seat of strumous disease; to this it is disposed by the alternations of temperature to which it is subjected, by its liability to sprains and injuries, and by the cancellous and spongy structure of its bones, together with its extensive articulating surfaces. When affected by strumous inflammation it becomes painful, the patient being unable to bear upon the toes or anterior ball of the foot. Swelling of an uniform character takes place, with tenderness at some point opposite the bones or articulations that are chiefly involved; and eventually abscess forms, leaving sinuses through which the probe passes down upon softened and carious bone. These evidences of disease are usually much marked about the dorsum and sides, the sole being often comparatively free from disease—an important point in reference to operation.

Strumous disease may commence either in the bones, or in the articulations of the foot. The bones that are most frequently the seat of primary disease are the calcaneum, the astragalus, the scaphoid, the cuboid, and the metatarsal bone of the great toe. When disease is limited to one or two of these bones, excision is usually practicable; but when the morbid action extends, through the influence of the connecting articulations, to other bones of the tarsus or metatarsus, partial amputation will be required.

Primary disease of the articulations of the foot is a less frequent cause of operation than caries of the tarsal bones leading secondarily to an implication of the contiguous articulations; and the particular operation required will, in a great measure, depend upon the extent of implication of the synovial membranes of the foot. When the calcaneo-astragaloid or the calcaneo-cuboid articulations are alone affected, with their contiguous bones, resection of the bones and joints implicated will often be attended by very satisfactory results; but when the large anterior tarsal synovial membrane is in a state of chronic disease, either as the result of primary morbid action set up in it, or secondarily to diseases of the scaphoid, the cuneiform, or of either of the metatarsal bones connected with it, then resection is scarcely admissible, and Chopart's amputation offers the best means of relief. The inflammation of the large and complicated anterior tarsal synovial membrane commonly commences in disease of the scaphoid. It may, usually, readily enough be recognised in its earlier stages by the pain and swelling that take place across the line of articulation between the scaphoid and cuneiform bones, the pain being greatly increased by bending the foot down, and extending across the whole breadth of the foot. For, although it is usually most severe at the inner side, which is the first affected, yet the external section of this complicated articulation, that between the external cuneiform and the cuboid, becoming involved, causes suffering to be experienced on the outer side of the foot as well. In the more advanced stages of this particular disease, the foot assumes a remarkable bulbous or clubbed appearance; the symmetry of the heel and the outline of the ankle are unimpaired, but the forepart and dorsum of the foot are greatly swollen, glazed, and possibly perforated by sinuses discharging thin unhealthy pus. I look upon this disease of the anterior tarsal synovial membrane as a distinct affection of the foot, requiring to be diagnosed from the other strumous inflammations, and in its advanced stages requiring Chopart's amputation.

TARSAL BONES.—Any one of the tarsal bones may be the seat of primary disease, which morbid action may be limited to the bone originally implicated, or may extend to neighbouring articulations, or through the whole tarsus. There are, however, four bones which may be looked upon as the most frequent centres of tarsal disease—viz., the Os Calcis, the Astragalus, the Scaphoid, and Cuboid; and they are commonly affected in the order given. Their diseases we shall now proceed to consider.

The *Os Calcis*, from its exposed situation, large size, and spongy structure, is more frequently the seat of caries and necrosis than any of the other tarsal bones. Very commonly the morbid action is limited to this bone; in other instances it extends into the calcaneo-astragaloid or calcaneo-cuboid articulations.

When the disease is situated in the *posterior or lateral parts of the bone*, the neighbouring articulations are seldom involved, and then the removal of the morbid structures by gouging will usually succeed in effecting a cure. I have frequently had occasion in this way to scoop out great portions, sometimes the whole of the interior of the calcaneum, with the most excellent results. Even when the cuboid is extensively implicated as well, and the calcaneo-cuboid articulation is the seat of diseased action, the disorganised structures may often be removed by gouging and partial resection, as in the case of which the cut (Fig. 264) is a good representation, where, by means of a \perp -shaped incision, these bones were exposed, and their carious portions gouged out. Should, however, the caries have affected the *superior or anterior portions of the bone*, then the implication of the astragaloid or cuboid articulations may render the excision of the whole bone necessary,

as the only means of preventing extension of secondary morbid action to the tarsus generally. So infrequent, however, is disease of the articular

Fig. 264.—Disease of Os Calcis and Cuboid, and of Calcaneo-Cuboid Joint. Lines of Excision.

aspects of this bone, that its complete removal is very seldom necessary. Out of eighteen or twenty cases of caries of the os calcis that have been under my care, I have never had occasion to excise the bone but once; and Fergusson states that he has never yet found it necessary to do this operation. Indeed, excision of the os calcis should not be lightly undertaken. The large size of the bone, its importance as a basis of support to the body, and as the point of at-

tachment to the strong muscles of the calf, should induce the surgeon, whenever practicable, to avoid its complete extirpation, and to limit himself to the application of the gouge, even though he may have to scoop out the whole of the interior of the bone, leaving little more than an osseous shell. This will fill up by the deposit of a dense fibroid tissue, which probably, eventually undergoing partial ossification, leaves the foot as useful as ever for all purposes of support and progression.

Mr. Greenhow, lately of Newcastle, appears to have been the first surgeon who successfully excised the whole of the os calcis. This case occurred in 1848; and since then the operation has been performed in a considerable number of instances in this country and in America, and established as one of the many important developments made by conservative surgery of late years. In France, however, it seems to have found little favour, if indeed, it has been performed. Guérin, one of the most recent French writers on operative surgery, states that excision of the os calcis should not be attempted, and gives as his only reason for describing the operative procedure, that English surgeons have not feared to undertake it.

The operation is a very successful one, and leaves a flat but useful foot. Occasionally, however, after the removal of the bone, disease is set up in the neighbouring parts requiring amputation; this I have seen more than once happen; and of 10 cases collected by Mr. T. M. Greenhow, it became requisite in 2 eventually to remove the foot.

Operation.—Excision of the os calcis is usually performed by turning a heel-flap back, as in disarticulations at the ankle-joint, and then carrying incisions forward into the sole of the foot, by which another flap is turned up, and the calcaneo-cuboid articulation exposed and opened (Fig. 33), after which the knife is carried between the astragalus and calcaneum, and the latter bone detached. By this operation the sole of the foot is somewhat extensively incised, and cicatrices are left over the heel.

In order to avoid this inconvenience, I have found that disarticulation of the os calcis may readily be performed in the following way. The patient lying on his face, a horseshoe incision is carried from a little in front of the calcaneo-cuboid articulation round the heel, along the sides of the foot, to a corresponding point on the opposite side. The elliptic flap thus formed is dissected up, the knife being carried close to the bone, and the whole under-surface of the os calcis thus exposed. A perpendicular incision, about two inches in length, is then made behind the heel, through the tendo Achillis,

in the mid-line and into the horizontal one. The tendon is then detached from its insertion and the two lateral flaps are dissected up, the knife being kept close to the bones, from which the soft parts are well cleared (Fig. 265). The blade is then carried over the upper and posterior part of the os calcis, the articulation is opened, the interosseous ligaments are divided, and then, by a few touches with the point, the bone is detached from its connections with the cuboid. This bone, together with the astragalus, must then be examined; and if any disease be met with, the gouge should be applied. Should anchylosis have taken place between the os calcis and the astragalus, as I have found in one case, the bones may readily be divided by means of Butcher's saw. By this operation all injury to the sole is avoided; and, the open angle of the wound being the most dependent, a ready outlet is afforded for the discharges.

The following drawing (Fig. 266) gives an excellent representation of the state of the foot of a girl before and after the excision of a diseased os calcis—a somewhat flattened but most useful foot resulting:—

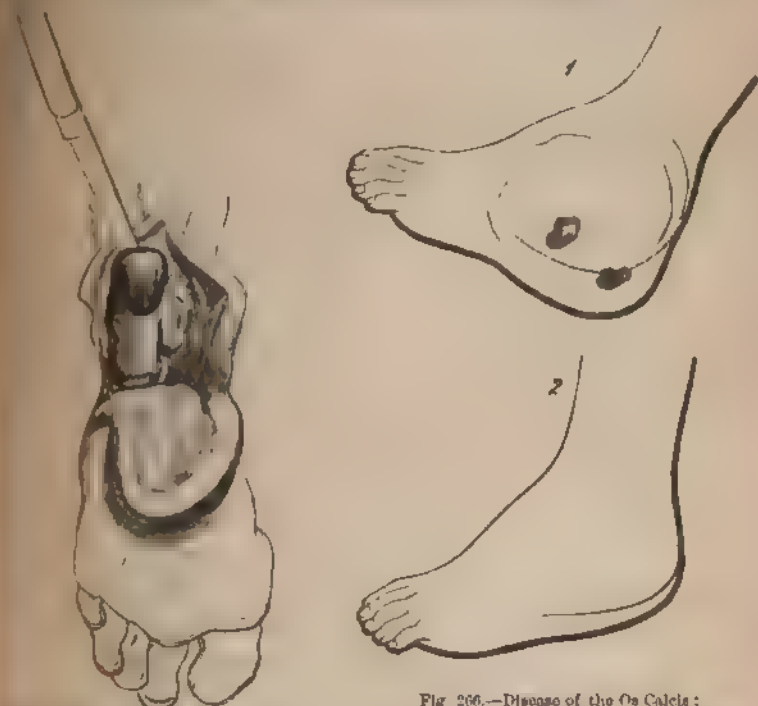

Fig. 265.—Excision of the Os Calcis.

Fig. 266.—Disease of the Os Calcis:

1. Foot before Operation, 2. Foot after Excision.

The *Astragalus* is situated in a position of great surgical importance. Articulating with the malleolar arch above, with the calcaneum below, and with the scaphoid in front—forming, as it were, the keystone of the foot—it is perfectly evident that any morbid action commencing in it is very likely to spread to and involve all the more important structures of the foot. Seldom, indeed, does disease originating in this bone long remain confined to it; and, so far my experience goes, gouging operations, even if performed at an early period, are rarely of much benefit, the morbid action continuing to extend notwithstanding their employment. Indeed,

in diseased astragalus, I believe that excision ought, as a rule, to be practised in preference to gouging, contrary to what is the case in the calcaneum.

Disease primarily originating in the astragalus may spread in three directions: upwards into the ankle-joint, downwards to the calcaneum, and sideways to the scaphoid, and thence through the large anterior tarsal ligaments to the rest of the tarsal bones. The treatment will vary according to the direction and extent of the disease. It may be arranged under two heads.

1. When the astragalus alone is diseased, we find what is seen in the drawing below (Fig. 267), which represents the foot of a boy whose

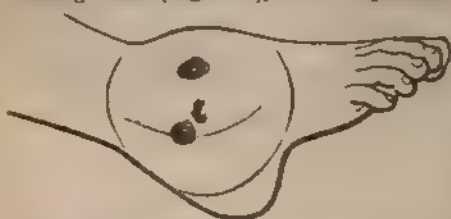

Fig. 267.—Disease of Astragalus.

astragalus I excised—a sinus was in front of the malleolar arch, with fistulous openings leading down to the diseased astragalus; the anterior part of the foot and the heel were quite sound. If the excision be limited to the outer side of the bone, or to its head, it is possible that, by freely opening up the sinuses and applying the gouge, the caries may be entirely removed. But this operation is not so satisfactory here as elsewhere in the foot, as it is by no means easy to avoid opening the astragalo-scapoid articulation; and if this be done, disease will almost inevitably extend through the tarsal articulations. Excision of the astragalus alone, though sometimes required for disease, is perhaps more frequently called for in those cases of compound dislocation in which the bone, having been thrown out of its bed, eventually becomes carious or necrosed. The operation may be done by making an incision across the outer and anterior aspect of the ankle, exposing the bone, cutting across its neck with pliers, and then with strong forceps freely elevating it from its bed and detaching it by the cautious application of the knife, more particularly to the inner side, where the plantar arteries are in danger. If the bone has been dislocated, and its ligamentous connections thus torn through, or if these have been disorganised and softened by disease, it may readily enough be removed as just described. But if the osseous tissue itself be carious and softened, and the ligamentous connections tolerably sound, then the operation becomes extremely troublesome, tedious, and prolonged—the bone breaking down, and having to be removed piecemeal by means of the gouge and pliers. The result of this operation is very satisfactory; a good and moveable articulation may be left between the malleoli and calcaneum, and the limb is but little shortened.

2. When the disease has extended from the astragalus to the malleolar arch, excision of the ankle-joint will be required. This operation may most conveniently be performed in the following way. A semilunar incision, about four inches in length, should be made along the outer and anterior aspect of the joint, round the lower border of the external malleolus (Fig. 268), and should be carried sufficiently forwards to give space without dividing the extensor tendons or the dorsal artery. A perpendicular cut should then be made along the fibula. The peroneal tendons having been divided, the lower end of the fibula should be cut across and detached. The astragalus, which will now be exposed, should then be separated from its connections, which, if they be much diseased, may usually be readily done.

deeply affected, it will be more firmly held, and should then be cut with pliers, and each fragment lifted out of its bed with gouge or

The foot now be well exposed to the inner side of the lower end of the tibia, the tibia being isolated; the tibia being with great care and kept in position, the bone, the posterior artery be

When the ligamentous tissue is attached to the bone have been separated, the

talus may be cut off with bone-forceps, and as much as necessary of the lower end of the tibia removed by a gouge or a chain-saw. Should any disease in the articular surfaces of the calcaneum or scaphoid be gouged away.

It should then be dressed, and the limb in a Laston's splint.

When the disease has spread from the astragalus into the malleolar and downwards into the calcaneum, the line of incision will depend on the extent of the implication of the talus. If the greater part of the whole of this be removed, no resource is left but amputation — resection of the foot.

However, the calcaneum is partly involved, its surface only being diseased, a great deal may be saved by conservative sur-

The treatment in such cases consists, generally, in separating the astragalus from the calcaneum and gouging away the diseased bone which may be either on the upper or under surface of the arch. Very large pieces of bone may be removed from this situation.

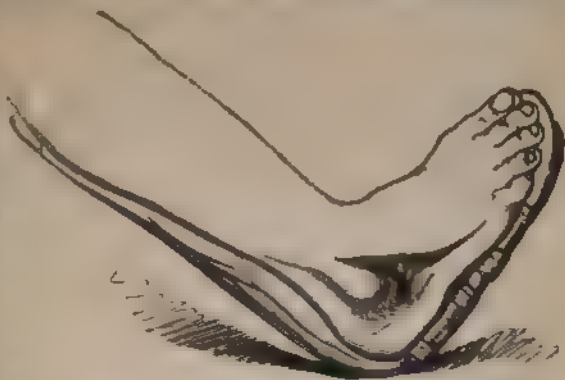

Fig. 268 — Limb after Excision of the Ankle joint.

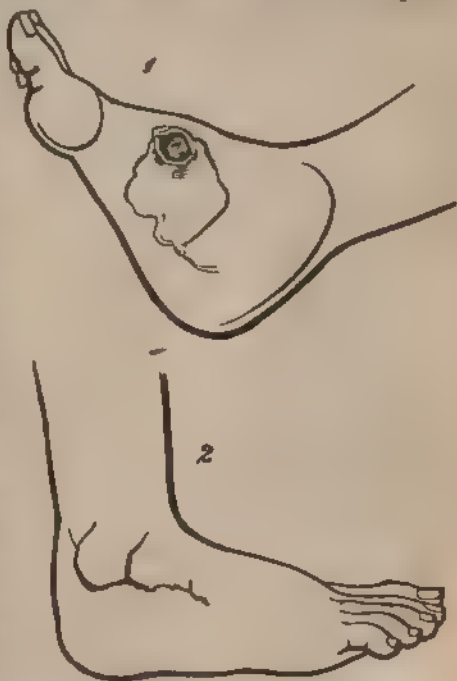

Fig. 269 — Excision of Astragalus.

(1) Foot before Operation. (2) Foot six months after the Removal of the Malleolar Arch, the Malleolus, the Astragalus, and a portion of the Upper Surface of the Calcaneum.

I have taken away the whole of the mal-

leolar arch and astragalus, and gouged out the upper surface of the os calcis very freely; and yet the patient has recovered with a strong and movable foot, but very little shortened or deformed.

The preceding cuts (Fig. 269) are taken from a young man on whom I performed the operation just described. The foot is perfectly movable and strong, and the false joint at the ankle moveable. There are cases, however, in which we find that the disease has extended so far beyond its primary seat, that amputation rather than resection is required. But in the majority of instances, removal of the astragalus and gouging away the upper surface of the calcaneum will suffice.

4. If the disease have extended from the astragalus to the scaphoid, and thence into the anterior range of tarsal joints, the foot will have become extensively disorganised, that partial resection will be of little or no service, and disarticulation at the ankle-joint should be practised.

Excision of the *Cuboid Bone*, either in whole or in part, may be required. Partial excision is here done with the gouge. When the whole of the bone is taken away, the fifth metatarsal bone with the little toe will probably require removal. This may be done by making the flap, as depicted in Fig. 27, only commencing the incision about an inch further back, towards the calcaneo-cuboid articulation, and opening this instead of the metatarsal cuboid.

The *Scaphoid* is very commonly the seat of primary disease; and as this bone is connected in front with the large tarsal synovial membrane, and posteriorly with that which is common to the calcaneo-astragalum and astragalo-scaphoid articulations, the greater part of the tarsus is apt to become speedily involved in the morbid action. It stands, indeed, next to the astragalus in its power of implicating a great extent of the foot in disease. The extent of this implication is such that excision of the primarily diseased bone would probably seldom be attended by much benefit, and Chopart's amputation or disarticulation at the ankle-joint would be necessary.

Next to disease of the astragalus, I look upon strumous inflammation and caries of the scaphoid as most destructive to the integrity of the foot.

Fig 270.—Disease of Cuneiform Bones.

When the *Cuneiform Bones* are the seat of caries, it will generally be found that the middle cuneiform is the bone primarily affected. Thence the disease extends to the lateral and to the bases of the second and third metatarsal bones (Fig. 270). In such cases the anterior tarsal synovial membrane usually becomes extensively implicated, and Chopart's amputation will be required. But if the morbid action continue to be limited to the middle cuneiform and the contiguous metatarsal bone, and the patient's general health be good, removal of the diseased osseous structures with the gouge, with extraction of the caries of the cuneiform, may be attended by successful results.

In chronic disease of the ankle and of the tarsal bones, it will occasionally happen that an excellent and useful foot may be left, after excision, of a less formal kind than those just described. In a lad who was some time since under my care with very extensive

In chronic disease of these parts, I removed the lower three inches of the fibula, and gouged away considerable portions of the end of the tibia and of the astragalus, calcaneum, and cuboid—removing a whole handful of carious bone. yet a perfect cure resulted, the patient recovering with a strong and useful foot. In infants and very young children, disease of the tarsal articulations and even bones may often be recovered from, without the necessity of having recourse to operation, by attention to the child's general health, and by giving the part rest.

The Malleoli alone seldom require resection. Should either of them do so, the operation may readily enough be accomplished, in the outer malleolus, by dividing the bone with cutting-pliers; but in the inner malleolus, more care is required in avoiding the flexor tendons, the artery and nerve, and the bone had better be cut across with a chain-saw. The removal of the outer malleolus, or rather of the lower end of the fibula, is apt to be followed by the inconvenience of a tendency to twist of the foot outwards,—in fact, to a kind of valgus.

The Metatarsal Bones with their Toes occasionally require removal. This is more particularly the case with the first and the fifth (pp. 41, 42). The middle metatarsal bones cannot advantageously be taken away, leaving merely the first and last; but the two, three, or even the whole four of the external metatarsal bones may be advantageously resected, and an useful foot left. Aston Key has recorded a case in which, in consequence of injury, he amputated the four outer metatarsal bones, the cuboid, and the external and middle cuneiform, leaving merely the line of bones supporting the great toe. The first metatarsal bone was left, supported only by the slender articular surface of the internal cuneiform; but it soon got firmer attachments, and a very good foot resulted, by which the patient retained in a great measure his elasticity of tread.

The Phalanges and Articulations of the Toes seldom require resection; as a general rule, their amputation is preferable. The only case with which I am acquainted where resection of a phalanx is required, is when an exostosis has formed under the nail of the toe, pushing it up: here the removal of that portion of bone from which it springs is the best course to pursue.

The Great Toe not unfrequently requires removal, in whole or in part; but, as it enters largely into the formation of the arch of the foot, no more of it should be taken away than is absolutely necessary. It is especially of importance that the ball of the great toe be, if possible, preserved; and occasionally this may be effected by excision of the metatarsophalangeal articulation rather than by the amputation of the member. With regard to the removal of the toe and its metatarsal bone, I must refer to p. 41. Whenever it is practicable, the proximal end of the bone should be saved, in order that the insertion of the tendon of the peroneus longus may be preserved.

AMPUTATION IN JOINT-DISEASES.—In those cases in which excision of the diseased joint is not advisable, in consequence of the acute character of the articular disease, the existence not only of considerable suppuration but of great local and constitutional irritation, or the peculiar nature of the joint affected, amputation may be the sole resource left to the surgeon. It is especially in articular disease of the fingers and toes, of the tarsus, carpus, ankle, and knee, that this operation is required; and though it is much less frequently practised now than formerly, yet the cases of destructive disease of joints requiring amputation are amongst the most frequent in operative surgery, and will doubtless continue to be so. The surgeon, however, must

leolar arch and astragalus, and gouged out the upper surface of the os calcis very freely; and yet the patient has recovered with a strong and moveable foot, but very little shortened or deformed.

The preceding cuts (Fig. 269) are taken from a young man on whom I performed the operation just described. The foot is perfectly useful and strong, and the false joint at the ankle moveable. There are cases, however, in which we find that the disease has extended so far beyond its primary seat, that amputation rather than resection is required. But in the majority of instances, removal of the astragalus and gouging away the upper surface of the calcaneum will suffice.

4. If the disease have extended from the astragalus to the scaphoid, and thence into the anterior range of tarsal joints, the foot will have become so extensively disorganised, that partial resection will be of little or no service; and disarticulation at the ankle-joint should be practised.

Excision of the *Cuboid Bone*, either in whole or in part, may be required. Partial excision is here done with the gouge. When the whole of the bone is taken away, the fifth metatarsal bone with the little toe will probably also require removal. This may be done by making the flap, as depicted in Fig. 27, only commencing the incision about an inch further back, opposite the calcaneo-cuboid articulation, and opening this instead of the metatarsal-cuboid.

The *Scaphoid* is very commonly the seat of primary disease; and as this bone is connected in front with the large tarsal synovial membrane, and posteriorly with that which is common to the calcaneo-astragaloid and astragalo-scaphoid articulations, the greater part of the tarsus is apt to become speedily involved in the morbid action. It stands, indeed, next to the astragalus in its power of implicating a great extent of the foot when diseased. The extent of this implication is such that excision of the primarily diseased bone would probably seldom be attended by much benefit, and Chopart's amputation or disarticulation at the ankle-joint becomes necessary. Next to disease of the astragalus, I look upon strumous inflammation and caries of the scaphoid as most destructive to the integrity of the foot.

Fig. 270.—Disease of Cuneiform Bones.

When the *Cuneiform Bones* are the seat of caries, it will generally be found that the middle cuneiform is the bone primarily affected. Thence the disease extends to the lateral ones, or to the bases of the second and third metatarsal bones (Fig. 270). In such cases the anterior tarsal synovial membrane usually becomes extensively implicated, and Chopart's amputation will be required. But if the morbid action continue to be limited to the middle cuneiform and the contiguous metatarsal bones, and the patient's general health be good, removal of the diseased osseous structures by the gouge, with extraction of the carious cuneiform, may be attended by successful results.

In chronic disease of the ankle and of the tarsal bones, it will occasionally happen that an excellent and useful limb may be left, after excision, of a less formal kind than those just described. In a lad who was some time since under my care with very extensive and

the tumour joints, the question of amputation under these circumstances becomes one of very considerable importance. If the phthisis be rapidly increasing, and there be a strong hereditary tendency to the disease, or if it have advanced to softening of the lung and the formation of vomica, it will be useless to operate. If, however, the phthisis be very slight and incipient, and be apparently due to the local irritation of and discharge from the diseased joint, to the confinement to bed that this necessitates, and to the general deprivation of health that ensues, amputation may not only be safely but advantageously practised; and I have performed it in many such cases to the manifest advantage of the patient.

CHAPTER L.

DISEASES OF THE SPINE.

SPINA BIFIDA.

It occasionally happens that, from congenital malformation, the spinous processes of some of the vertebrae are deficient, and their laminae either absent or separated; in consequence of which, the meninges of the spinal cord are unprotected, and project through the aperture in the bones, giving rise to a tumour at the part where the arrest of development in the osseous structures occurs.

CHARACTERS.—The tumour is usually oval, its long axis corresponding with that of the spine. It generally varies in size, from that of a walnut to an orange; but occasionally it attains an immense bulk, equal to that of a child's head. In some cases the tumour is lobulated, having an imperfect septum stretching across it; in other instances, two or more of these tumours have been met with in the spine. The skin covering it is usually of its normal colour; but when the tumour is of considerable size, it may be thin and have a bluish or congested appearance, and present a certain degree of transparency. In these circumstances, ulceration from distension and thinning of the skin may eventually take place. On examining the tumour, which is hard though elastic when the child is held upright, it will be found that it becomes soft when the child is laid horizontally. It usually becomes tense during expiration, and softer during inspiration. In some cases fluctuation is perceptible, and by pressure the bulk may be lessened.

Spina bifida may be met with in any part of the vertebral column; it is, however, almost invariably found in the lumbar region, the cases in which it appears higher up being of rare occurrence; instances of the kind are, however, mentioned by Cruveilhier. When it occurs higher up, in the cervical or upper dorsal region, it has been found that the spinal cord and nerves are usually adherent to the walls of the tumour; in the lumbar region this is not the case.

The fluid contained in the tumour is of a clear limpid character. It contains chloride of sodium; and, as in the cerebro-spinal fluid, a trace of sugar is generally present.

PROGNOSIS.—The prognosis of spina bifida will depend upon the size of the tumour and on the condition of the skin covering it. If it be of small size, with healthy integumental investment, and without a tendency to increase, the patient may live to an adult age, provided care be taken to protect the tumour. If of large size, it is generally fatal, the child usually

be careful, whilst he avoids continuing to make ineffectual attempts to save the limb at the great hazard of the patient's life, not to amputate until it is clear that all other means have failed; the patient continuing to lose ground so, that a further perseverance in local and constitutional treatment would probably end in his death, excision not being practicable. So far from amputation being an opprobrium to surgery in such cases as these, I look upon it as one of the greatest triumphs of our art, that by a simple and easy operation, which removes the spoiled and useless limb, the life of the patient may be saved, and his health speedily restored.

In amputating in cases of chronic joint-disease, where the limb has been the seat of prolonged suppuration, it will be found, just as in cases of many secondary amputations after injuries, that the condition of the muscles of the limb is peculiar. Instead of, as in cases of primary amputation, being dark in colour and retracting forcibly and unequally when cut across, they will be found to be pale, soft, flabby, and retracting but little if at all; resembling in this respect the muscles in a dead body, with the inter-muscular cellular tissue often infiltrated. In consequence of this alteration in their structure and physiological properties, the flaps need not be cut so long in amputation for chronic suppurative joint-disease as in cases of primary amputation.

Circumstances influencing Mortality.—The mortality after amputation for joint-diseases is specially influenced by three conditions: viz, the seat of the operation, the acute or chronic character of the disease, and the constitutional condition of the patient.

The influence of the seat of operation has already been discussed at p. 28.

The duration of the disease exercises a most important influence, especially in the larger joints—more particularly the knee. As a general rule, it may be stated that, the more acute the suppurative destruction of a joint, the less successful is the amputation of the limb likely to be; pyæmia and low secondary inflammation being especially apt to supervene.

In very acute cases, the surgeon ought to evacuate the pus by means of free incisions, and endeavour to delay the necessity of amputation until the active suppurative stage has passed, and the affection has subsided into a chronic form. In chronic cases, the success of amputation is very great. It commonly happens that a patient who has been racked with pain, and been wasting in body for weeks before the local source of irritation was removed, sleeps soundly the night after the operation, and rapidly gains flesh and strength.

In determining upon the advisability of resecting a diseased joint or of amputating the limb, the surgeon must be guided not only by the amount of disease in the articulation, but by the constitutional condition of the patient. In amputation the chief dangers are immediate—from shock, or secondary hemorrhage. In excision the shock is not so severe, in consequence of the incision being farther from the trunk, and through comparatively superficial and unimportant parts; no large bloodvessels, nerves, or even muscles are divided, and there is no danger of secondary hemorrhage. But in excision the dangers are chiefly remote; the suppurative process is long continued, and the discharge of pus abundant, the patient may consequently not have sufficient constitutional power to carry him through. So far as erysipelas and pyæmia are concerned, the danger is probably the same in both operations. In addition to this, it must be borne in mind that a patient will often consent to have a joint or bone excised who would not agree to part with a limb.

As phthisis not unfrequently co-exists with the advanced forms of

struous joints, the question of amputation under these circumstances becomes one of very considerable importance. If the phthisis be rapidly progressing, and there be a strong hereditary tendency to the disease, or if it have advanced to softening of the lung and the formation of vomica, it will be useless to operate. If, however, the phthisis be very slight and incipient, and be apparently due to the local irritation of and discharge from the diseased joint, to the confinement to bed that this necessitates, and to the general deprivation of health that ensues, amputation may not only be safely but advantageously practised; and I have performed it in many such cases to the manifest advantage of the patient.

CHAPTER L.

DISEASES OF THE SPINE.

SPINA BIFIDA.

It occasionally happens that, from congenital malformation, the spinous processes of some of the vertebræ are deficient, and their laminae either absent or separated; in consequence of which, the meninges of the spinal cord are unprotected, and project through the aperture in the bones, giving rise to a tumour at the part where the arrest of development in the osseous structures occurs.

CHARACTERS.—The tumour is usually oval, its long axis corresponding with that of the spine. It generally varies in size, from that of a walnut to an orange; but occasionally it attains an immense bulk, equal to that of a child's head. In some cases the tumour is lobulated, having an imperfect septum stretching across it; in other instances, two or more of these tumours have been met with in the spine. The skin covering it is usually of its normal colour; but when the tumour is of considerable size, it may be thin and have a bluish or congested appearance, and present a certain degree of transparency. In these circumstances, ulceration from distension and thinning of the skin may eventually take place. On examining the tumour, which is hard though elastic when the child is held upright, it will be found that it becomes soft when the child is laid horizontally. It usually becomes tense during expiration, and softer during inspiration. In some cases fluctuation is perceptible, and by pressure the bulk may be lessened.

Spina bifida may be met with in any part of the vertebral column; it is, however, almost invariably found in the lumbar region, the cases in which it appears higher up being of rare occurrence; instances of the kind are, however, mentioned by Cruveilhier. When it occurs higher up, in the cervical or upper dorsal region, it has been found that the spinal cord and nerves are usually adherent to the walls of the tumour; in the lumbar region this is not the case.

The fluid contained in the tumour is of a clear limpid character. It contains chloride of sodium; and, as in the cerebro-spinal fluid, a trace of sugar is generally present.

PROGNOSIS.—The prognosis of spina bifida will depend upon the size of the tumour and on the condition of the skin covering it. If it be of small size, with healthy integumental investment, and without a tendency to increase, the patient may live to an adult age, provided care be taken to protect the tumour. If of large size, it is generally fatal, the child usually

there may be no appearance of excurvation. In these cases of caries *without angular curvature*, it will be found that the spine has lost its natural free mobility and flexibility, moving fixedly, stiffly, and as a whole when the patient leans forwards or sideways. The patient, when laid flat on his back, cannot raise himself into a sitting position without the aid of his hands or elbows, and he cannot turn sharply and suddenly over upon his face. Occasionally the incipient curvature, when it occurs, assumes more of a lateral than of an angular direction. The lower limbs now become weak, and the patient walks with a peculiar shuffling tottering gait, the legs being outspread, and the feet turned out. The weakness of the limbs is especially marked in going upstairs, and may be tested by directing the patient to stand unsupported on one leg, and raise the other so as to place the foot upon the seat of a chair, which he will probably be unable to do. The deformity of the spine now slowly increases; the patient becomes unable to stand; and spasms of the muscles of the lower extremity come on, together with a tendency to relaxation of the sphincter ani, and retention of urine.

Abscess now commonly makes its appearance; and in some cases it occurs before any of the other signs except pain and weakness of the spine, but certainly before any deformity has taken place. When the abscess forms, as Stanley has observed, the pain and irritation of the spinal cord are usually lessened for a time.

It must not, however, be supposed that abscess necessarily forms in all cases; indeed, the formation of matter will, I believe, chiefly depend upon whether the disease of the vertebrae be tuberculous or not. Simple congestive or inflammatory caries of the spine may take place to a very considerable extent, and yet no suppuration occur; the bodies of the vertebrae undergoing erosion and absorption, and coalescing so as to become fused together into one soft and friable mass of bone, across which bridges of osseous tissue are sometimes thrown out, so as to strengthen the otherwise weakened spine. In these cases, masses of porcellaneous deposit will not unfrequently be found intermixed with and adherent to the carious bone. Indeed, this anchylosis and fusion of the bodies of the diseased vertebrae may be looked upon as the natural mode of cure of angular curvature of the spine; the only way in which it can take place when once the disease has advanced to any considerable extent.

When abscess forms in connection with diseased spine, it is probably the result of the continued irritation produced by the tuberculous deposit; and it may become the most prominent and marked feature of the affection, giving rise almost to a distinct and independent disease. The situation and course of the abscess depend entirely upon the part of the spine affected; thus, for instance, when the cervical vertebrae are diseased, the abscess may come forwards behind the pharynx, and may occasionally extend under the sterno-mastoid muscle to the side of the neck, where it opens, sometimes, though very rarely, it passes into the chest, and in other cases down into the axilla. When the disease is seated in the dorsal vertebrae, it usually passes forwards under the pillars of the diaphragm, down the side of the aorta and the iliac vessels, into the iliac fossa, and then presents through the anterior wall above Poupart's ligament; sometimes the pus sinks into the pelvis, and then passes out through the sacro-sciatic notch, giving rise to a large accumulation in the *gluteal* region. In other instances, again, the pus passes directly backwards, and large dorsal or lumbar abscesses are the result. In other cases, when the lower dorsal or upper lumbar vertebrae are diseased, the pus enters the sheath of the psoas muscle, thus constituting the common affection termed *Psoas Abscess*; and, passing along this, under

Psoas ligament, presents in the thigh; or it may continue its course downwards, burrowing under the muscles of this region, until it reaches the inguinal space, and may even pass from this some distance downwards on either calf or ankle. I have seen an abscess, which took its origin in disease of the dorsal vertebra, opened by the side of the tendo Achillis (Fig. 146). In other cases again, these abscesses take a different course; and, descending into the subperitoneal cellular tissue of the pelvis, may present by the side of the rectum in the perineum, or pass out of the sciatic notch, and down by the side of the trochanter. The quantity of pus contained in these collections is sometimes enormous, and abscesses of this description attain a greater magnitude than those of any other part of the body. In other cases the abscess may follow the course of both psoas muscles, and project on each groin at the same time.

Diagnosis.—The diagnosis of caries of the spine is made at the first sight of a patient affected by the disease, when once the angular deformity has taken place. It is, however, difficult before excoriation occurs, being only indicated at this period by the existence of pain in the back, and by some symptoms of spinal irritation. At this stage it may be mistaken for spinal or intercostal neuralgia, for rheumatism, or for chronic nephritis. The persistence, however, of a continuous fixed pain in the back should always lead to a suspicion as to the true nature of the disease, lest the grievous error be committed of treating as mere neuralgia or rheumatism what may turn out to be incurable disease of the spine itself. Here the tenderness on pressure, the increased sensibility to the application of heat, with a tendency, though it be very slight, to projection of some of the spines, the feeling of weakness in the back, the loss of its natural flexibility, and especially the occurrence of these symptoms in early childhood or youth, at a period when the other diseases rarely occur, would lead one to suspect the true nature of the affection.

The diagnosis of the connection between abscesses in the situations mentioned and those arising from diseased spine, is not always easy; as purulent collections of various kinds may form in the different planes of cellular tissue in the neighbourhood of the vertebral column, without any disease existing in it. Abscesses dependent on caries of the vertebra often attain a very considerable bulk before they present externally, which they usually do in the groin. Abscess in the groin may arise from the following causes.—1, from large lymphatic collections in the subcutaneous or intermuscular planes of cellular tissue; 2, from disease of the cellular tissue around the kidneys; 3, from pericecal abscess (on the right side only); 4, from iliac abscess, whether forming merely in the iliac fascia, or dependent on disease of the pelvic bones; 5, from hip joint disease, the abscess being pelvic; 6, from large buboes or glandular abscesses; 7, from an empyema perforating the pleura and finding its way down behind the diaphragm. The diagnosis of these various collections may, however, with a little caution, be readily made from the ordinary form of spinal abscess that descends along the psoas muscle. In the first place, in all these cases there is an absence of that dorsal pain and tenderness, with more or less excoriation, which, though not invariably present, is commonly met with in psoas abscess. Then again, if the collection be perinephritic, there would have been previous, or there are coexisting, symptoms of renal disease. If it occur in the cellular tissue around the cæcum, the pus will be peculiarly offensive, will present itself in a less distinct manner, and will probably be associated with symptoms of intestinal irritation. In those rare cases in which an empyema has found its way between the layers of the abdominal muscles, and presented in the groin, the stethoscopic signs will point

out the nature of the affection. In *abscess connected with disease of the hip-joint* there will be special evidences of the source of the pus. The only real difficulty consists in diagnosing large psoas abscess presenting in the thigh or in other parts of the lower extremity, and dependent on disease of the vertebral column, from *iliac abscess* taking its origin in the loose cellular tissue of the iliac fossa, whether it be connected or not with disease of the corresponding bone; and in these cases the difficulty is often not a little increased in consequence of the iliac abscess finding its way into the sheath of the psoas muscle.

In iliac abscess, the disease usually commences at or after the middle period of life, always in adults; and, as Stanley has observed, usually presents itself externally immediately above Poupart's ligament, being conducted forwards to this situation by the iliac fascia. Psoas abscess, on the contrary, most commonly occurs in the earlier periods of life; and extends down into the thigh along the course of the psoas muscle, so that it always presents below Poupart's ligament. It is also commonly associated with some indication of irritation of the muscle in the sheath of which it is situated; thus, there is an inability to stand upright, to extend the leg, and pain is complained of in walking. Psoas abscess also, in many cases, occurs suddenly, the patient finding on washing himself in the morning, that he has a large soft tumour in the upper part of the groin; whereas iliac abscess comes on more gradually, and presents in a more diffused and less circumscribed manner.

Iliac and psoas abscesses also require to be diagnosed from certain forms of *aneurism of the abdominal aorta or iliac arteries*; which, having become diffused by the rupture of their sac, have formed large non-pulsating extravasations in the sheath of the psoas in the iliac fossa. In such cases the previous history, the absence of distinct fluctuation, and possibly stethoscopic examination, together with the sudden appearance of the tumour, will throw light on the true nature of the case.

In other cases, again, when the abscess, after deeply burrowing, has perforated the fascia lata at one point, its feel closely resembles that of certain *fatty tumours*. Here, however, the possibility of emptying or diminishing the size of the swelling on pressure, and perhaps impulse on coughing, enable the surgeon to effect the diagnosis.

From *femoral hernia* the soft and fluctuating character of the swelling, its gradual return when pressure is taken off, and all absence of gurgling, constitute the chief distinguishing characters.

Prognosis.—The prognosis in caries of the spine is always bad. The deformity always continues more or less marked; and the patient, though he may eventually recover by ankylosis taking place, continues hump-backed in after-life. Very commonly the disease terminates in abscess and death. It was long ago remarked by Boyer, that the most fatal cases were generally those in which the spine preserved its straight position; whereas, when it was much curved, death seldom resulted. The truth of this remark I have had frequent occasion to verify; and the circumstance would appear to be owing to the fact that, when the spine continues straight at the same time that the bodies of the vertebrae are tuberculous and carious, ankylosis cannot occur, so that the spinal canal is opened and the cord irritated; whereas, when they have fallen together and very considerable gibbosity has resulted, ankylosis more readily takes place, and thus an imperfect cure is effected.

Treatment.—In infants, the utmost that can be done is to direct that they be laid prone upon a pillow or small couch constructed for the purpose, that

the general health be improved by tonics suited to their age: that they have the advantage of country or sea air; and that some counter-irritant, as the tincture of iodine, be applied by the side of the spine. In children that are somewhat older, and in adults, great advantage may be derived by strictly forbidding them to walk, stand, or sit erect; confining them rigidly to the prone couch, and adopting a general plan of tonic treatment. In fact, the principles of treatment are extremely simple: the improvement of the general health by good diet, tonics, and sea-air, in order to remove the morbid condition with which this disease is always associated. With regard to the value of active pyogenic counter-irritation, by means of issues or the actual cautery, much discrepancy of opinion exists. I cannot but think that these means are employed far too indiscriminately, and often in cases in which more harm than good results from their use. The rule for their employment appears to me to be this—that in the earliest stages of caries of the spine, and before the formation of abscess, they are of considerable service, possibly in arresting the progress of the disease in the osseous structures, and certainly in relieving pain and removing irritation of the cord and spinal nerves; but that, after abscess has formed, and is preventing either in the lower iliac fossa or in the thigh, they are not only useless in arresting mischief or inducing repair, but injurious by weakening, and being a source of additional irritation to, the patient. Rest in the horizontal position is the most important element in the treatment; if the patient be allowed to stand upright or to sit, the weight of the head and shoulders will tend to curve forward the weakened spine, and by their pressure increase the already existing irritation in it. The horizontal position relieves the diseased parts of this additional source of distress. In these cases the prone position is preferable to the supine, and the patient, if old enough, should always be laid upon a properly constructed prone couch. The prone position is certainly the best; for not only is the projecting angle formed by the excurvated spine not injuriously compressed, as it would be in the supine or lateral position, but the patient is more comfortable; and it is far easier to make the necessary application in the way of issues and moxas than could otherwise be done. At the same time, the back not being the lowest part of the body, there is a less tendency to congestion of the spinal veins, and to consequent increase of the inflammatory softening of the bones. When the disease has in this way been arrested, for which many months—at least twelve or eighteen—will be required, the patient may be allowed to get up and move about, by wearing proper apparatus so as to support the trunk. This may be constructed on the plan shown in the accompanying figure (Fig. 272). It combines three principles in its action—1, a broad pelvic band, making a firm basis of support round the lower part of the trunk; 2, lateral upright stems, terminating in crutches, by which the weight of the head and shoulders is taken off the diseased spine, and transmitted directly to the pelvic base; and 3, a posterior plate, which by means of a ratchet can be brought to bear directly upon the excurvated part of the spine, and support, and in some degree rectify, the position of this. It is of considerable importance in the treatment of this disease that

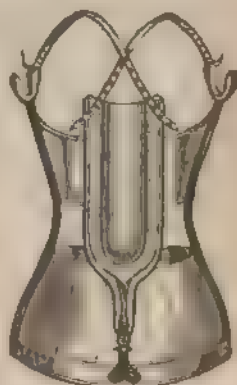

Fig. 272.—Apparatus for Supporting the Trunk in Vertebral Caries.

the patient should not be allowed to get or sit up too soon before the consolidation of the diseased vertebrae has taken place, otherwise he will to a certainty suffer a speedy relapse, and excruciation will greatly increase.

If debility of the lower limbs or paraplegia should come on, the administration of bichloride of mercury, in doses from the twentieth to the sixteenth of a grain, has been strongly recommended by Latham and Stanley. Issues will also be of use in relieving the nervous symptoms, though they may have had little effect on the disease of the bones.

When abscess has formed, the surgeon should be in no hurry to open it: but, in accordance with the principles laid down when treating of this affection, he should delay doing so, lest injurious fatal constitutional irritation be set up. When it becomes necessary, from the approach of the matter to the surface, to give exit to it, this should be done by valvular incision, closed, as soon as the pus has been discharged, by means of hare-lip pins, or in the way described on pp. 420—421.

The hectic or constitutional irritation that supervenes about this period, must of course be treated on general principles.

DISEASE OF THE ATLAS AND AXIS, AND OF THE ATLAS AND OCCIPUT, constitutes one of the most serious forms of vertebral caries. In these cases there are pain and swelling, with great difficulty or absolute inability in moving the head; after a time induration of the cellular tissue, with swelling and fluctuation behind the pharynx, come on, pushing forwards its posterior wall against the nasal apertures, causing the tongue to be extruded, occasioning much difficulty and distress in breathing, and giving rise to a peculiar nasal tone in the voice. The abscess may point here, or may extend outwardly under the muscles of the neck. Patients affected by this disease truly present a remarkable as well as distressing appearance. The sternomastoid muscles are remarkably tense and prominent, and, the neck being perfectly rigid, they are unable to turn the head, but when they want to look round have to twist their whole body; at the same time, the weakness in the neck usually compels them to support the head with both hands, putting one under the chin, the other under the occiput, and so holding it. The disease often terminates fatally by luxation of the vertebrae forwards, compression of the cord, and sudden asphyxia; or more slowly by hectic and gradual interference with the respiratory functions.

The *Treatment* must be conducted on precisely the same principles as that of angular curvature, by absolute rest, counter-irritation, and tonics. As great and immediate danger may result from the sudden displacement of the vertebrae, and the consequent compression of the cervical cord, the head usually requires to be steadied by proper machines calculated to support it and limit its movements.

CHAPTER LI.

DISEASE OF THE SACRO-ILIAC JOINT.

Disease of the *Sacro-Iliac Articulation* is a rare affection. With but few exceptions, systematic writers on surgery are altogether silent upon this subject. Boyer and Chelius mention the disease; but it is only by Nodden that any detailed description of it has been given. This may be partly

accounted for by the rarity of the affection, and partly, perhaps, by its having not unfrequently been confounded with some of the varieties of coxalgia or of spinal disease.

The sacro-iliac disease is essentially a very chronic affection, lasting for months and years. The disease appears to be strumous in its origin, partaking of the nature and ordinary character of "white swellings." I have never seen it in young children, and in all the cases which form the basis of these observations it has occurred in young adults from 14 to 30 years old. The exciting causes of the disease are obscure: I have not been able to trace it to blow or injury in any of the cases that have been under my care, although there can be very little doubt that such causes might excite it.

PATHOLOGY.—The disease may commence primarily either in the pelvic bones, or in the articular structures of the sacro-iliac junction. The annexed drawings (Figs. 273, 274), taken from a boy who died of tetanus from the irritation of an issue, six weeks after the commencement of disease in the sacro-iliac articulation, show the existence of erosion of the cartilages in patches, and clearly illustrate the existence of primary disease in those structures. The next drawing (Fig. 275), taken from a man about 30 years of age, who died of this affection after nearly two years of suffering, shows the disease in its most advanced stage. The bones, though bare and rough, are neither carious nor necrosed. They appear simply to be deprived of their incrusting cartilage and its investing synovial membrane. There is no deep erosion of them, no cavity, no sign of tuberculous infiltration; no evidence, in fact, of primary osseous disease. The ligamentous structures also of the articulations are only partially destroyed. The interosseous ligament was especially in a sound state; it had preserved to a great extent its firmness, and required to be divided with the scalpel in order to expose the interior of the joint and the opposed osseous surfaces. The structures that appear chiefly to have suffered are the synovial and cartilaginous elements of the joint. These are normally but imperfectly developed in the sacro-iliac articulation, and may, probably enough, readily undergo disorganising changes somewhat analogous to those which take place in the so-called "pulpy degeneration of the synovial membrane" in strumous joints.

Sacro-iliac Disease in its early Stage.

Fig. 273—Sacrum

Fig. 275—Sacro-iliac Disease, more advanced

SYMPTOMS.—The symptoms characteristic of this affection arrange themselves in five distinct groups—viz., Pain, Swelling, Lameness, Alteration in the Shape of the Limb, and Abscess. These we must study separately.

1. *Pain.*—One of the earliest symptoms of this disease is a sensation of painful weakness at the lower part of the back and sacrum, increased by movements of the body in walking, stooping, or even in standing, giving the sensation as if the body were falling asunder. As the disease advances, the pain becomes more continuous, of a gnawing or rheumatic character. It is accompanied by a peculiar feeling of weakness, of falling asunder, or of want of support in the lower parts of the body. This pain is confined to the gluteal region and groin, and does not extend down the limb. When the patient is lying on his back or side, the limb on the affected side may be ab- or adducted, or the head of the thigh-bone may be pressed up against the acetabulum, without any increase of pain, provided the pelvis be fixed by the pressure of the hands. If this be not done, considerable pain will be experienced on moving the limb. So, also, if the surgeon seize the sides of the pelvis in his hands, and move them to and fro, or press them together transversely, pain will be elicited, the affected joint being then influenced by the movement communicated to it. There is tenderness on pressure about the gluteal region; but this is less about the hip-joint than in coxalgia, and gradually increases as the finger is pressed backwards upon the sacro-iliac articulation and sacrum.

2. *Swelling.*—A puffy intumescence is perceptible early in the disease, along the line of the affected articulation. It assumes a somewhat elongated appearance from above downwards, and does not extend to any distance outwards under the gluteal muscles, nor does it invade the natural hollow behind the trochanter. As the disease advances, and suppuration takes place, the swelling increases materially, and assumes different and peculiar characters, owing to the formation and diffusion of abscess.

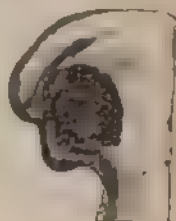

3. *Lameness* is an early symptom. The patient walks insecurely; has a feeling of want of proper support to the body; leans forward, and uses a stick. He puts the foot on the affected side to the ground, but does not tread upon it so firmly as upon the other. He cannot stand on the foot of the affected side, or twist himself suddenly round. As the disease advances, the powers of support and progression diminish, and at last the patient becomes unable to assume the erect position, lying in bed usually on the unaffected side.

4. *Alteration in the Shape of the Hip and Length of the Limb* are early and marked symptoms. From the very commencement of the disease, the limb on the affected side will be seen to be longer than the sound one; the tip of the inner malleolus being usually, as the patient lies on his back, half an inch below the level of the same point of bone on the opposite side. But, on close examination, it will be found that the measurement from the anterior superior spine to the inner malleolus gives equal results on both sides; hence the elongation cannot be owing to any change that has taken place in the bones or in the three large joints of the lower extremity, but must be dependent on some disturbing cause situated beyond the anterior superior spine of the ilium. On pushing our investigation more closely, we shall find that this point of bone is at a lower level, and at the same time more prominent, than its fellow on the opposite side, and that this displacement is produced, not by any obliquity of the pelvis consequent on a twist on the lumbar spine, as in hip-joint disease, but by the tilting forwards and rotation downwards of the whole side of the pelvis; for the displacement which takes place is a double one. The anterior superior spine is not only

accounted for by the rarity of the affection, and partly, perhaps, by its having not unfrequently been confounded with some of the varieties of osteitis or of spinal disease.

The sacro-iliac disease is essentially a very chronic affection, lasting for months and years. The disease appears to be strumous in its origin, partaking of the nature and ordinary character of "white swellings." I have never seen it in young children, and in all the cases which form the basis of these observations it has occurred in young adults from 14 to 30 years old. The exciting causes of the disease are obscure: I have not been able to trace it to blow or injury in any of the cases that have been under my care, although there can be very little doubt that such causes might excite it.

PATHOLOGY.—The disease may commence primarily either in the pelvic bones, or in the articular structures of the sacro-iliac junction. The annexed drawings (Figs. 273, 274), taken from a boy who died of tetanus from the irritation of an issue, six weeks after the commencement of disease in the sacro-iliac articulation, show the existence of erosion of the cartilages in patches, and clearly illustrate the existence of primary disease in those structures. The next drawing (Fig. 275), taken from a man about 30 years of age, who died of this affection after nearly two years of suffering, shows the disease in its most advanced stage. The bones, though bare and rough, are neither carious nor necrosed. They appear simply to be deprived of their incrusting cartilage and its investing synovial membrane. There is no deep erosion of them, no cavity, no sign of tuberculous infiltration; no evidence, in fact, of primary osseous disease. The ligamentous structures also of the articulations are only partially destroyed. The interosseous ligament was especially in a sound state, it had preserved to a great extent its firmness, and required to be divided with the scalpel in order to expose the interior of the joint and the opposed osseous surfaces. The structures that appear chiefly to have suffered are the synovial and cartilaginous elements of the joint. These are normally but imperfectly developed in the sacro-iliac articulation, and may, probably enough, readily undergo disorganising changes somewhat analogous to those which take place in the so-called "pulpy degeneration of the synovial membrane" in strumous joints.

Sacro-iliac Disease in its early stage.

Fig. 273—Sacrum.

Fig. 274—Ilium.

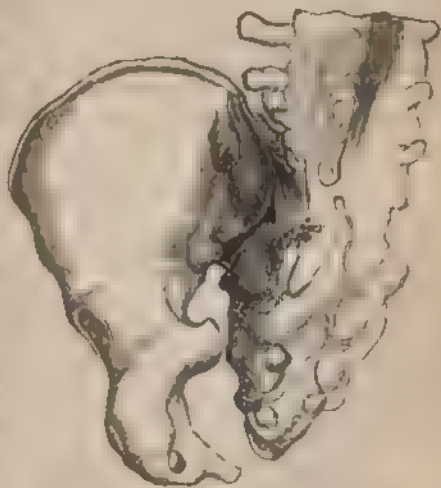

Fig. 275—Sacro-iliac Disease, more advanced.

3. From *spinal disease*, the diagnosis is usually sufficiently easy; for, although the situation of abscess resulting from caries of the vertebrae may in many cases be the same as that which is occupied by the collections of pus resulting from sacro-iliac disease, yet in caries of the spine, in the vast majority of instances, excavation of the vertebrae has become prominently marked by the time that the abscess has assumed so great a magnitude as to occupy the inferior lumbar or gluteal regions. In those rare cases in which, as in an instance that was some time ago under my care, caries of the vertebrae, with consecutive abscess, takes place without any angular curvature, it will be found that the patient complains of tenderness on the surgeon percussing the spine opposite the seat of disease; that the spinal column has lost its flexibility, moving stiffly and as a whole; that there is an absence of that elongation of the limb on the affected side, dependent on displacement of the wing of the pelvis, which is so early observable in sacro-iliac disease; and lastly, that examination of the sacro-iliac synchondrosis neither elicits pain nor reveals swelling or any of the other signs of disorganisation of that articulation.

4. *Coxalgia* is the affection that is most easily confounded with sacro-iliac disease, and that from which it is of most importance to make the diagnosis. It is especially from that variety of hip-disease which commences in the acetabulum, primarily involves the pelvic bones, and only secondarily implicates the joint, that it is difficult to distinguish sacro-iliac disease; and the importance of effecting this diagnosis is great when we reflect that these cases of hip-disease may now successfully be subjected to operative interference, whilst sacro-iliac disease does not admit of relief or removal by these means. The diagnosis between coxalgia in all its forms and the disease we are at present considering may be effected by attention to the following circumstances.

a. The seat of pain on pressure varies. In hip-disease the patient suffers most severely when pressure is exercised deeply behind and above the trochanter, in the hollow behind that osseous prominence, or when the compression is exercised against the anterior part of the hip-joint through the pectineus muscle. In sacro-iliac disease little or no pain on pressure is experienced in these situations; but tenderness is elicited by pressure upon the sacrum and along the line of junction between the sacrum and ilium, behind and altogether away from the hip.

b. The movements that occasion pain are different in the two diseases. In hip-disease, abduction and rotation outwards, or pressure of the head of the thigh-bone into the acetabulum, aggravate, to a greater or less degree, often to an unbearable extent, the sufferings of the patient. In sacro-iliac disease the thigh may be moved in all directions, ab- or adducted, rotated, flexed, or extended, whilst the patient is lying on the back, without any increase of suffering, provided the side of the pelvis be fixed by the surgeon. Should this precaution not be taken, the movement impressed on the thigh will be communicated to the diseased articulation, and will necessarily occasion suffering.

c. The signs connected with the alteration in the length of the limb differ in the two diseases. In hip-disease there may be, and usually is in the advanced stages, considerable shortening. This never occurs in sacro-iliac disease. In the earlier stages of coxalgia there may be, as there is throughout in sacro-iliac disease, elongation of the limb. But there is an important point connected with this. The elongation in hip-disease is always appreciable by measuring from the anterior superior spine of the ilium to the inner ankle. In sacro-iliac disease, however, the measurements between

at a lower level, but is also more prominent on the diseased than on the sound side. This is owing to the swelling of the affected articulation, not passing forwards, but rotating downwards, the anterior and superior portion of the ilium. The limb itself usually lies straight, is wasted, and inflexible.

5. Abscess occurs only at a late period of the disease. Many months, a year or more, may elapse before suppuration is fairly established, or, at all events before the formation of pus is so abundant and so circumscribed as to admit of recognition as an abscess. I have observed abscesses occur in connection with this disease in five situations—viz., over the articulation, in the gluteal and in the lumbar regions, within the pelvis, and in connection with the rectum.

The first indication of abscess is met with over the diseased articulation. The puffy swelling which is there perceptible in the earlier stages of the affection, gradually softens, until at last fluctuation is established in it. From this point it may spread outwards into the gluteal region, nearly as far as, but not enveloping the trochanter; or it may take another course, and stretch upwards, forming a considerable accumulation in the loin, upon and just above the crest of the ilium. These forms of sacro-iliac abscess are *extrapelvic*; the other varieties are *intrapelvic*. These latter are of three kinds. In one form the pus passes out of the sciatic notch, and thus gets under the gluteal muscles; in the other variety it gravitates downwards into the ischio-rectal fossa, and presents by the side of the rectum; and, in the third variety which I have observed, the abscess opens into this gut, abundant puriform discharge takes place *per anum*, and, flatus from the bowel passing into the suppurating cavity, a tympanitic abscess results.

Prognosis.—The prognosis of this disease is always most unfavourable. I am not prepared to say that it is of necessity fatal, but I have never seen a patient recover after the full development of the disease, and after suppuration had set in. I have, however, seen a case cured, in which, from the history of the symptoms, the thickening over the sacro-iliac articulations, and the permanent displacement of the side of the pelvis, there was every reason to believe that this disease had existed. But in this instance no abscess had formed.

Diagnosis.—The diagnosis of sacro-iliac disease is important, and not always easy. There are five distinct affections with which it may be confounded—viz., neuralgia of the hip, sciatica, spinal disease, coxalgia, and disease of the pelvic bones.

1. *Neuralgia of the hip* in young females may readily enough be confounded with the earlier stages of sacro-iliac disease. But the widely spread and superficial nature of the pain in the neuralgic affection, the coexistence of the hysterical temperament, the sex of the patient, and the absence of all limitation of morbid action to the neighbourhood of the diseased articulation, render the true nature of the affection sufficiently clear. The obliquity of the pelvis which occasionally occurs in neuralgia of the hip, and causes apparent elongation of the limb, is readily removed when the patient lies on her back; whereas, in sacro-iliac disease, position does not affect the displacement of the limb on the affected side.

2. *Sciatica.*—In this affection, the age of the patient, usually more advanced than that of the subjects of sacro-iliac disease; the seat of the pain, below the articulation, and its extent down the back of the limb; with the absence of elongation, will enable the surgeon to effect the diagnosis.

CHAPTER LII.

DISEASE OF THE HIP-JOINT.

HIP-DISEASE presents so many points of peculiar and serious importance that it is usually, and not improperly, considered as a distinct affection, apart from other joint-diseases. Like all these it may be of an acute, subacute, or chronic inflammatory character, most commonly occurring in strumous subjects; indeed, I think its connection with scrofula is generally more distinctly marked than that of most other affections of the joints. It almost invariably occurs before the age of puberty. Out of 48 cases of this disease, of which I have taken notes, I find that in 16 only did it take place at or after fifteen years of age, and, of these, in 6 cases only it happened above the age of twenty, thus it may be considered essentially a disease of childhood or early youth. It commonly comes on from very slight causes; over-exertion in a long walk, a sprain in jumping, a fall, or sitting in the wet, are usually the circumstances to which its occurrence is attributed.

FORMS OF THE DISEASE.—All the inflammatory affections attacking the coxo femoral articulation are usually confounded under the term "Hip-Disease" or "Coxalgia." This is too general an expression; and we shall find included under it several distinct forms of disease that differ from one another in pathology, symptoms, result, and treatment. On looking at the hip-joint in a surgical point of view, we find it to be composed of three distinct parts; viz., the soft structures, the acetabulum, and the head of the thigh-bone. Any one of these may be principally or primarily affected, and we may accordingly divide hip-joint disease into the three distinct forms of Arthritic, Acetabular, and Femoral.

This division is not a purely pathological one, but is of a practical character, especially in its bearing on the question of excision.

GENERAL PATHOLOGICAL CONDITIONS.—Before proceeding to describe each separate form of coxalgia in detail, we may consider briefly the six pathological conditions which are more or less common to each variety of the affection—viz., Pain, Attitude, Suppuration, Sinuses, Dislocation, and Anchylosis.

1. *Pain*.—The pain in the hip-joint disease varies greatly according to the form the affection assumes. In the more chronic forms of the disease it is at first slight, and, perhaps, rather referrible to the knee than to the hip; this is particularly the case in the femoral variety; and may be explained by the irritation of the articular branch of the obturator nerve. In the arthritic form it is always very acute, even intense, seated in the joint itself, and greatly increased by any movement, however slight, of the limb. In the acetabular form of the disease the pain is not at first referred to the joint, but rather to the iliac fossa or side of the pelvis; it afterwards becomes severe, gnawing, and deeply seated in the articulation. However slight the pain may be, it is always greatly increased by moving the limb, by pressing the surfaces of the articulation together, or by abduction. Hence the usual position of the patient with the foot raised and merely supported on the point of the toes, the knee and hip being flexed and adducted.

2. The *Attitude* of the limb is peculiar, and varies in different stages of the disease. In the early stage the limb is usually straight, carried slightly forwards, or perhaps somewhat abducted, owing to the irritation and con-

two points on the opposite sides of the body exactly correspond, the seat of the elongation being situated still higher up.

d. The alteration of the level and of the prominence of the two anterior superior spines, in sacro-iliac disease, may be confounded with that arising from the obliquity of the pelvis usually occurring in the early stages of coxalgia. But here also the diagnosis may be effected by observing that the displacement of the bone in sacro-iliac disease is permanent, and is not influenced by position. The obliquity of the pelvis in hip-disease, giving rise to apparent elongation of the limb, is dependent on a twist in the lumbar spine, which may be rectified by placing the patient on his back, and making a little manipulation. The alteration in the level of the two ilia, in sacro-iliac disease, is not modified by change of position, or by any movement that may be impressed upon the spine.

5. *Disease of the pelvic bones* may of course occur independently of any affection of the sacro-iliac articulation; and, when so occurring, it always commences at a distance from the joint—the crest of the ilium, the tuberosity of the ischium, or the acetabulum being the usual seats of the disease. When it occurs in the first of these two situations, the resulting abscess seldom attains a very large size, and is altogether above or below the synchondrosis, the outline of which can be felt clear and unobscured by swelling of any kind. When the abscesses are opened, the sinuses that result will lead directly down to the rough and carious bone, examination of which will leave no doubt as to the nature of the cases. In these cases, also, no change takes place in the length of the limb, or in the position of the side of the ilium.

When the acetabulum is primarily affected, the difficulty of diagnosis may be greater, in consequence of the large size and often intrapelvic nature of the abscesses, and the co-existence of a certain amount of displacement or elongation of the limb. But here the same circumstances that enable the surgeon to effect a diagnosis in ordinary coxalgia—viz, the pain in movement influencing the hip-joint merely, and the increased length of limb, as determined on measuring from the anterior superior spines—will prevent his falling into error as to the true nature of this disease.

TREATMENT.—With respect to treatment I have but little to say, and that by no means of a satisfactory character. The treatment must be conducted on the same general principles that guide us in the management of cases of carious diseases of the spine. Long-continued rest in the prone position; fixing the pelvis and hip-joint by means of a large leather cap; counter-irritation, in the earlier stages, before suppuration has set in (after that has occurred it is worse than useless); opening abscesses, when large and chronic, by valvular incision; and keeping up the powers of the patient by ordinary dietetic means and medicinal tonics, are the means that must be employed, with the view of procuring anchylosis; but usually, unfortunately, with little advantage beyond the mitigation of suffering and the prolongation of life for a limited time. When once suppuration has set in, our hopes of a cure are materially lessened. I am not prepared to state that the affection is inevitably fatal when it has reached this stage, but certainly in the very great majority of instances it is so; the profuse discharge from the large abscesses connected with it inducing hectic, and exhausting the powers of life. No operative interference is admissible in sacro-iliac disease.

acetabulum. When it appears *above* the ligament, it probably leads to intra-pelvic abscess. On the other hand, when the abscess opens *below* Poupart's ligament, there is generally disease of the rami of the pubes or ischium.

The situation of the sinuses, as well as their direction, will thus be found to be of the greatest value in leading the surgeon to a more accurate diagnosis of the seat and extent of the osseous disease than he could otherwise form. And, indeed, it is only by attention to these circumstances that he is enabled in many cases to form an approximate opinion on these points; for the diseased bone is often so covered in by healthy osseous structure, and by plastic matter, that the probe cannot touch it; or the sinus may be so tortuous that a straight probe cannot follow its sinuities.

But there is other important information obtainable from an attentive consideration of the situation of the sinuses. It is with reference to the probable nature of the osseous disease. In *femoral* coxalgia, this is almost invariably caries—sometimes simple, in other cases of a tuberculous character: hence those sinuses that indicate the existence of primary disease of the upper epiphysis of the thigh-bone prove this to be of a carious nature; whilst, on the other hand, sinuses occurring in the pubic region and by Poupart's ligament are almost invariably dependent on the presence of necrosed bone—necrosis being the form of disease that affects the acetabulum and pelvic bones.

5. *Dislocation*.—In the advanced forms of hip-disease, dislocation of the head of the thigh-bone commonly occurs, and may arise from three causes—
a. The destruction of the joint; the capsular ligament having given way in consequence of inflammatory softening and ulceration, and the head of the bone being thrown out of the cavity by the action of the surrounding muscles.
b. Caries and partial absorption of the head of the thigh-bone may have taken place, so that it no longer fills up the cotyloid cavity; and, the ligaments being at the same time destroyed, it slips out on to the dorsum ili.
c. A fungous fibro-plastic mass may sprout up from the bottom of the cavity, and thus tend to push the bone out of it; and, after it has been so extruded, this growth will completely fill the acetabulum.

The occurrence of dislocation is, in the great majority of cases, preceded by the formation of abscess in and around the joint; but in some instances it happens in consequence apparently of the softening of the ligaments, the head of the bone being thrown out of the acetabulum without the supervention of abscess or any sign of suppuration. In these cases, a false joint may be formed upon the dorsum ili, where the head of the bone lodges. When it is lying in a suppurating cavity it will always be found to be in a carious state, and then no attempt, or at least an imperfect one, is made at the construction of an articulation around it.

Dislocation takes place chiefly in the *femoral* variety of the disease, in which the head of the thigh-bone is more or less destroyed, and the acetabulum is filled with fibro-plastic deposit, which is material of a reparative character, developed in those cases in which the lining cartilaginous surface of the joint has been removed, leaving roughened bone, which thus becomes covered. The formation of this material is interesting, as showing the possibility of repair in the acetabulum when it is only secondarily affected. In the *acetabular* form, the position of the head of the bone is more uncertain. In some cases it is dislocated upon the dorsum ili; in other instances, the head of the bone is not thrown out of the cotyloid cavity; but this, being carious, and becoming at last perforated, may allow the upper end of the thigh bone to slip into the pelvic cavity.

6. *Anchylons* may occur either with or without previous suppuration. If

the joint has suppurated and the head of the bone is thrown on the dorsum ili, a false joint may eventually form, or osseous ankylosis in a more or less faulty position take place. If the head of the bone continue in the acetabulum without suppuration, osseous ankylosis (Fig. 248) may ensue with but little shortening of the limb.

ARTHRITIC COXALGIA.—The arthritic form of hip-joint disease may commence in any of the soft structures of the joint; in the capsule, the synovial membrane, the cartilages, or the round ligament. These are alone primarily affected, usually with acute inflammation presenting the characters of arthritis in other joints, and the disease generally continues limited to these structures throughout. Aston Key believed that the round ligament was very frequently the starting-point of inflammation of the hip-joint, and other surgeons have referred its origin to each of the other structures mentioned. Without denying the possibility of disease sometimes commencing in the ligaments, illustrative of which we have a beautiful model in the Museum of University College, I believe that it more frequently appears first in the cartilage incrusting the head of the thigh-bone; for, though it is extremely difficult to prove this, opportunities of dissecting this form of hip-disease in its early stages being very rare, yet the symptoms that attend it so closely resemble those accompanying the diseases of the articular cartilage in other joints, that it is difficult not to infer that this may be the case in the hip.

Symptoms.—In this form of the disease the patient is seized with signs of acute inflammation of the joint, coming on rather rapidly, and with great constitutional disturbance and pyrexia. The pain in the joint in these cases is of the most excruciating character, accompanied by spasms and twitchings of the limb, and marked by nocturnal exacerbations. The suffering is so intense, that the patient cannot bear the slightest movement of the limb; a sit of coughing, the weight of the bed-clothes, or the shaking of the bed by a person leaning against it, will give rise to the most intense agony; and in the intervals of his suffering the patient is in constant fear of a return of the pain, to which he looks forward with much anxiety. In these cases the limb is everted, abducted, perfectly helpless, and motionless; the nates will be found flattened, and there is usually some fulness about the anterior part of the joint, under the pectineus muscle, or to its outer side, above the trochanter. There is also sometimes true elongation of it, in consequence of the capsule becoming distended with fluid, and pushing the head of the bone downwards. On measuring the limb, in order to ascertain its true length, it is necessary to examine the two together, and to place the sound in exactly the same position as the diseased one; unless this be done, error will very probably creep in, for, on measuring the lower extremity from the anterior superior iliac spine to the lower border of the patella or the inner ankle, it will be found to be of greater length when adducted or extended than when abducted or bent.

In some cases the distension of the capsule with synovial fluid, as the result of the inflammation in the joint, may be so great as to lead to its rupture, and to the sudden dislocation of the head of the bone on to the dorsum ili, with great pain and much shortening; this, however, is of very rare occurrence, the dislocation seldom taking place until after abscess has formed within the joint, and the articulation has been thus destroyed.

Results.—In this, the acute form of hip-disease, various terminations may take place; the result depending greatly upon the constitution of the patient, and on the manner in which the affection is treated. Under the most favourable circumstances, as the inflammatory action is subdued, the disease falls into

the subacute condition, and recovery gradually but very slowly takes place, with a limb that continues somewhat stiff and partially ankylosed, as well as wasted and somewhat shortened from disuse. Sometimes, complete ankylosis occurs without the previous formation of abscess. In other, and the majority of instances, abscess forms, and then the patient may either be worn out by the continued irritation of diseased bone, or by the profuseness of the discharge; or, great shortening taking place either by the absorption of the head of the bone, or its dislocation out of the acetabulum, the cavity of the abscess may ultimately contract, the carious portions of bone exfoliate, and the sinuses close after years of suffering. Under the most favourable circumstances, when once the joint has been acutely inflamed, a year or two will elapse before the patient can use his limb with any degree of security. The safety of the patient depends in a great measure on preventing the occurrence of suppuration. If the constitution be very strumous this can rarely be done; but, if it be tolerably healthy, the disease may be prevented from passing on to this stage, and then the patient may recover with an useful, though somewhat stiff and crippled limb. If suppuration occur, it is very seldom that an adult patient recovers, hectic and exhaustion speedily carrying him off. The life of children may, however, be saved even under these circumstances; but they will be left permanently lamed.

ACETABULAR COXALGIA.—In the acetabular form, the disease originates in the pelvic bones, and the articulation and head of the thigh-bone are only secondarily involved. The disease of the pelvic bones has more of the character of necrosis than of caries; but the two morbid conditions are in many cases compound, the acetabulum being carious, whilst the rami of the pubes and ischium are necrosed. The soft articular structures speedily become disorganised; the cartilage incrusting the head of the thigh-bone is absorbed, the femoral head itself becomes eroded rather than carious; but the disease does not extend into the neck or trochanters.

This form of hip-joint disease is more common in adults than any other variety.

The *Symptoms* are usually obscure in the early stages, but become very unequivocal as the disease advances. There is pain around the hip rather than in the joint itself; this, however, becomes tender on pressure, and the patient cannot bear on the limb, but no alteration takes place in its length, although it becomes greatly wasted. Abscess invariably forms, perhaps at first within the pelvic cavity; but it soon presents externally. Sometimes it passes down by the side of the rectum, or through the sciatic notch to the gluteal region; but generally it points near the pubes, under Poupart's ligament. Hectic comes on; the sufferings are greatly increased; and death from exhaustion speedily ensues in this, which is by far the most fatal form of hip-disease. In cases of this form, dislocation, though it is met with now and then, rarely takes place. Sometimes, however, the destruction of the acetabulum is so extensive that the head of the thigh-bone penetrates it, and passes into the pelvic cavity. Dislocation is most frequent when the disease has destroyed the head of the bone; so that, the head being no longer present, no impediment is offered to the action of the muscles around the joint, and the bone at length slips from its position in the cavity of the acetabulum.

FEMORAL COXALGIA.—In the femoral form of coxalgia, the morbid action commences in the upper epiphysis of the thigh-bone. The progress of this variety of coxalgia is very insidious; its symptoms are by no means prominent; it generally occurs in young children, and is usually, I believe, of

tubercular origin. In it the yellow, somewhat soft, friable matter fills up the cancelli of the head and neck of the thigh-bone, resembling, and indeed being identical with, tubercular deposit in other organs. This form of coxalgia is accompanied inevitably by the formation of abscess in the soft parts around the joint, commonly on the outside of the thigh, and in the gluteal region, the articular surfaces are eventually destroyed, and the head of the bone becomes carious and is displaced, leading to shortening and distortion of the limb; the disease very generally terminates in death from exhaustion and hectic.

Symptoms.—The disease usually commences in a very insidious manner. It assumes a subacute character, and is chiefly met with in young children. The first symptom that usually attracts attention is, that the child limps and walks in a peculiar shuffling, hopping manner; he does not stand firmly upon both feet, but rests on the toes of the affected one, the knee of which is bent. On examining the condition of the limb it will be seen to be everted, somewhat abducted, slightly flexed upon the thigh, with the knee partly bent, and apparently shorter than the other. This shortening, however, is apparent and not real; for on laying the child on its back, it will be found that the pelvis is placed obliquely, the anterior superior spine on the affected side being raised to a higher level than that on the sound one, and at the same time turned somewhat forwards. Measurement of the limb from this point to the ankle will show that there is no alteration in its length. The obliquity of the pelvis, which is of very early occurrence in diseased hip, is owing to the child lifting the foot off the ground in order to avoid pressure on it in walking or running; and in doing this he is obliged to raise, not only the limb, but the corresponding side of the pelvis. This apparent shortening will commonly give place, after keeping the child in bed for a few days, to a simulated elongation of the limb; the pelvis on the affected side descending below its natural level. At the same time that these symptoms are noticed, the child usually complains of pain in the hip, especially on pressing over the pectineus muscle, or behind the trochanter; this is increased by standing, walking, or any attempt to bear upon the joint; abduction also, and rotation of the limb outwards, are particularly painful, and any concussion of it, as by striking the heel or knee, will greatly increase the suffering. At this stage of the disease, the patient will often refer to the knee rather than the hip as the seat of pain, and a careless surgeon might be misled and treat the wrong joint; the more so, as there is not unfrequently a good deal of cutaneous sensibility about the inner side of the knee-joint. This pain appears to be seated in the obturator nerve; the articular branch of which sent to the hip joint, becoming implicated in the disease, communicates a radiating pain that is felt at the extremity of the long descending branch which is distributed to the knee. On turning the child upon its face it will be observed that the nates are somewhat flattened, the fold being in a great measure obliterated; and, if it be a female, the vulva on the affected side will be seen to be placed at a lower level than on the sound one.

As the disease advances, abscesses may form at any part in the vicinity of the joint. They most commonly occur under the glutei muscles; but sometimes at the anterior part, under the pectineus muscles. When in this situation, they occasionally give rise to very severe suffering down the inner side of the thigh by exercising pressure upon the obturator nerve, which may sometimes become tightly stretched over the subjacent cyst of the abscess. It is about this period that true shortening of the limb takes place, which at the same time becomes abducted and inverted, thus assuming a very dif-

ferent position from that which it presented in the early stage of the disease. The different positions into which the limb falls in the two stages of the complaint are evidently due to alterations in the muscular action brought to bear upon it. In the early stage, the strong external rotators, which are in close relation with the joint, become irritated by the extension of inflammatory action to them, or by the pressure to which they are exposed by the distended capsule; and hence, these being called into increased action, the limb is everted, at the same time that it is slightly flexed and abducted by the irritation to which the psoas and iliacus are subjected. As the disease advances, these muscles become wasted, undergo fatty degeneration, absorption, or disintegration, by the formation of abscesses underneath and around them; hence, the action of the adductor muscles being no longer counter-

balanced, the limb is drawn upwards and forwards, and turned inwards (Fig. 276).

The shortening of the limb may arise, in very chronic cases, from general atrophy of the member, consequent upon disuse; and this, no doubt, in all instances after a time influences its condition. Most commonly, however, shortening occurs from absorption of the head of the bone, which is usually at the same time dislocated upon the dorsum of the ilium. In these cases, the remains of the dislocated head can be felt through the thin and weakened muscles in its new situation, and in other in-

Fig. 276.—Chronic Disease of Hip-joint.

stances may be found lying at the bottom of a cavity in a carious state (Fig. 277).

PROGNOSIS OF HIP-JOINT DISEASE.—The prognosis in cases of diseased hip must be regarded from two points of view—1, as concerns the *life of the patient*; 2, as to the *utility of the limb* that will be left.

1. *Life.*—Disease of the hip-joint, and of the contiguous osseous structures, is dangerous to life in proportion to the abundance and the long continuance of the suppuration; and this is dependent partly on the patient's constitution, but chiefly, and in the first degree, on the extent and nature of the osseous disease. In the *arthritic* form of coxalgia, suppuration is often prevented by rest and appropriate treatment; and when this is the case, the patient will usually recover. If suppuration take place in cases of this kind, recovery need not be despaired of; but convalescence will be greatly protracted. In such cases much will depend on the patient's constitution. If that be highly scrofulous, tubercularization in other organs, more particularly in the lungs or spine, may very probably take place, and destroy life.

When the bones that enter into the composition of and that surround the hip-joint are diseased, the case at once assumes a much graver aspect. Some surgeons are of opinion that if caries exist the patient must die. In this doctrine I cannot concur. I believe that much will depend on the situation and extent of the caries, and on the question whether it be primary and tuberculous, or secondary to disease of the soft joint-structures. In the latter case the head of the bone, denuded of its incrusting cartilage, softened and carious upon the surface, may be thrown on to the dorsum ilii; profuse and long-continued suppuration will ensue, yet, under good and careful management, and without operation, I have in some instances seen recovery take place.

In those cases in which the disease is primarily *femoral*, and dependent upon tuberculosis of the head of the thigh-bone, the prognosis, if the case be not subjected to operation, is very unfavourable. Here we have a form of caries in which there is no prospect of spontaneous cure; and the patient will be worn out by hectic, induced by the long-continued and irremediable suppuration resulting from the irritation excited by the dislocated and carious femoral head in the gluteal region.

The condition of the *pelvic bones* is one that more materially than any one other circumstance influences the prognosis in cases of coxalgia. When the acetabulum alone of these bones is affected, the prognosis will turn upon whether this acetabular disease be primary or secondary. If it be *primary*, intrapelvic abscess will probably form, pointing above Poupart's ligament; and whether the head of the thigh-bone be dislocated or not, I believe that death must necessarily ensue, unless the diseased osseous structures be excised. If it be *secondary* to disease of the head of the thigh-bone, in which the primary mischief has developed, the condition of the acetabulum need not seriously affect the prognosis. In these cases the head of the bone becomes dislocated, and this very displacement is the first step towards the cure of the disease in the acetabulum. The surface of this cavity, which is roughened, and deprived of its incrusting cartilage, speedily becomes covered by plastic exudation. This undergoes fibroid transformation; and in the course of a short time the whole cavity becomes filled up by a dense elastic fibroid growth, which is in fact the medium of repair of the diseased and disused acetabular cavity.

When the morbid action extends to the osseous structures around the acetabulum, such as the rami of the ischium and pubes, the body and the tuberosity of the ischium and the upper lip of the acetabulum, and even the dorsum of the ilium, the disease usually partakes more of the nature of necrosis than of caries, and is perfectly incurable, except by operation. In such extensive pelvic disease as this, natural means are quite unable to effect a cure, and the patient must die of hectic or intercurrent disease, unless recourse be had to excision of the head of the thigh-bone and the whole of the necrosed and carious osseous structures.

2. *Utility of the Limb.*—This will depend chiefly upon the form of the disease, and to some extent upon the treatment adopted. When the coxalgia is *arthritic*, and suppuration has not taken place, ankylosis of a more or less complete form will usually ensue; and if the thigh have been kept in the straight position, a sufficiently useful limb will be left, but slightly shortened, and possessing free compensating movement in the lumbar spine, enabling the patient to swing it with facility as he walks.

If suppuration have taken place, and the head of the bone have been absorbed or dislocated, the limb, even under the most judicious treatment, will be left considerably shortened, weakened, wasted, and more or less

adducted, with the knee carried somewhat forwards, as well as inwards, and the patient walking often most imperfectly and with great difficulty on the points of his toes.

DIAGNOSIS.—In making the diagnosis of coxalgia, care must be taken not to confound it in its early stages with an ordinary attack of *rheumatism*, a mistake that not unfrequently happens. The alteration in the shape and position of the limb, the obliteration of the fold of the nates, and the limitation of the pain to one joint, will usually prevent the surgeon from falling into this error. With *disease of the knee*, care must be taken not to confound hip-disease, in consequence of the pain in the early stages being commonly referred to that joint; here the absence of any positive sign of disease about the knee, and the existence of all the signs of disease in the hip that have already been noticed, will enable the surgeon to diagnose the true seat of the affection. *Lateral curvature of the spine*, accompanied by neuralgic tenderness in the hip, occasionally gives rise to apparent shortening of the limb with pain and rigidity; but in these cases the existence of the spinal affection, the superficial nature of the pain, and the absence of increase of suffering when the joint is firmly compressed, or of painful startings at night, will indicate the true nature of the affection. *Abscess* may occasionally, though rarely, form in the vicinity of the hip without that joint being diseased. Should this take place towards the anterior aspect of the articulation under the pectineus muscle, it may, by its pressure upon the obturator nerve, occasion pain in the thigh and knee, as in those cases in which the articulation is affected; here, however, the sound state of the joint at its posterior and outer part, the absence of all obliquity of the pelvis, and of the other signs of the true hip-disease, will enable the diagnosis to be effected. The diagnosis from *sacro-iliac disease* has been described at p. 796.

TREATMENT.—The treatment of disease of the hip must be conducted with reference to the form of the disease, the acuteness of the attack, and the severity of the local and constitutional symptoms. In all cases this affection must be managed in accordance with those general principles that guide us in the treatment of inflamed joints.

It is of especial importance to adopt early measures. If we wish to prevent the occurrence of suppuration, dislocation, or ankylosis, the child must, on the supervention of the earliest symptoms of impending mischief about the joint, be put under proper constitutional treatment, and complete rest of the limb must be secured by a well-fitting leather splint. By early attention, a cure may be effected; whereas, if the case be neglected in its earlier stages, the utmost the surgeon can do is to save the life of the patient; the limb invariably falling into a shortened, withered, and distorted condition.

When the disease is of the acute *Arthritic* kind, the patient must of course be kept in bed, and absolutely at rest, and be treated with calomel and opium, freely administered, having a full dose of opiate at night, in order to prevent the painful startings of the limb. The inflamed joint should be leeches, or, if the patient can bear it, cupping-glasses may be applied near the trochanter; it must also be comfortably arranged upon pillows, so as to be kept in as easy a position as possible; and great relief will be afforded to the patient by the application of hot poppy-fomentations. When the inflammatory action has been somewhat subdued, the joint may be conveniently fixed by means of a leather splint or the starched bandage. Of the two, I prefer the starched bandage, as being more easily applied, and forming a better fitting and more secure casing to the limb. In applying it, the limb should be bandaged from the toes upwards, and well padded

When the bones that enter into the composition of and that surround the hip-joint are diseased, the case at once assumes a much graver aspect. Some surgeons are of opinion that if caries exist the patient must die. In this doctrine I cannot concur. I believe that much will depend on the situation and extent of the caries, and on the question whether it be primary and tuberculous, or secondary to disease of the soft joint-structures. In the latter case the head of the bone, denuded of its incrusting cartilage, softened and carious upon the surface, may be thrown on to the dorsum of the ilium, profuse and long-continued suppuration will ensue, yet, under good and careful management, and without operation, I have in some instances seen recovery take place.

In those cases in which the disease is primarily *femoral*, and dependent upon tuberculousness of the head of the thigh-bone, the prognosis, if the case be not subjected to operation, is very unfavourable. Here we have a form of caries in which there is no prospect of spontaneous cure; and the patient will be worn out by hectic, induced by the long-continued and irremediable suppuration resulting from the irritation excited by the dislocated and carious femoral head in the gluteal region.

The condition of the *pelvic bones* is one that more materially than any one other circumstance influences the prognosis in cases of coxalgia. When the acetabulum alone of these bones is affected, the prognosis will turn upon whether this acetabular disease be primary or secondary. If it be *primary*, intrapelvic abscess will probably form, pointing above Poupart's ligament; and whether the head of the thigh-bone be dislocated or not, I believe that death must necessarily ensue, unless the diseased osseous structures be excised. If it be *secondary* to disease of the head of the thigh-bone, in which the primary mischief has developed, the condition of the acetabulum need not seriously affect the prognosis. In these cases the head of the bone becomes dislocated, and this very displacement is the first step towards the cure of the disease in the acetabulum. The surface of this cavity, which is roughened, and deprived of its incrusting cartilage, speedily becomes covered by plastic exudation. This undergoes fibroid transformation; and in the course of a short time the whole cavity becomes filled up by a dense elastic fibroid growth, which is in fact the medium of repair of the diseased and disused acetabular cavity.

When the morbid action extends to the osseous structures around the acetabulum, such as the rami of the ischium and pubes, the body and the tuberosity of the ischium and the upper lip of the acetabulum, and even the dorsum of the ilium, the disease usually partakes more of the nature of necrosis than of caries, and is perfectly incurable, except by operation. In such extensive pelvic disease as this, natural means are quite unable to effect a cure, and the patient must die of hectic or intercurrent disease, unless recourse be had to excision of the head of the thigh-bone and the whole of the necrosed and carious osseous structures.

2. *Utility of the Limb.*—This will depend chiefly upon the form of the disease, and to some extent upon the treatment adopted. When the coxalgia is *arthritic*, and suppuration has not taken place, ankylosis of a more or less complete form will usually ensue; and if the thigh have been kept in the straight position, a sufficiently useful limb will be left, but slightly shortened, and possessing free compensating movement in the lumbar spine, enabling the patient to swing it with facility as he walks.

If suppuration have taken place, and the head of the bone have been absorbed or dislocated, the limb, even under the most judicious treatment, will be left considerably shortened, weakened, wasted, and more or less

being perhaps adducted and inverted so far as to be twisted over the other, or drawn up upon the abdomen, much may be done to lessen the deformity by putting the patient under chloroform, bringing down the limb, and fixing it in a starched bandage. Ankylosis in a good position may thus be sometimes obtained, and the patient's condition be greatly improved. It is a question whether an attempt at reduction should be made in these cases of consecutive dislocation, as it is very rarely that it would prove permanently successful, the acetabulum being either filled up with fibrous matter, or the head of the bone so diseased and lessened in size, that it would not remain in its cavity when put back. Occasionally, however, reduction may be successfully effected. In a woman under my care at the Hospital, with spontaneous dislocation of the hip of about a month's duration, reduction was effected by means of the pulleys, and the head of the bone replaced in the cotyloid cavity, where it remained for some weeks; becoming, however, displaced again in consequence of its being necessary to remove a bandage that was applied, as she became affected with inflammation of the chest, and could not bear its pressure. If ankylosis be likely to occur, the surgeon must endeavour to secure it with the limb in a straight position. After a stiff joint has formed, the mobility of the lumbar vertebræ, and more particularly of the lumbo-sacral articulation, will be found to be greatly increased; so that at last the patient will walk with little inconvenience, rotating the pelvis on them. If the ankylosis be not osseous, but the result of the *Arthritic* form of the disease, and especially if the head of the bone be still in the acetabulum, the limb may be straightened by forcible extension and rotation under chloroform, and the heel thus brought to the ground.

EXCISION OF THE HEAD OF THE THIGH-BONE AND OF THE HIP-JOINT.—White of Manchester, in 1769, was the first to propose, and Anthony White, of the Westminster Hospital, in 1821, was the first to perform, this operation. This he did on a boy about eight years of age, who had suffered from disease of the hip-joint for three or four years, and in whom the carious head of the thigh-bone rested on the *dorsum ilii*. Mr. White removed the head and trochanters of the bone, and the patient recovered from the operation, dying of phthisis five years afterwards. The preparation is in the Museum of the College of Surgeons. This operation was repeated by Hewson of Dublin, in 1823; and then seems to have been forgotten in Great Britain until its revival, in 1845, by Fergusson. But in the meanwhile it had not entirely escaped the attention of continental surgeons. Oppenheim, in 1829, and Seutin, in 1832, excised the head of the femur for gun shot injury; and in 1842, Textor published an essay on this subject. Since the operation was revived by Fergusson, in 1845, it has been frequently performed, certainly more than a hundred times, and may now be looked upon, notwithstanding the violence with which it has been assailed in some quarters, as being an established surgical procedure in appropriate cases.

Cases requiring Operation.—Diseases of and about the hip-joint may, so far as the question of operation is concerned, be divided into two great classes—those in which no suppuration takes place, however acute the inflammation may have been; and those in which abscess forms.

To the first class belongs the *Arthritic* variety of the disease. In this form of coxalgia, the patient commonly recovers with a stiffened or even completely ankylosed, though useful and straight limb, dislocation of the head of the bone not having occurred. In such cases, I believe that excision is never needed; at least, I have never had occasion to do it, nor have I ever seen a case that seemed to me to justify such a procedure.

The second class of cases—those in which abscess forms—are by far the most numerous. In the great majority of these, however, the head of the bone is the part chiefly affected, and in these recovery will take place eventually, under properly conducted medico-surgical treatment. But the recovery in such cases is always so far incomplete that the limb is left much crippled, and often of but little utility. In cases of this kind, after years of suffering and of confinement to bed, and after a hard struggle for existence, we find the unfortunate patient left eventually with a limb that is shortened to the extent of from two to four inches, wasted and adducted, with a projecting deformed hip seamed with cicatrices; the remains of the upper epiphysis of the thigh-bone being dislocated from the acetabulum, and adherent to the dorsum ilii by firm ankylosis. The limb is unable to support the body, and cannot be extended, nor can the sole of the foot be firmly planted on the ground; but the leg is to a certain extent useful in progression, the patient using it as a kind of paddle to push himself on with, as he limps on the point of the toes. In these cases, it is interesting to observe how nature compensates for the loss of all abduction and rotatory power in the hip by giving an extremely increased degree of mobility to the lumbar vertebrae; so that the patient, in walking, swings the pelvis from these, and thus in a great degree makes up for the loss of the natural movements in the coxo-femoral articulation.

But, though recovery takes place eventually in the great majority of cases of coxalgia that have even advanced to suppuration, yet in some, and not a few instances, the patient's constitution becomes unequal to the drain imposed upon it, and fatal hectic will eventually supervene. This fatal result is the direct consequence of the wasting and exhausting influence of the long-continued discharge of pus from masses of carious or necrosed bone, too extensive or too deeply seated to be eliminated by the natural actions of the part. It is in such cases as these that conservative surgery steps in, and endeavours to save the patient's life by the removal of the morbid cause that keeps up the discharge which is wasting it away. The object here is simply to save life by the removal of diseased bone. For the same reason—the preservation of life from hectic—that the surgeon amputates in an extreme case of suppurating disorganisation of the knee-joint, he excises in an extreme case of disorganisation of the osseous structures that enter into the formation of the hip-joint: amputation is here too formidable a proceeding to be undertaken, and yet the removal of the diseased bone, the irritation and suppuration from which is rapidly destroying the patient, is an imperative necessity. And here it is impossible not to be struck with the strange inconsistency of those surgeons who, looking upon caries of the bones entering into the conformation of the hip-joint as necessarily fatal, yet condemn as improper the only means of saving the patient's life—viz., the excision of the diseased osseous structures—and blame others for performing an operation which has saved the lives of numerous patients affected by a disease which they themselves have declared to be incurable.

The *Femoral coxalgia* is that form of the disease that is most amenable to operation. In severe and extreme cases of this variety of hip-joint disease, the upper epiphysis of the thigh-bone will be found lying in a state of caries on the dorsum ilii, in a suppurating cavity, with sinuses leading down to it. The pelvic bones are sound; the acetabulum is filled by fibro-plastic matter of a reparative character, though possibly it may be slightly roughened and necrosed at one lip. The soft structures in the gluteal region are thinned and wasted; the limb is incurably shortened, atrophied, and adducted. In such cases as these, the patient will probably perish, if left to the unaided

efforts of nature ; or if he recover, after years of suffering, it will be with a limb shortened, deformed, and but little useful. Resection, being limited to the upper end of the thigh-bone, or at most to the roughened lip of the acetabulum as well, is an easy operation, removes the cause of the wasting discharges and hectic, and in no way increases the already existing shortening, as it is limited to that portion of diseased bone which is already lying above and behind the acetabulum, and which is affected by incurable caries of too extensive and deep-seated a character to disintegrate and crumble away in the discharges, so that a natural cure without operation could take place.

In the *Acetabular Pelvic* form of coxalgia, the ultimate result is, I believe, inevitably fatal, if the disease be allowed to run its own course unchecked by operation. Large portions of the pelvic bones in and around the acetabulum—such as the ischium, the tuber and ramus of the ischium, the ramus of the pubes and the dorsum ili—fall into a state of necrosis ; that cavity becomes perforated (Fig. 278) ; and the head of the thigh-bone, still lying in

Fig. 278.—Perforation of the Pelvic Bones in Acetabular Coxalgia.

it, becomes denuded of its cartilaginous investment, roughened, and carious, as is well seen in the annexed drawing (Fig. 279), taken from a patient of mine who died of this form of the disease ; or it may be dislocated in a carious state on to the dorsum ili. Large abscesses, intra- as well as extra-pelvic, form, and the patient dies worn out by hectic ; the natural efforts of the part being entirely unavailing to separate and to eliminate such large necrosed masses, deeply lying, and covered in by the upper end of the thigh-bone.

Fig. 279.—Carious Head of Thigh bone in Acetabular Coxalgia.

Removal of Diseased Acetabulum and Pelvic Bones.—Until a very recent period, surgeons feared to undertake the removal of large carious and necrosed portions of the pelvic bones, and acetabular disease of the hip-joint was accordingly allowed to run its fatal course unchecked. Mr. Hancock was the first surgeon who undertook the removal of large portions of these bones, and since then the operation has been done several times by others. In no case has, I believe, more extensive disease been removed with a good result than in a girl who was sent to me some years ago by my friend Mr. Tweed, and from whom I removed the upper end of the thigh-bone, the acetabulum, the rami of the pubes and of the ischium, a portion of the tuber ischii, and part of the dorsum ili. This patient, when admitted into the hospital, was in the last stage of disease, exhausted by the constant discharge, and must inevitably have speedily sunk under the effects of the disease, had no effort been made to remove the cause of the prostration. At the operation, she was so exhausted that it was necessary to leave her on the operating-table for some hours before she was sufficiently restored

to bear moving into bed. Nevertheless, by the free use of stimulants and nourishing food, she recovered rapidly; and when I saw her, nearly three years afterwards, the limb presented the appearance in this drawing (Fig. 280); it was straight, shortened about two inches; good movement existed at the hip; and she could walk with much ease. Constitutionally, she was in perfect health. In two other cases I have successfully removed large portions of the acetabulum and of the contiguous portions of the ilium and ischium. In cases such as these, the result, if they are left to themselves, must inevitably be fatal. There is no danger of laying open the pelvic cavity during the removal of these masses of pelvic bone; for, as Hancock has shown, during the progress of the disease, the fasciæ, muscles, &c., lining the pelvis, become so thickened and infiltrated with plastic matter, that they form a barrier which effectually protects the pelvic cavity.

Fig. 280.—Result of Operation for Extensive Acetabular Coxalgia.

Method of Operating.—From the preceding considerations, it will be observed that there are two distinct operations practised on the coxo-femoral articulations. The first is simple resection of the epiphysis of the thigh-bone; the second, the removal of more or less of the acetabulum and of the contiguous pelvic bones as well. For the removal of the epiphysis of the thigh-bone only the following plan should be pursued. The patient lies on the sound side. If the disease be femoral, the gluteal region perforated with sinuses, and the soft parts thinned, the head of the bone lying dislocated on the dorsum ilii, it suffices to pass a director down one of the chief sinuses leading to the carious bone, and to slit this up. If, however, the bone be more thickly covered, and be not easily reached with the probe, and if the sinuses open on the thigh at some considerable distance from the seat of disease, then a T-shaped incision should be made over the upper end of the thigh-bone, so as to expose it (Fig. 281). The limb should now be forcibly

Fig. 281.—Excision in Femoral Coxalgia.

adducted, rotated inwards and pushed upwards by an assistant, and the soft structures separated by a probe-pointed knife from around the upper end of the bone, so that the whole amount of disease may come into view. The carious epiphysis is then cut off with a saw, the soft parts around being protected, if necessary, by means of retractors.

There is one practical question with regard to the amount of the upper end of the thigh-bone to be removed, which requires consideration; and that is, Should the bone be sawn through below the great trochanter; or through the neck only, leaving the trochanter? The practice should, I think, differ according to the nature of the disease. If this be femoral, it is best to take away the great trochanter, as the caries has generally reached its cancellous structure, or it may be infiltrated with tubercle. But if the disease be acetabular, and the pelvic bones be the parts most extensively and deeply affected, it will suffice to remove the head only, leaving the trochanter, which is not affected in these cases. After removing the head of the bone, the upper end should be examined, and any carious parts gouged out. After the epiphysis of the thigh-bone has been removed, the acetabulum must be examined, and any rough or necrosed bone lying at its edge should be gouged away.

In the acetabular form of the disease, where large portions of the pelvic bones require removal, the early stages of the operation require to be conducted in the way just described; the incisions, however, being made more freely, but not carried so far forwards as to endanger the anterior crural, or so far back as to wound the sciatic nerve. After the removal of the head of the thigh-bone, all loose necrosed pieces are to be taken out, and then, by means of ordinary cutting or gouge-forceps, the acetabulum and other carious osseous structures cut away piecemeal. Those portions of bone which have necrosed are usually separated, and lying loose, or else may generally be readily separated by the finger, or by the handle of a scalpel, from the subjacent soft structures; and the muscles and fascia lining the pelvic bones, being thickened and infiltrated with lymph, effectually protect the contained parts from all injury.

After the operation the wound must be dressed in a simple manner, and a long splint applied. Fergusson recommends that the extension should be made from the opposite thigh, round the upper part of which a socket

Fig. 282.—Dressing after Excision of Hip Joint.

is fixed, to which the band is attached (Fig. 282). Much advantage will be derived from the use of the bracket thigh-splint.

Results.—The result of excision of the hip joint has to be considered from two points of view:—1. So far as the mortality immediately referrible to the operation is concerned; and 2. As to the utility of the limb that is left after its performance.

1. As to the fatality directly referrible to the operation itself, it is diffi-

to bear moving into bed. Nevertheless, by the free use of stimulants and supporting food, she recovered rapidly, and when I saw her, nearly three years afterwards, the last presented the appearance in this drawing (Fig. 230), it was straight, shortened about two inches, good movements existed at the hip, and she could walk with much ease. Constitutionally, she was in perfect health. In two other cases I have successfully removed large portions of the acetabulum and of the contiguous portions of the ilium and ischium. In cases such as these, the result, if they are left to themselves, must inevitably be fatal. There is no danger of laying open the pelvic cavity during the removal of these masses of pelvic bone; for, as Hancock has shown, during the progress of the disease, the ligaments, muscles, &c., lining the pelvis, become so thickened and infiltrated with plastic matter, that they form a barrier which effectually protects the pelvic cavity.

Fig. 230.—Result of Operation for Extensive Acetabular Coxalgia.

Method of Operating.—From the preceding considerations, it will be observed that there are two distinct operations practised on the coxo-femoral articulations. The first is simple resection of the epiphysis of the thigh-bone; the second, the removal of more or less of the acetabulum and of the contiguous pelvic bones as well. For the removal of the epiphysis of the thigh-bone only the following plan should be pursued. The patient lies on the sound side. If the disease be femoral, the gluteal region perforated with sinuses, and the soft parts thinned, the head of the bone lying dislocated on the dorsum ilii, it suffices to pass a director down one of the chief sinuses leading to the carious bone, and to slit this up. If, however, the bone be more thickly covered, and be not easily reached with the probe, and if the sinuses open on the thigh at some considerable distance from the seat of disease, then a T-shaped incision should be made over the upper end of the thigh bone, so as to expose it (Fig. 281). The limb should now be forcibly

Fig. 281.—Excision in Femoral Coxalgia.

disease; but a little careful examination with the probe and by manipulation of the limb, will soon convince the surgeon that the joint is free from disease, and that the morbid action is limited to the trochanter, and possibly the root of the neck of the thigh-bone. In such cases the diseased osseous structures may be successfully gouged away, after having been freely exposed by slitting up the sinuses leading to them. In such operations I have not only successfully removed the greater part of the trochanter, but have even scooped out a portion of the interior of the carious neck of the thigh-bone at its trochanteric end; thus preventing the inevitable disorganisation of the hip-joint which would have resulted if the carious bone had been allowed to remain in close proximity to the articulation. In this operation the surgeon necessarily comes into very close proximity with the capsule of the joint; and unless great care be taken this might be opened, and thus the very mischief induced which the operation is undertaken to prevent.

In strumous children long sinuses will occasionally form about the great trochanter and gluteal region, leading to the supposition that there is caries of the bones in the vicinity of the hip-joint. The movements of the articulation will, however, be found to be perfectly free, and the most careful examination with the probe fails to detect osseous disease.

CHAPTER LIII.

DISEASES OF SYNOVIAL MEMBRANES, AND OF MUSCLES.

DISEASES OF BURSÆ.

THE bursæ which naturally exist, either under the skin, beneath the muscles and ligaments, or around tendons, are subject to various diseases. Not only do the normal bursæ become affected, but these sacs are sometimes developed from continued friction in situations where they are not naturally met with, and here also they may undergo disease; thus, for instance, bursæ have been found to be formed at the projecting point of a hump-back, on the prominent parts of club-feet, or at the extremity of stumps.

SITUATIONS IN WHICH BURSÆ EXIST.—In the following situations bursæ naturally occur, and may consequently be expected to be met with in a diseased state:—behind the angle of the lower jaw, on the symphysis of the chin, on the angle of the thyroid cartilage; on the acromion, the external and internal condyles of the humerus, the olecranon, the styloid processes of the ulna and radius; on the dorsal surface of the metacarpo-phalangeal articulations, as well as on their palmar surfaces, and on the dorsal aspect of the phalangeal articulations; on the anterior superior spine of the ilium, the great trochanter, the tuberosity of the ischium, the lower, superior, and outer parts of the patella; on each condyle of the thigh-bone the tuberosity of the tibia, the two malleoli, the calcaneum, the dorsal aspect of the toes, and on the plantar aspect of the heads of the first and fifth metatarsal bones. Besides these situations, they occur under the deltoid and the gluteus maximus, between the lower end of the scapula and the latissimus dorsi, and in the ham.

MORBID ALTERATIONS.—The continued irritation of bursæ by the pressure that is exercised upon them, may cause them to inflame, to enlarge, to become thickened, or to undergo various changes in structure. This enlargement of the bursæ in particular situations is often connected with special employments, by which continuous and severe pressure is exercised upon

certain parts of the body; thus frequent kneeling will occasion enlargement of the bursa patellæ, hence called "housemaid's knee." Miners are occasionally subject to an enlargement of the bursa lying over the olecranon, called "miner's elbow;" and in any situation a new bursa may be formed by continuous pressure and friction conjoined.

The four following pathological conditions may occur in the bursæ in any part of the body.

1. The bursa may, in consequence of continued pressure or irritation, become simply enlarged and filled by the excessive secretion of a clear sero-synovial straw-coloured fluid.

2. Inflammation may take place in the bursa with or without previous enlargement. The inflammation so set up speedily runs on to suppuration; and when the tumour is opened, fluid, consisting of an admixture of the bursal excretion and pus, escapes. The bursa, when its contents have suppurated, may either give way externally, pointing like an ordinary abscess, and the integuments covering it sloughing; or the pus may escape subcutaneously, and form a widely spread abscess around the part.

3. The enlarged bursa may contain a dark fluid, usually of a brownish colour, with a large number of small flattened elongated bodies, of about the size of grains of rice or of melon-seeds, floating in it. These bodies are of a fibroid or fibro-plastic structure, resembling masses of imperfectly developed exudation cells, and are apparently portions of disintegrated lymph.

4. The wall of the bursa may gradually thicken by the deposit of lowly organised lymph in its interior, until the tumour becomes perfectly solid, or at most contains but a small cavity with a little serous fluid in its centre. The section of a bursa thus solidified presents a laminated or foliated appearance.

Burgomas.—Enlarged bursæ are readily recognised; forming, whilst their contents are thin and serous, indolent oval tumours with distinct fluctuation, commonly occurring in the situation of some of the normal bursæ. As they become more solid they become elastic and hard, and often crackle on being pressed when they contain the rice shaped bodies; but at last they acquire all the characters of an ordinary solid growth, as the deposition within them increases. Not unfrequently these enlarged bursæ inflame, or, indeed, an attack of inflammation in them may be the first cause of their enlargement. In either case they become hot and tense; the skin covering them is red, often doughy and cedematous; and although there is no connection between the bursa and the neighbouring joint, yet it may happen that the inflammatory action spreads to the latter, from simple continuity of tissue. Suppuration very frequently occurs in an inflamed bursa; the tension increases, the œdema and redness become more considerable, and the pain assumes a throbbing character. When the bursa is opened, thick pus, often mixed with shreds of sloughy tissue, is evacuated.

Treatment.—The treatment of these bursal tumours must depend entirely upon their nature and actual condition. When they are inflamed, rest, the application of leeches, followed by tepid lead-lotions or poultices, and general antiphlogistic treatment, will commonly subdue the increased action.

If suppuration take place, they must be freely opened and the pus evacuated. When they are in an indolent condition, the surgeon has the choice of various plans of treatment, conducted on different principles. If the sac be thin, the fluid of a serous character, and the disease recent, it may often be removed by blistering, more particularly when it occurs in the *ham* or *under the deltoid muscle*. In some cases it may conveniently be

obliterated by puncturing the cyst, and then employing pressure upon it. The surest mode, however, of closing the sac consists in exciting inflammation in it, either by the injection of iodine as recommended by Velpéau, or by passing a small seton through it. The injection is readily effected by tapping the cyst with a moderate-sized trochar, and then throwing in about a drachm of the compound tincture. Inflammation will be excited, some discharge will usually take place, and on its cessation the walls of the cyst will have become agglutinated together. In these cases I generally prefer, however, as the most certain method, the introduction of a seton composed of a double silk thread. This may conveniently be passed through the cannula after tapping the sac, in the way figured in page 421; a poultice should afterwards be applied, and the threads left in for about six days. Discharge will take place through the aperture by which they have been introduced, and which may, if necessary, be enlarged; the cyst gradually contracts around them, and after their removal it will be found to be closed. When the cyst contains a number of the rice-like bodies, the seton may still be used, but it should be thicker than that just recommended, and the aperture by which it is introduced should be very free, in order to admit of the escape of the pus and granules.

If the walls of the cyst be very thick, or its contents semi-solid, or if the tumour have become solid, it must be dissected out. This operation is most commonly required for solid bursal tumours, situated over the patella or the tuberosities of the ischium; from both of these situations they may be removed with facility.

DISEASES OF THE BURSA PATELLÆ.—The exposed situation of the bursa patellæ, covered as it is only by the integumental structures and fascia lata, and its liability to pressure and irritation in kneeling, render it in all respects more prone to take on diseased action than any other similar structure in the human body; and the morbid conditions which it presents may be looked upon as typical to a great extent of the diseases of the bursæ generally.

The various affections to which this bursa is liable, may be divided into two classes: 1. Inflammatory Affections; and 2. Enlargements, of a Fluid or of a Solid character.

1. INFLAMMATORY AFFECTIONS.—This bursa is frequently the seat of *Simple Inflammation*. Undue pressure in kneeling upon a hard, irregular, and cold surface, such as stone, is likely to excite inflammation; hence its frequency in housemaids, whose occupation obliges them to kneel a great deal on floors and stone steps; and hence, also, the common title of "housemaid's knee," given to this and to many other affections of this bursa. But this disease, although frequent amongst, is not limited to housemaids; for it occurs in females following other occupations, and in men as well as in women.

In simple inflammation, however occasioned, the bursa becomes rather suddenly swollen, tense, red, and hot, with some fluctuation deeply under the integuments. The swelling, heat, fluctuation, and redness, often of a dusky colour, all situated in front of the patella, point out the nature of the affection.

The *Treatment* of this inflammation is simple enough. Leeches, followed by evaporating lotions, and keeping the patient at rest, are the means to be employed. Under this treatment, the disease will frequently undergo resolution in the course of a few days. It may, however, go on to suppuration, disease of the patella itself, or sloughing of the bursa.

Suppuration of the Bursa occurs in perhaps the majority of cases of inflam-

mation. This is a matter of great consequence ; because the accumulation of pus, being of large size, and tending to diffuse itself around the knee-joint, is liable to be mistaken for abscess in that articulation. Sometimes it will point, and the pus discharge itself externally in the usual manner ; but very generally it gives way subcutaneously, and its contents speedily diffuse themselves somewhat widely around the joint.

The history of the case affords the means of diagnosis. In suppuration of the bursa patellæ, the abscess commences by a superficial swelling and inflammation in front of the knee, which, after a time, extends laterally, enveloping the joint, the fluid gravitating on each side, but more especially on the outer one, nearly as far, perhaps, as the ham-strings. There will have been none of the signs indicative of acute arthritis accompanying the formation of this large abscess ; no startings of the limb, no laxity or pain in moving the articulation, no grating of the articular ends ; and little if any constitutional disturbance. The movements of flexion and extension of the joint are free up to a certain point, where they are checked by the mechanical obstacle of the purulent accumulation. But perhaps the more important diagnostic sign is the relation of the abscess to the patella. In a suppurating bursa, the patella is invisible, being covered by the fluctuating swelling ; in effusion, whether synovial or purulent, into the joint, the patella is above, floating upon the fluid.

The *Treatment* of this condition is simple enough. A free incision should be made through the anterior part of the bursa, so as to let out the pus mixed with synovial fluid ; and if there be any burrowing of matter, as there almost invariably is, counter-openings must be made in proper dependent situations.

Disease of the Patella.—Sometimes, but very rarely, abscess of the bursa patellæ will go on to disease of the patella itself. Caries of this bone secondary to suppuration of the bursa is, so far as my experience goes, exceedingly rare. I have seen one case of the kind—that of a woman who was in the Hospital, under my care, several years ago. When admitted, she had several fistulous openings on the fore part of the knee-joint, through which the probe led down to a rough and carious patella. On inquiry, it was ascertained that she had had inflammation of the bursa patellæ—"house-maid's knee"—which had run on to suppuration, but that the abscess had never been freely laid open. The present condition had resulted from that suppuration. The joint itself was unaffected ; there was no pain in it, and its movements were perfectly free. I laid open the sinuses, and, finding the anterior surface of the patella soft and carious, removed with the gouge the diseased bone to which they led. About two or three weeks after this, the joint became suddenly swollen, evidently filled with pus, and the seat of acute pain. In consequence of the severity of the symptoms, it became necessary to remove the limb above the knee. After amputation, it was found that the morbid action had extended through the patellar cartilage, perforating it by a small aperture, and so giving rise to suppuration within the joint.

Sloughing of the Bursa Patellæ occasionally occurs as the result of its inflammation and suppuration. A woman was admitted into the Hospital, in whom this bursa had inflamed and suppurated ; and not only the bursa but also the integuments covering it had sloughed away, leaving in front of the knee a circular ulcer as large as the palm of the hand, having a flabby surface, and undermined, purple edges. The patella was not exposed. Under ordinary treatment, the ulcer slowly healed, but no vestige of bursa was left.

2. **ENLARGEMENTS.**—We now proceed to the consideration of the second class of diseases of the bursa patellæ—those in which there is no inflammation, but in which there is enlargement of the bursa, owing to the accumulation within it of bursal fluid, of this fluid mixed with solid bodies, or of solid fibroid deposits.

Simple Enlargement.—The bursa may present a simple enlargement, dependent on the accumulation of fluid in its interior. Continued pressure exercised upon the bursa, as in kneeling, is the common cause of this affection (hence its frequent occurrence amongst housemaids), and constitutes the true “housemaid’s knee.” But it is also common amongst other people, whose vocation necessitates long-continued kneeling. One case of the affection in University College Hospital was in a carpet-layer; it was to all intents and purposes a “housemaid’s knee,” and the tumour equalled in size an ordinary orange. A man, aged thirty, who, in consequence of habitually kneeling upon the left knee in laying down carpets, had a tumour there as large as an orange, indolent, soft, and fluctuating to the feel, evidently an enlarged bursa, was admitted into the hospital. It was tapped by means of a trocar, clear fluid was drawn off, and a seton was passed through the cannula, and left in for six or seven days. Suppuration took place along the seton, the tumour collapsed and contracted, and the patient left the Hospital, cured, on the twelfth day.

With regard to the *Pathological Nature* of the disease, it would seem to consist in excessive secretion into the interior of the bursa, which becomes enlarged, thickened, and filled with a clear sero-synovial fluid.

The *Treatment* of these tumours is very simple. In some cases the application of tincture of iodine, or the ammoniacum and mercury plaster, or blistering, will succeed in inducing absorption of the contained fluid. If these fail, as they very often do, or if their use be too tedious, a very simple, and at the same time a very safe and successful, mode of treatment consists in tapping the tumour with the trocar, and passing a seton through the cannula, either by means of a long straight needle, or by using an eyed probe, and cutting down upon the end of it with a scalpel. The seton threads should be left in for a week or ten days—at all events, until they excite free suppuration. This treatment is exceedingly simple, and perfectly certain in its results. The only point to be attended to is, to keep the apertures by which the seton passes sufficiently patent to allow the free escape of any fluid which may collect in the interior of the bursa before it is closed. This is especially to be observed with the lower opening, which is apt to become blocked up.

Chronic Enlargement.—The next affection to which the bursa patellæ is liable is closely allied to the last, and appears to be an advanced degree of it. It consists in a chronic enlargement of the bursa, the coats of which are much thickened. The contents of the bursa, so enlarged, consist of a dark fluid, in which float a number of smooth oval bodies, of the size and shape of melon-seeds. I have seen this condition in both the male and the female. It may be distinguished from simple enlargement of the bursa, by the peculiar crackling sensation which is communicated to the hand when the tumour is manipulated. This arises from the melon-seed bodies floating about and rubbing against each other.

The *Pathology* of this affection is as follows. There is enlargement of the bursa, and excessive secretion into its interior of simple synovial fluid; this, however, is dark-coloured, probably from admixture of blood which has undergone disintegration. This fluid will be found to contain a large quantity of cholesteroline, broken-up blood corpuscles, and granules. The

melon-seed bodies are composed of lowly organised fibroid matter mixed with cholesterine, and are probably separated from the wall of the bursa.

Solid Tumours may be formed in connection with the bursa patellæ. By many these are supposed to be the result of the deposition of a fibroid material, which gradually takes the place of the fluid of an ordinary "house-maid's knee," and which, instead of taking the form of melon-seed bodies, is deposited in concentric masses, and thus accumulated in the interior of the cyst. This has not been the case, however, in many instances that I have seen. In these cases I believe there is a true fibroid deposit in the bursa from the very first; the tumour is never fluid, but hard and solid from the commencement, and continues slowly to augment in size, until it occasions sufficient inconvenience to require removal. In some cases there has been a previous syphilitic taint; the patient complains of pain in the tumour like that which is experienced in nodes, and it is by no means impossible that there may be a syphilitic origin for these tumours. However that may be, in the cases that have fallen under my observation, the tumours have never been fluid, nor have they originated in pressure, but appear to have been primary deposits of fibroid matter.

Treatment.—There is nothing to be done with such tumours but to dissect them out. This may be required in one or in both knees. With the most ordinary care the joint runs but little risk; but much trouble may arise from opening up that layer of deep fascia which, after surrounding the knee, is fixed to the borders of the patella. Such an accident is liable to be followed by infiltration and deep abscess in the ham, and is to be avoided by keeping the scalpel well towards the centre of the patella when operating.

Bunion.—When the bursa which lies towards the plantar surface of the head of the metatarsal bone of the great toe becomes enlarged, or when a new serous sac is formed upon the inner and posterior aspect of this bone, the disease termed a *bunion* occurs. In this affection, the enlargement of the bursa is usually secondary to an alteration in the shape and position of the great toe, which, in consequence of the pressure of narrow-pointed boots, has been thrown outwards in an oblique direction, so as to lie over or under some of the contiguous digits (Fig. 283); in this way a sharp angle is formed at the junction between the first phalanx and the metatarsal bone of the great toe. This angle, being constantly pressed upon by the boot, becomes irritated; and, for its protection, the bursa that is there naturally situated becomes enlarged, or an adventitious one forms. From time to time the bursa and the projecting angle become irritated and inflamed; and the morbid action thus set up may run on to suppuration of a very troublesome kind, a thin, unhealthy pus being formed, which is discharged through an opening that speedily becomes fistulous, and may degenerate into a most troublesome indolent sore.

Treatment.—In the treatment of this affection, the first thing to be done is to change the direction of the toe by wearing properly shaped boots, made with the inner side of the sole straight from the toe to the heel. If accidental inflammation be excited in the part, it must be allayed by the application of leeches, warm foot-baths, and poulticing; the cutaneous irritation that is left may best be removed by painting the surface with a strong

Fig. 283 — Bunion

solution of nitrate of silver. The faulty direction of the toe may best be remedied by using the ingenious contrivance described by Mr. Bigg, the action of which consists in drawing the everted end of the toe inwards by the constant action of a slender steel spring. Should these means fail, the position of the toe may be remedied by the division of the external lateral ligament of the metatarsophalangeal articulation, or of the tendon of the adductor pollicis, or the inner head of the flexor brevis pollicis; the toe, when restored to its position, being for a time kept fixed upon an under-splint.

DISEASES OF SHEATHS OF TENDONS.

The synovial sacs connected with the sheaths of tendons, are liable to two forms of disease: viz., the accumulating of fluid in the interior of the sac, forming a cystic swelling, known by the name of Ganglion; and acute and chronic inflammation, or Tenosynovitis. The tendons of the hand are most liable to both these affections.

Ganglion.—Two distinct kinds of ganglion are met with: the *Simple*, situated upon the sheaths of tendons; and the *Compound*, consisting in a dilatation of the sheath itself.

Simple Ganglion consists of a cyst varying in size from a cherry-stone to a large marble, and containing a clear transparent fluid of a yellowish colour, which is sometimes thin and serous, sometimes gelatinous and semi-coagulated. It occurs as a smooth, globular, elastic, and tense tumour, usually situated on the back of the wrist, where it forms a distinct round projection; it may also occur on the dorsum of the foot. In both situations it is distinctly connected with the sheaths of the extensor tendons; and, indeed, Paget looks upon it as being a cystic transformation of the fringed process of synovial membrane lining these sheaths. As ganglion increases in size, it often gives rise to painful sensations in the parts below it, by pressing upon the neighbouring nerves; thus, a ganglion at the back of the wrist often produces pain and weakness in the hand, by compressing some of the branches of the musculo-spiral nerve which are stretched over it.

Compound Ganglion is chiefly met with in the palm of the hand, and the dorsum, sole, or inner side of the foot. It consists of a dilatation of the sheaths of the tendons in these situations, and may often attain a very considerable bulk, and then usually becomes irregular in shape, owing to several tendons being implicated by it. Often, in this form of ganglion, the sheath is simply thickened as well as dilated, and the contained fluid is clear and yellowish, though usually thinner than in the simple ganglion. The sheath itself is vascular, and lined by a red, fringed, and velvety membrane, the fluid may then be dark and bloody, and contain masses of buff-coloured fibrine or a large number of granular bodies, like those met with in certain forms of enlarged bursæ. These I have found to be composed of imperfectly developed granulations, in which the remains of blood-vessels were visible, probably thrown off from the inner wall of the vascular sheath. This form of the disease, at times, puts on almost a malignant appearance, is extremely chronic in its characters, and may occupy a very extensive surface; in a case of the kind that was under my care some time ago, the dorsum and greater part of the inner side of the foot were involved.

Treatment.—The treatment of a ganglion must depend upon its character and size. When small and simple, as on the back of the wrist, it may commonly be got rid of by being ruptured by forcible pressure with the thumb, or by a blow with the back of a book, or by being tightly com-

pressed, by means of a sixpence wrapped in a piece of lint and firmly strapped upon the swelling. If it do not disappear in this way, the best plan is to puncture it subcutaneously by means of a valvular opening, to squeeze out its contents, scarify the interior of the cyst, and employ pressure. If the ganglion give rise to much pain and weakness, and cannot be made to disappear by the use of the means just indicated, it may usually be very conveniently and safely obliterated by passing a seton of two threads through it, and leaving it in for four or five days, until sufficient inflammatory action has been induced for the obliteration of the cyst. Should this means fail, it may be dissected out, if it be thought advisable to have recourse to this somewhat severe procedure, which is attended with some risk of inflammation extending up the sheath of the tendon. I have, however, on several occasions performed this operation, without any troublesome consequences ensuing.

A Ganglion situated in the Palm of the Hand, and extending under the annular ligament some little distance up the flexor tendons of the forearm, is a very troublesome disease. Syme recommends that the cyst should be laid open, and the annular ligament divided. This seems to me an unnecessarily severe procedure; and I have in several instances cured the affection by milder means: in one, by injecting a small quantity of tincture of iodine into the cyst through a puncture in the palm, and in two or three other cases by the use of the seton. The seton is most easily introduced by squeezing the fluid from the palm into the sheaths of the flexor tendons above the wrist, making a puncture into these, and then pushing an eyed probe armed with two or three threads along the tendons under the annular ligament into the centre of the palm, where it is to be drawn out through a small incision made down upon it.

In the *Side and Sole of the Foot* these ganglionic tumours, when of large size, and filled with semi solid fibrinous matter, may require to be dissected out.

INFLAMMATION OF THE SHEATHS OF TENDONS—TENOSYNOVITIS.—This is occasionally met with as the result of strains and twists of the hand, about the wrist, of the extensor tendons, or the long head of the biceps. In this affection there is swelling of a puffy character, with tenderness when the part is pressed on or moved; and usually a peculiar fine crackling sensation is communicated to the surgeon's hand when he examines the affected part. The crackling is especially marked in cases in which the inflammation and effusion have become chronic, when the disease appears to partake of the nature of a diffused ganglion.

Treatment.—The treatment, when the disease is acute, consists in leeching and blistering, with rest of the part; when it has assumed a chronic character, the application of blisters and the mercury and ammoniacum plaster will be found most useful.

DISEASES OF MUSCLES.

The voluntary muscles are not often the seat of primary disease of any kind. *Inflammatory affections* of muscles of a rheumatic character undoubtedly occur, and abscess is occasionally met with inside muscular sheaths, more particularly that of the rectus abdominis. *Syphilitic tumours*, or rather inflammatory or plastic indurations of muscles, are not very unfrequently met with.

Tumours of Muscle.—Organic structural diseases of muscular tissue are rare, yet the records of Surgery contain scattered through them no inconsiderable number of cases. My friend and former pupil, Mr. Teevan, has, with much industry, collected the particulars of 62 cases of Tumours of Muscles of all kinds. About one third of these he finds to have been can-

cerous; 16 were fibrous; 8 cystic; 5 hydatid; and 5 erectile. The form of cancer that occurs primarily in muscles is, I believe, invariably the encephaloid. I have most frequently seen the muscles of the lower extremity the seat of organic disease. When the upper limbs are affected, the muscles that have, according to Mr. Teevan, been most frequently attacked are the pectoralis major, deltoid, and biceps. The muscles of the trunk and neck are seldom diseased, with the exception of the rectus abdominis, which appears to be very liable to tumours.

I have had under my care seven cases in which tumours of different kinds developed primarily in muscular tissue. The first case was that of a woman, about 48 years of age, in whom a fibro-cystic tumour, as large as a coconut, developed in connection with the tensor vaginæ femoris, forming a large mass, which I dissected out readily from over the hip. The second case was that of a lad about 18, in whom a cystic tumour, as large as a fetal head, thick walled, and containing clear fluid, developed in the substance of the adductor brevis of the thigh, from which it was dissected out with no little difficulty, and with a fatal result. The third case was that of a man from whom the accompanying drawings are taken (Figs. 284,

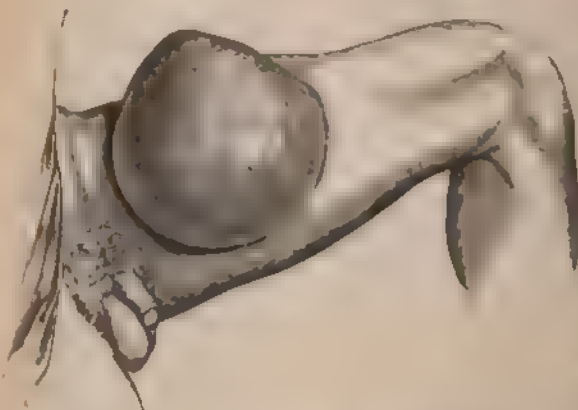

Fig. 284.—Fibro-Plastic Tumour of the Sartorius Muscle

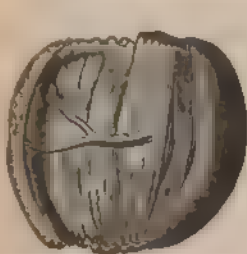

Fig. 285.—Back View of Tumour, showing Sartorius Muscle

Fig. 286.—Front View of Tumour, laid open, and showing Sartorius, &c.

285, 286), in whom a fibro-plastic tumour developed within the sheath of and in the substance of the sartorius muscle of the left thigh, in consequence of a strain. After growing slowly for about six years, it had attained the size of a child's head, when I removed it, together with seven or eight inches of the muscle from the inside of the sheath of which it had originated, and with which it was closely incorporated. The sheath of the femoral vessels, which was exposed for a considerable extent,

was unaffected by the disease. Recurrence took place in less than twelve months in the cicatrix, and when the secondary tumour had attained the size of an ostrich's egg, it was removed, the patient making a good recovery, but recurrence of the disease took place, which eventually proved fatal.

The fourth case was that of a man aged about 40, in the sole of whose foot a cystic tumour, about as large as a goose's egg, was developed, springing from the flexor brevis digitorum. This was carefully dissected out; but in a few months the patient returned, with a solid, elastic, rapidly growing tumour, evidently malignant, developed in the cicatrix. The foot was amputated, and on dissection the mass proved to be encephaloid, and to have developed from the muscular structure just named.

In two cases the tumours were hydatid. In one patient, a young woman, the disease was seated in the deltoid; in the other, a medical man, about 50 years of age, the tumour was seated at the outer edge of the latissimus dorsi. In both cases excision of the tumour was successfully practised.

In the seventh case the tumour was an enchondroma in the tibialis anticus. I have seen two other cases of enchondroma in muscles: one situated in the vastus externus of the thigh; the other, in connection with the pectoral muscle.

Tumours developing primarily in the intermuscular cellular planes are of very common occurrence; but these are very different from, and must not be confounded with, true muscular tumours.

The Treatment of these various muscular tumours must be considered on ordinary surgical principles. When of an innocent character, as cystic or hydatid, fibrous, erectile, or enchondromatous, they may be dissected out from the muscular tissue amongst which they lie, and no fear of recurrence need be entertained.

When they are malignant, amputation of the limb, if the tumour be favourably situated for such an operation, is usually the only resource: partial operations are usually worse than useless, as they lead to a speedy recurrence of the malignant action. Mr. Toevan has made the ingenious suggestion of applying to malignant tumours of muscle the same rule of practice that guides us in operations on bones affected by cancer; viz., to remove the whole of the organ that is the seat of disease, excising the entire muscle from its origin to its insertion, and thus eliminating from the system the whole of the morbid mass, which will be confined within its sheath—a structure that for a long time resists the outward pressure of a morbid growth. This suggestion is founded on correct pathological principles; the only objection to it is its difficulty of application in actual practice—there being few muscles so situated that they could with safety be completely extirpated.

CHAPTER LIV.

DEFORMITIES.

LATERAL CURVATURE OF THE SPINE.

THIS affection, on account of the frequency of its occurrence and the tediousness of its cure, has received a good deal of attention from various surgeons; and much has been written on it by those who have specially devoted themselves to its treatment; yet the whole of its pathology and management lie in a very narrow compass.

Lateral curvature of the spine most commonly commences at an early period of life, usually between the ages of twelve and eighteen—achieve

before the one, and not very commonly after the other. Girls are more frequently the subjects of this deformity, which but very rarely occurs in boys. It appears to consist simply in a relaxation of the muscles and ligaments of the spine; in consequence of which the vertebral column, being no longer able to support the weight of the head, neck, and shoulders, becomes curved to one side, a corresponding deviation taking place in the opposite direction at a lower portion of the spine, in order to preserve the equilibrium between the two sides of the body (Figs. 287, 288). The first curve

usually takes place in the upper or middle dorsal region, the convexity tending towards the right side; the second, or compensating curve, occurs in the lumbar region, the convexity looking towards the left. In some instances there is a quadruple curve (Fig. 289). At the same time that these lateral curves take place, there is a tendency to rotation of

Fig. 287.—Lateral Curvature and Rotation of Spina.

Fig. 288.—O-Aline of Double Lateral Curvature.

Fig. 289.—Quadruple Curve.

the bones of the spine upon one another, in such a way that the bodies of the vertebrae forming the dorsal curve are twisted slightly to the left, while those which enter into the formation of the lumbar curve are turned slightly to the right (Fig. 287). This twist is sometimes slight; but in other instances it is very marked, so that there is a double curvature—lateral and rotatory.

On examining the bones and intervertebral fibro-cartilages after death, even in cases of very considerable distortion, no disease will appear in them; except, perhaps, that the bodies of some may have been slightly compressed where they form the principal concavity of the arch. The ligaments appear to be stretched, relaxed, and somewhat weakened; and the muscles are usually pale, flabby, and apparently wanting in power.

MECHANISM. From a consideration of the pathology of this affection, and from the particular age at which it manifests itself, before the bones have become completely ossified, or the ligaments have acquired their due degree of rigidity, its mechanism becomes sufficiently apparent. The spinal column, being composed of a number of separate bones, possesses no firmness in itself, or power of self support, but is maintained in the erect position by the close manner in which its separate elements are knit together by ligamentous and

muscular structures, and by the way in which, when thus bound together as a whole, it is supported on each side by the strong mass of the erector spine muscles. The proper tension of these ligamentous supports and muscular masses, is especially necessary for it to maintain the weight of the head and shoulders, which is thrown on the cervical and the upper portion of the dorsal spine. If, from any cause, the ligaments become relaxed, and the muscles lose their tension, or if the weight of the upper part of the body increase disproportionately to the augmentation in the strength of the ligaments and muscles that support the spine, the vertebral column will necessarily give way under the pressure to which it is subjected in a direct line from above downwards, and will consequently become curved. Most commonly, indeed almost invariably, this takes place in a lateral direction, the spine yielding more readily in this than in any other. In some

rare cases, however, the lower portion of the cervical or the upper dorsal region will project backwards in an angular manner, constituting the disease termed *Cyphosis* (Fig. 290); and in other cases, of still less frequent occurrence, there may be incurvation of the spine in the dorso-lumbar region, giving rise to *Lordosis* (Fig. 291).

The directions in which these various curves take place are exaggerations of the natural inclination of the spinal column. In *lateral curvature*, the chief convexity takes place towards the right side, causing a projection of that shoulder which in most people is somewhat more prominent than the other. In *cyphosis*,

Fig. 290.—*Cyphosis*.

Fig. 291.—*Lordosis*.

the excurvation takes place in the lower cervical and upper dorsal regions, which are naturally prominent; and, in *lordosis*, the incurvation is most marked in the lumbar region, in which there is naturally a curve forwards.

CAUSES.—These various kinds of deformity, as has already been stated, chiefly occur in girls about the age of puberty; at a time of life when the tonicity of the muscular system not unfrequently becomes lessened by the occurrence of anemia and those states of impaired health that so frequently attend the establishment of the uterine function; and before the osseous and ligamentous structures of the body are fully developed. At this period of life, also, it frequently happens that the spine becomes rather suddenly elongated by a rapid increase in growth taking place; or that it becomes overweighted by the system developing itself, and the shoulders and bust becoming stont and expanded. Indeed, so frequent is the occurrence of a certain degree of lateral curvature of the spine from these various causes, about the age of puberty in girls, that few escape a tendency to deviation; of so slight a kind, however, as not to admit of recognition as a disease. But if this tendency be allowed to go on unchecked, or if it be increased by injurious habits, amongst which are all one-sided postures in which the body is twisted, as in playing some musical instruments, or in leaning over a table in drawing and writing, the slight deviation may rapidly increase until it assume the true characters of lateral curvature of the spine. I do not think that there is any evidence to show that this is either a strumous or a rickety affection; indeed, so far as my observation goes, I

should certainly say that strumous girls are less liable to the disease than those of a nervous or bilious temperament. A rickety tendency would, of course, increase the disposition to the affection; but I think this is very rarely associated with it. Amongst the more common predisposing causes must undoubtedly be reckoned the indolent and sedentary occupations, and the luxurious enervating habits that are commonly encouraged in girls in the higher ranks of life, and which, by preventing due muscular development, at the same time that they induce a general loss of tone in the system, may directly occasion the disease.

The causes of the antero-posterior curves are usually to be found in some faulty habits of the patient; either giving rise to an habitual stoop, and thus laying the foundation for cyphosis, or throwing too great a weight on the loins, and thus giving rise to lordosis. A kind of spurious lordosis is developed in some cases of ankylosis of the hip-joint.

SIGNS OF LATERAL CURVATURE.—The signs of this affection, when it is well marked, are distinctly obvious. The serpentine character of the curve, its double nature, the convexity on one side looking to the right shoulder, and on the other to the left loin, will render its nature evident. Most commonly it commences in a gradual manner, the first condition that frequently attracts attention being the prominence of the right scapula, which is supposed to be "growing out;" or the sterno-clavicular articulation on the same side, or some of the cartilages of the ribs, have been observed to project. Whenever the surgeon is consulted for such symptoms as these, he should at once examine the spine, which he will generally find to have an inclination to the right side. In the early stages of the disease, when the deviation is not very distinctly marked, the readiest mode of determining it is to let the patient stand up-right, taking care that the feet are well placed together, and that the attitude is not forced, but natural; the surgeon should then run his finger down the back from one spinous process to another, touching each as he passes it with a pen dipped in ink; in this way, when he has reached the lower part, he will have mapped out the course of the vertebral column, and thus may see at a glance the nature and extent of its displacement. At the same time, he will probably observe that the two hips do not exactly correspond, the left being somewhat thrown out. Very commonly there is a good deal of neuralgic tenderness about the spine, and at this early stage there may be anæmia and symptoms of impaired nutrition. As the disease advances, the curvature becomes more distinct, and at the same time, owing to the torsion of the column, assumes a slightly angular character where most convex.

The ribs on the right side are thrown out and bulging, and carry up the scapula

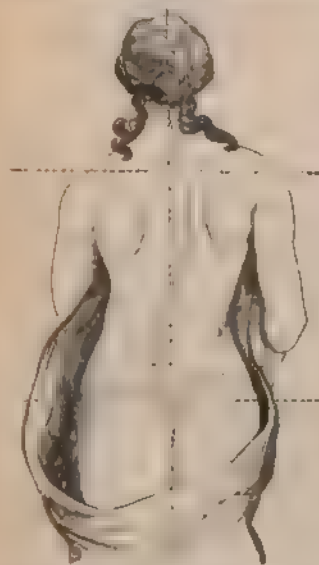

Fig 292.—Lateral Curvature of Spine

with them, whilst those on the left are sunk and depressed (Fig. 292). In fact, the whole of the right side of the chest and body partakes in the projection of the spine on that side, and thus adds much to the general de-

torquity; whilst the left side of the chest is correspondingly hollowed and sunk in. When the disease has advanced in this way, it always occasions great general debility, emaciation, and pallor; the nutrition of the body being impaired, partly by the compression to which the thoracic and abdominal organs are subjected, and partly, doubtless, by irritation set up in the spinal cord, induced by the curvature.

During the early part of the disease the spine preserves its flexibility; and whilst the curve is still recent, and the patient young, if the weight of the head and shoulders be taken off, it will at once resume its straight direction. Thus, if the patient be lifted off the ground by raising her up with the hands under the axillæ, or if she be laid down on her face on a flat couch, the back will fall into a straight position, or may readily be made to do so by slight traction. After the disease, however, has existed for some years, or if the patient have passed that age at which consolidation of the bones and ligaments takes place, the distortion will continue permanently, in whatever position she may be placed. This is not only owing to the deformity of the spine, but to the ribs, and ligamentous and muscular structures generally of the trunk, having become fixed in their abnormal position.

TREATMENT.—The treatment of lateral curvature of the spine should be conducted on rational principles; and when divested of the mystery with which some interested specialists have surrounded it, becomes as simple as that of any other chronic surgical affection of the bones, joints, or muscles. There are three principles of treatment that require to be carried out in the management of these cases. The first is the improvement of the general health,—unless this be effected, nothing can be done; the second is to strengthen the muscles of the spine; and the third, to take away as much as possible the weight of the head, neck, and upper extremities.

The administration of some of the milder preparations of iron, with a course of aloetics for the regulation of the uterine function, is of great moment; at the same time, a nourishing diet of animal food should be allowed, and the patient encouraged to take exercise in the open air. By these means the nutrition of the system will be improved, and the tone of the muscles greatly restored. The muscular power may be more directly strengthened by having the back well sponged with cold salt or vinegar and water every morning, and methodically rubbed from top to bottom. The friction should be principally directed to the erector spinae muscles on either side of the vertebral column, and may be done either with the naked hand, or with some slightly stimulating embrocation. At the same time, if the patient's strength will permit it, but not otherwise, the use of the hand-awing may be allowed, or calisthenic exercises practised; these, however, should not be continued if they induce a feeling of fatigue or exhaustion. Whilst this plan is being persevered in, the patient should be made to lie recumbent for a few hours daily, sitting or standing as little as possible. By these means, assiduously continued for some length of time, the muscles of the back may be strengthened, and the increase of the deformity prevented; and in this way the slighter cases of lateral curvature, those in which there is rather a tendency to than a full development of the disease, may be cured.

When the affection is further advanced, though the spine still continues flexible, if there be decided projection of the ribs on one side, and the shoulder and hip be prominent, with apparent difference in the length of the limbs, and much impairment of the general health, more decided measures of treatment must be had recourse to. In these cases, as in those just described, the constitutional powers must be carefully attended to on ordinary medical

principles; iron, and good living, with fresh air, being the basis of the treatment. At the same time that we endeavour to improve the strength of the system in this way, and that of the muscles of the back, specially by cold bathing and frictions, it is essential to adopt means to take off the weight of the head and shoulders, and to prevent its continuing to keep up and to increase the deformity. This may be done in two ways: by keeping the patient in the recumbent position, or by allowing her to go about, wearing proper supports.

The *recumbent position* in the treatment of lateral curvature of the spine, though a valuable means as an adjunct to other measures, has been greatly abused, by being employed as an exclusive plan. This, I think, should not be, except when the patient is unable to stand or walk with comfort, as happens in some of these cases, when it may be necessary to confine her for a time to this position, until the proper muscular power is restored by other means. These instances, however, are very rare; too much so to constitute the rule in the treatment. Whenever the recumbent position is employed, the prone seems to me far preferable to the supine, for reasons mentioned when speaking of angular curvature of the spine (p. 791); and the best couch for the purpose is certainly Verral's. The patient should be kept on this during the intervals of exercise, not being allowed to sit or stand, even at meals; she will very soon become accustomed to a position that at first appears constrained, and will, probably, speedily be enabled to sleep in it.

The *Mechanical Contrivances* constructed for the purpose of taking the weight of the head, neck, and other extremities, off from the weakened spine, are of very various forms, and have had much ingenuity expended in their construction. They all have three principal objects, however much their details may vary; viz.: 1, to take a broad basis of support round the pelvis, by means of a strong well-fitting band; 2, to carry off the weight of the head and upper extremities from the spine by means of lateral crutches, which transmit it to this band; and 3, to influence the con-

voxities of the spinal curve by means of movable plates, acted upon by rack-and-pinion or screw power. The best of these mechanical contrivances for supporting the weight of the head and shoulders, is the apparatus represented in the accompanying woodcut (Fig. 293), taken from an instrument constructed by Mr. Bigg. By it the projection of the right shoulder may be gradually brought down, the left one raised, and the weight of the whole of the upper part of the body supported. By this contrivance alone, properly and carefully adjusted to the condition of the deformity, most patients may be treated without the necessity of any confinement whatever, the spine being gradually restored to

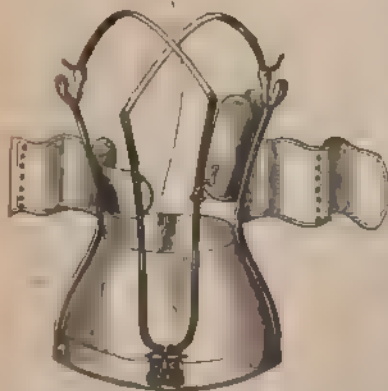

Fig. 293.—Spinal Support for Lateral Curvature

its proper direction by very gradually increasing the pressure and support of the instrument, at the same time that the general health is carefully

attended to, and the patient has the benefit of good air. At first the instrument need only be worn during the day, but after a time it should be kept on at night as well. In long standing and severe cases of lateral curvature of the spine, when its flexibility is lost, and the projection of the ribs has become permanent, a cure cannot be expected, nor can it be brought about by any means; but the patient will derive great comfort and support from the use of this excellent instrument, and the increase of the disease may thus be prevented.

The treatment of *Posterior Excurvation* of the spine, without caries or

other organic disease of the vertebral column, is best conducted by the use of the instrument here figured (Fig. 294), which is constructed essentially on the same principles as that for lateral curvature, with the exception that the backplate is so arranged as to press upon the projecting spine, and thus gradually to bring it into proper position.

In *Posterior Incurvation* the apparatus here figured (Fig. 295) will be found the most useful

Fig. 294.—Spinal Support for Posterior Excurvation.

Fig. 295.—Spinal Support for Posterior Incurvation.

appliance. In fact, all these varieties of spinal curvature may be successfully remedied by instruments constructed on the most simple mechanical principles, if carefully attended to and carried out.

CONTRACTIONS AND RETRACTIONS OF MUSCLES.

Under the head of *Muscular Contractions* are included various deformities, such as squint, wry-neck, club-foot, club-hand, some of which are congenital, others acquired. In all of these conditions, the deformity is primarily owing to an affection of the muscular system, and not to disease of the bones or ligaments, which are only secondarily implicated.

CAUSES.—The causes of these deformities are very various; but they may be referred to three heads.

1. *Continuous Faulty or Abnormal Position* of a limb, as in an unreduced dislocation or an ankylosed joint, will be followed by the disuse of a certain set of muscles, which consequently become shortened and atrophied, and acquire a rigid state. This condition is consecutive to the displacement, but renders it permanent; it is apt to occur after fractures, if the parts be kept for too long a time in one position, and more particularly if they be bound and matted together by the pressure of tight bandages. A somewhat similar cause sometimes operates on the fetus in utero; an abnormal position in the uterine cavity being very frequently the immediate occasion of some of the varieties of congenital club-foot. These deformities must not be confounded with congenital dislocations, in which there is always an arrest of development of some of the articular ends of the bones connected with the affected joint.

2. *Irritation set up in the Central Portions of the Nervous System*, may produce deformity by deranging the proper antagonistic action of certain

groups of muscles. This condition gives rise to many of the congenital as well as of the non-congenital deformities. It may act by producing more or less complete paralysis of one set of muscles, the contractility of their antagonists continuing normal; and thus, the relative balance of action being destroyed, the stronger will draw the part over to their side. The influence of this want of proper balance of parts in paralysis, producing deformity, may be well seen in palsy of the portio dura where the face is distorted by being drawn to the sound side; or in squint, where, the external rectus being paralysed, the eye is drawn inwards. According to Tamplin, deformity from paralysis is never congenital, though it is not unfrequently met with in the non-congenital cases. Central irritation may occasion deformity in another way, by producing tonic or permanent spasm of one set of muscles, the other remaining perfect in their contractility, but overbalanced by the continued contraction of their antagonists. This would appear to be the case in some forms of squint. Dr. Little has made the important observation, that many cases of deformity appear to be due to mischief inflicted on the base of the brain during protracted and instrumental labours.

3. *Peripheral Nervous Irritation* may occasion contraction of the muscles and deformity. This we commonly see happen in cases of contraction occurring from the irritation of worms in the intestinal canal, in the so-called hysterical contractions from uterine irritation, &c. From all these various causes contraction and deformity may arise. In some cases deformity will cease after the removal of the cause; but in other instances in which it has been of long duration, the deformity will continue, owing to the muscles having fallen into a kind of rigid atrophy, being shortened and wasted, and consequently unfitted for the proper exercise of the actions of the part.

TREATMENT.—The *General Treatment* of deformities consists in removing the cause of the contraction in those cases in which it is dependent on central, peripheral, or nervous irritation that admits of remedy. Thus, if squinting arise from pressure upon the brain, the eye will assume its straight direction when the congested vessels are relieved, or the effused fluids absorbed; or if a contraction of the ham-string muscles arise from the irritation of worms in the intestinal canal, a dose of purgative may cure the affection. When, however, the deformity is congenital or more permanent, the employment of *mechanical means* and the *Division of the Tendons* is the only mode of restoring the natural condition of the part. This *orthopædic* department of surgery owes, in a great measure, its existence to the labours of Delpech and Stromeyer, and its perfection to those of Little, Tamplin, and Adams.

TENOTOMY.—By tenotomy, as at present practised, is meant the subcutaneous division of a tendon by means of a very fine narrow-bladed knife (Fig. 296) introduced obliquely through a puncture by its side. In doing

Fig. 296.—Tenotomy-knife.

this it should be borne in mind, that the normal anatomical relations of parts are often a good deal disturbed in cases of deformity; and thus tendons may be approximated to arteries and nerves, from which, in the healthy condition of the limb, they are widely separated. The tendon may most conveniently be divided, in the majority of cases, by introducing the blade beneath it sideways and then turning the edge against it, scratching through it by a kind of firm sawing movement, the handle of the knife being used

a lever to press the edge against the tendon, whilst the parts are made secure by an assistant. A drop or two only of blood are lost in this simple operation, and, as the divided tendon retracts with a kind of snap, a gap will be left between the two ends, from half an inch to an inch in width, according to the previous amount of tension in the part. If the muscles have been contracted for some years, it will commonly be found that the fasciæ in the neighbourhood of the tendon have become rigid and unyielding, forming cords or bands stretching across from the side of the gap. If these be very tense, they may be divided in the same way; but in many instances it will be found after a lapse of a short time that they will yield, and consequently will not require division. After the section has been made, the small puncture should be closed with a pad of lint and a strip of plaster, the admission of air into the wound being carefully guarded against. The whole success of the operation depends on this. Should air enter, inflammation and suppuration will to a certainty be set up; whereas, if this be avoided, the wound will heal by the effusion of plastic matter without any inflammation. It is the entry of air, and not the subcutaneous wound, that gives rise to inflammation. The part should then be left without any apparatus being applied for three or four days. At the expiration of this time lymph will have been thrown out, and then proper mechanical contrivances may be adjusted for gradually restoring the normal position of the limb or part; if this be done too soon, the cicatrix will be extended at too early a period after the deposit of the plastic matter, and the tendon will become weakened and too much elongated.

Chloroform is not always admissible in these operations. In some cases it will be found that the muscle under its influence becomes so much relaxed, that the defined edge of the tendon disappears, and the proper section cannot be made.

The mode of *Repair in Divided Tendons* has given rise to some controversy, there being two theories with regard to the process. According to one, the plastic matter deposited between the divided and retracted ends gradually undergoes a process of contraction, analogous to what takes place in the cicatrix of a burn, so as to cause approximation of the cut ends of the tendon at the expense of the muscle, which becomes partially lengthened, until at last a transverse linear cicatrix merely is left at the line of section. Adams has, however, conclusively shown that this theory is erroneous, and that repair is effected by the deposit of plastic matter between the cut ends, chiefly from the sheaths and soft parts around; that this plastic matter undergoes gradual transformation into tendinous tissue; and that the tendon is actually lengthened, and remains permanently so, by the deposit of this new material, which eventually resembles the normal structure of tendon so closely that the microscope fails to detect any appreciable difference in structure, and that it can only be distinguished by its more translucent appearance from the old tendon. In fact, the divided tendon is completely regenerated or reproduced.

In cases of congenital malformation, the question frequently arises as to whether tenotomy should be performed in early infancy, or delayed to a more advanced age. As a general rule, I think that, if imperative, the sooner these operations are done the better; they are not more difficult at an early period of life than at any other, no danger attends them, and when they are performed during infancy, there is a far less chance of the deformity being permanent, than if the operation be delayed for some years. But it must be remembered that many slight deformities and contractions in infants may be removed without operation, by attention to proper mechanical and

hygienic means. The surgeon should, therefore, not be too ready to operate in slight cases at tender ages.

DEFORMITIES AFFECTING THE FACE AND NECK.

SQUINT.—By *Squint* or *Strabismus* is meant a want of parallelism in the position and motion of the eyes. Most commonly a squint is convergent, the edge of the cornea being buried under the inner angle of the lids, more rarely the divergent form is met with. In convergent strabismus, one eye only is generally affected, but in some cases both are implicated, though one eye is almost invariably worse than the other; and this gives an appearance as if there were an alternation of squinting in the two eyes. In order to ascertain which eye squints, the simplest plan is to direct the patient to look at a distant object; when the sound eye only will be directed towards it, the affected one being turned inwards.

Causes.—Squint may arise from a variety of causes; it not unfrequently comes on in children after infantile complaints, such as measles or scarlatina, and, as Sir C. Bell has observed, commonly depends upon weakness of the external rectus, arising from some paralytic affection of the sixth nerve, seldom upon spasm of the internal rectus. In many cases it is indicative of disease of the brain or nervous centres, occasioning paralysis or irritation of the motor nerves of the eye; in other instances it may occur from the irritation of worms in the intestinal canal; and not unfrequently it is dependent upon some disease of the eyelids or eyeball. Thus the various inflammatory affections of the conjunctiva and eyelids may occasion it; or it may, as not unfrequently happens, when it occurs in adults, be dependent on difference in the focal length of vision, owing to amaurosis or the failure of sight in one eye; and lastly, in children it may be induced by habit or imitation.

Treatment.—The treatment of squint must to a certain extent be influenced by its cause. Thus, the removal of congestion of the brain or the expulsion of worms from the intestines may cure the affection; or, if it have followed simple debility in children, it will disappear as their strength improves, and they will thus outgrow it. If, however, the deformity be of a permanent character, it may readily be remedied by the simple operation introduced by Dieffenbach. The operation for squint should not, I think, be performed until the child has attained its eighth year, as it is not very easy to do it satisfactorily before this period, owing to the restlessness of infants; and, in very many instances, the squint gradually disappears as a child grows older, without recourse being had to any operative procedure. Indeed, in many cases it may be better to defer it till the adult age is reached. On the other hand, it should not be delayed too long, lest some contraction of the features or deformity in the other eye be left, and thus a very satisfactory result be not obtained. The operation is sufficiently simple; it may most conveniently be done by bandaging the sound eye, and then directing the patient to look outwards with the affected one; a fold of the conjunctiva near the inner canthus is then seized with the forceps, and snipped transversely with a pair of rather sharp-pointed scissors. By dilating the wound slightly with the scissor-blades, the tendon of the internal rectus will be exposed, which may be seized with the forceps, and readily cut across; or a very convenient plan consists in passing a curved director underneath it, raising it upon this, and then dividing it either with the scissors or a small curved bistoury. During the operation the eyelids must be held apart by an assistant, who may, if necessary, use the eye-speculum for this purpose. After the operation, a piece of wet lint should be laid upon the eye; and, if

any fungous granulations spring from the wound, they must be snipped off or touched with the nitrate of silver; some double vision may be left, but this gradually wears off. Critchett advocates the subcutaneous section of the muscle in strabismus, as being less likely to be followed by those inconveniences and deformities that attend its division in the ordinary way; viz., depression of the caruncle, slow healing, an unsightly cicatrix, and often more or less prominence and eversion, that are as disfiguring as the condition for which the operation is done.

WRY-NECK.—Wry-neck, *Torticollis*, or *Caput Obstipum*, arises from spasm of one of the sterno-mastoid muscles; the head being drawn to the affected side. On close examination in wry-neck it will be found that there is a triple displacement of the head, which is drawn downwards, rotated outwards, and inclined laterally towards the affected side. The features lose their symmetry; the half of the face, and even of the head, on the affected side, becomes less perfectly developed; the true line of the eyebrows, eyes, and mouth becomes displaced and lowered.

In torticollis the affected sterno-cleido-mastoid will be found hard, defined, and shortened; and sometimes both divisions of the muscle are equally tense, standing out in strong relief, so as almost to look like two distinct muscles. In other cases one division, and then most usually the sternal, is chiefly affected. After a time the cervical vertebrae participate in and maintain the displacement, becoming rotated on their axes and curved. Eventually the whole spinal column participates in the displacement, and lateral curvature sets in. The deeper muscles also become shortened, and the anterior margin and clavicular attachment of the trapezius will often be found tense and preternaturally defined.

Causes.—Wry-neck occasionally appears to be congenital: more frequently it is acquired, coming on in childhood after measles or scarlatina, or as a consequence of inflamed cervical glands. It not unfrequently commences with an ordinary stiff neck from cold. In whatever way it originates, the spinal accessory nerve is probably at fault, and it is owing to the irritation of it that the sterno-mastoid and trapezius muscles take on a spasmodic action. In spasm of both sterno-mastoids the head is thrown forwards, the muscles projecting in great relief. In these cases, the disease will usually be found to have had a rheumatic origin. Deformity in this situation may also occur from diseased cervical vertebrae, or from the traction of the cicatrix of a burn. The conditions here, however, are peculiar, depending upon causes that are irrespective of the state of the muscles, and may readily be distinguished from the true form of the disease produced by the causes above mentioned.

Treatment.—The treatment of torticollis arising from permanent spasm of one of the sterno-mastoids, which is the common form of the affection, may best be conducted by dividing the inferior attachment of the muscle, and thus allowing the head to regain its proper position. The division of the muscle is a somewhat delicate operation, on account of the important structures that lie immediately behind it. By making the incision, however, through it, from behind forwards, close to the sternum and along the clavicle, there can, if ordinary care be employed, be little risk of doing any damage, as these bones carry the lower attachment of the muscle forwards, and separate it from adjacent parts. The tension also into which it is thrown by its spasm draws it away from the carotid sheath. In several instances in which I have had occasion to perform this operation, no difficulty whatever has been experienced in dividing the sternal attachment of the muscle, which is usually very tense and prominent, by passing an

ordinary tenotome behind the tendon, with its flat side towards it, just in front of the upper margin of the sternum, and then cutting forwards, whilst the muscle is put well upon the stretch. In dividing the clavicular insertion, the safest plan, I think, consists in making a puncture with a scalpel upon and down to the clavicle in the cellular space which lies between the two attachments of the muscle, and then pushing a long blunt-pointed, narrow-bladed tenotome between that bone and the insertion of the muscle, dividing this in a direction forwards. Care must be taken to divide the muscle completely, but not to carry the incision too freely or deeply. I have heard of more than one case in which, from want of due precaution, abundant hemorrhage occurred, and of three in which fatal results followed the operation:

After the operation, the position of the head must be gradually rectified by proper apparatus (Fig. 297). The best instrument for this purpose is the one

Fig. 297.—Bigg's Apparatus for Wry-neck

invented by Mr. Bigg, and here figured. It consists of a pelvic band, a vertebral stem, and arm-pieces, the object of which is to secure a firm basis of support to the neck lever (1), and the maxillary lever (2). The neck lever passes round the head, and takes its bearing against the temporal bone on the side towards which the head is deflected. The maxillary lever acts against the lower jaw on the opposite side—that which is turned up. By means of a ratchet-joint the neck lever, the action of which is vertical, turns the head from the side to which it is deflected, whilst the maxillary lever, acting horizontally, rotates the head on its vertebral axis. By the combined action of these two forces the head is restored to its vertical position, and the chin replaced in the mesial line. In this way the curvature of the cervical vertebrae may gradually be corrected; should it, however, have existed for a considerable time, it may have assumed a permanent character, and a twist in the neck will continue for life. If the operation be not delayed too late in life, the features will gradually regain their symmetry. After the division of the tendon, the deep fascia of the neck will sometimes be found stretching across in firm and tense bands; these,

however, had better not be interfered with, as they will yield in time, and much risk of injuring the subclavian and carotid vessels would attend any attempt at their division. The exposure and division of the spinal accessory nerve has been practised, but not, I believe, with much benefit.

In those cases in which the wry-neck appears rather to be dependent on paralysis of one sterno-mastoid, than on spasm of the other, electricity, and the application of strychnine to a blistered surface over the muscle, will be found most useful.

DEFORMITIES OF THE ARM AND HAND.

CONTRACTION OF THE ARM is not of very common occurrence, except as the result of burns. I have, however, met with four distinct forms of contraction of the forearm:

1. There may be anchylosis of the elbow-joint, the forearm being bent at

a right angle with the arm, the result of disease of or around the articulation. If the ankylosis be fibrous, and the muscles strong and firm, a very useful limb may be restored by breaking down adhesions, under chloroform, by forcible flexion and extension, and then using passive motion, friction, and douches. Should the muscles be very flaccid and wasted, forcible extension may leave a permanently weakened limb, over which the patient has lost the power of flexion. In such cases I have found gradual extension, made by means of an angular splint, acted upon by a ratchet-apparatus, the safest means of restoring the utility of the arm. If the ankylosis be osseous, the bones should be resected, a wedge-shaped piece being sawn out, and a false joint allowed to form.

2. The biceps may, by its contraction, occasion a permanent flexion of the arm. This contraction of the biceps may be hysterical or rheumatic. When hysterical, occurring in young women, it requires the ordinary constitutional treatment of hysteria; should this fail in removing it, extension may be made under chloroform, and the arm kept in the straight position for a time. When it is rheumatic, or of organic character, and permanent, section of the tendon and its aponeurosis may be practised, due care being taken of the artery and nerve. This operation is most safely done by introducing the tenotome to the inner side of the tendon, slipping it under, and cutting upwards and outwards; the artery being guarded and pushed to the inner side by the pressure of the left forefinger.

3. The forearm may be forcibly pronated and flexed as the result of chronic inflammation of the radio-humeral articulation. Here forcible supination and extension, under chloroform, is the best remedy.

4. The forearm may be bent on the arm in consequence of the contraction of the cicatrix of a burn along the inside of the limb. In this case the plastic operation described at page 150 must be practised.

ANKYLOSIS OF THE ARM IN THE STRAIGHT POSITION is a condition of very serious inconvenience to the patient, the limb being almost useless for all ordinary purposes of life. In cases of this kind, the treatment to be adopted must depend upon whether the ankylosis be fibrous or osseous. If it be fibrous, however firm, the forearm may always readily be brought into a rectangular position by flexion under chloroform, and the mobility of the joint may then be improved or restored by passive motion, friction, and douches. If osseous, the bony union must be sawn across, and the case treated as an ordinary instance of excision of the elbow, with the view of establishing a false joint.

ACQUIRED CONTRACTION OF THE MUSCLES OF THE FOREARM IMPLICATING THE HAND is occasionally met with in adults. I have seen it in two opposite conditions; that of forcible extension (Fig. 208), and that of forcible flexion and pronation (Fig. 209). In both instances it appeared to have been the

Fig. 208 — Contraction of Extensors of the Hand

result of over use of certain muscles; in the first case in wringing out clothes, in the other in cutting with very heavy shears. In the case of flexion and pronation, it was interesting to observe that, when the fingers were extended, the wrist became flexed, and when the wrist was extended

the fingers became bent in. In these cases change of occupation, friction, and galvanism, with the use of a straight splint, were advantageously resorted to, a cure being eventually effected.

Fig. 399.—Contraction of Flexors and Pronators of the Hand.

CLUB-HAND.—A deformity resembling club-foot has occasionally, though very rarely, been met with in the hand. The contraction may occur in two directions: either in the sense of

preternatural flexion, or in that of abnormal extension of the member. It has been described by Cruveilhier, Voillermier, and Smith of Dublin. In most of the cases that have been met with, there was a certain amount of deformity of the lower end of the radius, with congenital dislocation of the wrist; and in Smith's case there was an accessory semilunar bone in the carpus. Little, if anything, can be done by surgery for the relief of this deformity; though some benefit might possibly result from the division of any tendons that were preternaturally tense.

CONTRACTION OF THE FINGERS.—A contraction of the fingers, which are drawn into the palm of the hand, is often met with. Most commonly this commences in the little finger, and thence gradually extends to the ring and middle fingers, which become so forcibly and firmly curved inwards, that their extension is not practicable. It commonly results from frequent and continued pressure on the palm of the hand, as in leaning on a round-ended stick in walking, or in those trades in which an instrument requires to be pressed into the hollow of the hand. In many cases, however, it occurs in persons in the prime of life without any apparent exciting cause. In such cases I have always found it associated with a rheumatic or gouty diathesis; the disease in fact consisting in chronic thickening of the fasciæ of the palm and fingers, resulting from rheumatic inflammation of these parts. On examining the contracted fingers, projecting ridges will be felt extending from the palm to their anterior aspects; and on endeavouring to straighten them, these ridges will be found to become stretched, and the palmar fasciæ to be rendered tense. The skin covering these ridges is usually healthy, but sometimes adherent to them. So firmly are the fingers contracted, that by no effort can they be extended.

Pathology.—The pathology of this contraction has given rise to a good deal of difference of opinion amongst surgeons. Dupuytren appears to have been the first who endeavoured, by dissection, to ascertain its true character. He found, on examining a hand which was the seat of this disease, that after the removal of the skin, which was loose and flaccid, the contraction continued as before, and this, therefore, could not be its seat; but that the palmar fascia, which was exposed, was tense and diminished in size, whilst from the lower aspect some cord-like prolongations passed up by the side of the fingers; and that, when these were divided, the contraction was immediately removed, the tendons, the bones, and the joints being perfectly sound. He considered these fibrous cords to be digital prolongations of the palmar fascia, and consequently looked upon this membrane as the seat of the disease. Goyrand, who has carefully dissected hands affected in this way, states that these fibrous cords, which he looks upon as the seat of the

affection, are not prolongations of the palmar fascia, but are ligamentous structures that extend from its anterior inferior aspect to the sheaths of the flexor tendons, into which they are inserted opposite the second phalanx; being an hypertrophied condition of the subcutaneous filaments of fibro-cellular tissue which naturally exist in this situation.

Treatment.—The treatment of this deformity, when slight and recent, consists in dividing each tense digital ligamentous prolongation by a subcutaneous incision. This should be done opposite the second phalanx, where it is usually most tense; but, if the other finger-joints be affected, a separate section may be required opposite each phalanx. Should it be found to be impossible to straighten the fingers with such limited incisions, or should the skin be firmly adherent to the subjacent fibrous band, a long crucial incision may be made through the skin, this dissected back, the bands divided or dissected off the sheaths of the tendons, and the fingers straightened. As the flexor tendons are not primarily affected, they need not be divided. After the operation, the hand should be placed on a digitated splint.

REMARKABLE CONGENITAL DEFORMITY OF FINGERS.—The accompanying figures (300, 301) give an accurate representation of a remarkable congenital deformity of the hands that was under my care. In it the fingers appear to have suffered in some instances complete, in others partial, amputation *in utero*. Some were marked by deep transverse sulci, others

Fig. 300.—Left Hand.

Fig. 301.—Right Hand.

Remarkable Congenital De-
formity of Fingers.

shortened and terminating in rounded nodules, with a narrow pedicle connecting them with the proximal phalanx.

DEFORMITIES OF THE LEG AND FOOT.

KNOCK-KNEE.—The deformity termed *Genu-Valgum*, Knock or X-Knee, usually affects both extremities, though it is generally more fully developed in one than in the other. In it the knee forms the apex of a triangle, the base of which would be represented by a line drawn from the trochanter to the outer ankle. It is usually conjoined with some curvature of the bones of the leg. It is not a congenital affection, but commonly occurs in consequence of children being put upon their feet too early, the limbs thus giving way under the weight of the body. Bock states that out of 221 cases which he examined, 17 originated about the period of the first dentition; and about 200 between that age and the 15th or 18th year. Some occupations are said to predispose to it, smiths being especially liable to the disease. In it there is relaxation of the internal lateral ligament; the biceps, the external lateral ligament, and often the vastus externus, are very tense, and the patella is thrown outwards. The external condyle of the femur

will generally be found to be small, and the hollow of the ham to be obliterated.

Treatment.—The treatment consists, in the slighter cases, in applying an apparatus consisting of a well-padded iron stem along the outside of the leg and thigh; this must extend from the trochanter to the outer ankle, being fixed to a pelvic band at the upper part, and into a boot below (Fig. 302).

Fig. 302.—Apparatus for Knock-knee.

Where it corresponds to the knee it should be provided with a hinge, and should have a broad well-padded strap passing from its under side, over the inner side of the joint, and attached by buckles to the upper part of the stem, in such a way that by tightening these the knee may be drawn outwards. This apparatus should be constantly worn for many months; and, if properly adapted, may effect a cure.

When the deformity is of old standing, and the parts about the outer side of the joint very tense, the biceps tendon may require division. In doing this, care must be taken not to injure the peroneal nerve. In some cases the vastus externus and contiguous portion of the fascia lata may also be advantageously divided, and the apparatus then applied as directed.

CONTRACTION OF THE KNEE-JOINT —

Contraction of the knee-joint is one of the most distressing deformities to which the human frame is liable. If it be severe, the

leg is bent at nearly, or perhaps at quite, a right angle with the thigh. It is fixed in this position, so that the patient cannot put the sole of the foot, nor even the points of the toes, to the ground; hence the limb becomes useless for the purpose of progression, and, from want of exercise, atrophies. But a leg with a badly contracted knee is worse than useless—it is a positive incumbrance; for, as the foot cannot be brought fairly to the ground, the limb projects behind in a most awkward manner, swaying as the body moves round, constantly in the way, and liable to injury. From want of exercise, the nutrition of the limb thus affected becomes impaired: the foot is usually habitually cold, the circulation in it is languid, and the toes become liable to chilblains and troublesome ulceration.

In the less severe forms of contracted knee, the inconvenience, though not so great as that just described, is yet very considerable, for, as the patient can never bring the heel or sole to the ground, he rests insecurely on the tips of his toes, and walks but unsteadily with the aid of a crutch or stick.

Varieties.—This deformity may be of two kinds. 1. It may consist of simple flexion of the leg on the thigh, at a greater or less angle, and with more or less mobility, according to the degree of ankylosis. 2. In addition to this, there may be horizontal displacement of the bones, the head of the tibia being thrown backwards, the femur and patella remaining *in situ*, but apparently projecting more than is natural.

In examining a case of contraction of the knee-joint, the patient should be placed on his face, with the thigh extended. The leg on the affected side will then be raised more or less perpendicularly, and the amount of

contraction may be judged of by the angle that it forms with the thigh. The degree of mobility also may readily be ascertained. In this way a more correct idea of the amount of contraction can be obtained than by examining the patient whilst lying on the back, when, in consequence of the thigh being flexed on the abdomen, the extent of the angular deformity cannot be so well determined.

Causes.—Contraction of the knee-joint may arise from a great variety of pathological conditions. Some of these are altogether external to the joint, being seated in the nerves or muscles of the limb; whilst others, and the majority, consist in some morbid change that has taken place within the joint itself in its ligamentous or osseous structures. As the contraction depends on such very varied causes, the *Treatment*, having reference to the cause as well as to the actual morbid conditions, must be equally diversified.

Contraction from Nervous Irritation is usually associated with general hysteria, of which it is but a local symptom, and commonly occurs in girls and young women. In this form of contraction there is no evidence of disease within the joint; no redness, swelling, or other sign of inflammation; but there is great pain and tenderness about it. This pain, as usual in hysterical cases, is superficial and cutaneous, and radiates to some distance beyond the articulation. Any attempt at straightening the limb not only greatly increases the pain, but also calls the adjoining muscles into such forcible action that it is impossible to improve the position. These callo symptoms are connected with the ordinary signs of an hysterical temperament, with spinal irritation, and often with uterine derangement.

The *Treatment* of these cases of *hysterical contraction* of the knee is simple. The first thing to be done is to straighten the limb. This can only be effected by putting the patient under the influence of chloroform, when, all sensibility being suspended, the muscular opposition, which is partly voluntary, and no doubt in some measure reflex, is no longer called into action, and the limb falls of its own accord almost into the straight position, in which it must be retained by means of a long splint, lest the retraction recur with returning consciousness; and then, the hysterical condition being removed by treatment calculated to improve the general health, the tendency to the return of the deformity will be obviated.

We occasionally see contraction of the knee from spasmodic action of the hamstrings, produced by some irritation applied to the nerves at a distance from the part. Just as spasm of the internal rectus muscle of the eye occasions squint, so long as the irritation that gives rise to the spasm lasts; so there may be spasm of the hamstrings, with contraction of the knee as a consequence.

Most commonly, however, the joint itself is at fault, either in consequence of subacute inflammatory action within it, or of the chronic and permanent changes induced by former inflammatory attacks.

Contraction from Inflammation of the Knee.—In inflammation of the knee, the patient naturally and instinctively places the limb in the semi-flexed position, as being that in which there is least tension exercised on the structures that enter into the joint, and consequently that which is most congenial to his feelings. This position, which is immediately assumed on the occurrence of acute and active inflammation in the joint, comes on more gradually in cases of subacute inflammation; and here the symptoms of disease in the joint may be so slight that the contraction may be considered the chief ailment, and engross too exclusively the surgeon's attention.

Chronic Contraction.—The next class of cases that we have to consider are those of a more chronic and intractable kind, lasting often for years, dependent upon structural lesions of a deep and important character in and around the joint, and requiring very active surgical interference for their cure. These chronic forms of contracted knee appear to arrange themselves in three distinct varieties, being dependent—1, on Consolidation and Contraction of the Ligamentous Structures in or around the joint; 2, on Permanent Contraction of the Muscles, with or without the last-named condition; and, 3, on Osseous Ankylosis. Each of these varieties will require separate consideration, as each demands a special mode of treatment for its cure.

1. Those cases of contraction of the knee that depend on *Consolidation of the Ligamentous Structures* in and around the joint, resulting from former inflammatory attacks, are not only the most numerous, but the most readily amenable to treatment. When the structures outside the joint, such as the capsule and ligaments, are the parts chiefly affected, the inflammation has usually been of a rheumatic character. When the internal structures have been disorganised, and fibroid deposits have taken place within the joint, the inflammation has generally been strumous. In these cases the knee is usually fixed at or near a right angle, and is capable of but very limited motion; to such a degree only, in most instances, as will allow the foot to move to the extent of two or three inches. The hamstring muscles are not tense, even when the knee is extended to its utmost; and, indeed, in some cases they are flaccid, and feel soft. Not unfrequently the leg admits of extension up to a certain point, with as much freedom as in the natural state, and then the further movement of the limb is checked by a sudden stop. If this be not dependent on the tibia coming into contact with an ankylosed patella, it is owing to shortening of the crucial ligaments, or to the formation of adhesions within the joint. In this form of contraction, the knee is often much distorted, in consequence of the head of the tibia being partially dislocated backwards, or having its axis directed more or less to one side, most commonly inwards, constituting a kind of genu valgum. This distortion is, I believe, dependent on softening and consequent relaxation, either of the ligamentum patellæ or of one or other of the lateral ligaments. When the head of the tibia is displaced backwards, it will most generally be found that the ligamentum patellæ has been

Fig 303.—Contraction of Knee joint; Head of Tibia drawn backwards.

either partially absorbed, and thus weakened; or that it is elongated, the patella being drawn upwards or to one side. In either way, the action of the extensor muscles of the thigh upon the head of the tibia is weakened; and that bone, being consequently brought under the influence of the hamstrings without a counterpoise, is drawn backwards (Fig. 303). In those cases in which there is lateral rotation of the tibia, the faulty position may have arisen from the attitude

that the limb has been allowed to assume during the progress of the disease in the joint.

In the *Treatment* of this form of contraction of the knee, simple extension of the limb will often prove sufficient. This may either be done gradually by means of the screw-splint behind the knee, or forcibly and at once under the influence of chloroform. I prefer the latter method, not only as being the speediest, but as being perfectly safe and effectual. The mode of effecting forcible extension is as follows. The patient being fully under the influence of chloroform, and lying on his face, the surgeon, standing above him, seizes the foot of the affected limb with one hand, whilst with the other he steadies the limb just above the knee. He now extends the leg gradually but forcibly; as it comes forwards, the bands of adhesion in and around the joint will be felt and heard to give way with loud snaps and cracks, distinctly audible at some distance. Should there be much resistance within the joint, the surgeon may apply his own knee or elbow to the upper surface, and thus increase the force with which the limb is acted upon. In this way I have never found any contractions of the kind now under consideration able to resist the surgeon's efforts, nor any difficulty in effecting at once the extension of the limb. Nor have I ever seen any evil consequences result; indeed, it is surprising to what an amount of force a joint that has been contracted for any length of time may be subjected without inconvenience. In these cases it would appear as if the synovial membrane lost its susceptibility to inflame, just as is the case with serous membranes that have been the seat of chronic inflammation and its consequences. Beyond some pain for a few days, and slight heat, easily subdued by cold evaporating lotions, I have never seen any ill results arise; but then care must be taken that no inflammatory action is going on within the joint at the time of this manipulation, as, if such action were present, the operation would certainly be followed by injurious results. After the extension has been made, the limb should be fixed on a long splint, well padded, some evaporating lotions applied, and the patient kept in bed for a few days, when, with the aid of a starched bandage, he may walk about.

After extension has been effected, the position of the head of the tibia backwards may still occasion considerable deformity and weakness of the limb (Fig. 304). This condition is best removed by the use of the instrument of which the sketch on next page (Fig. 305) is a good representation; it was designed and constructed by that excellent surgical mechanic, Mr. Bigg. The diagram (Fig. 304) represents a limb with the tibia displaced backwards, the angular contraction having been remedied. In the centres of the end of the thigh-bone and of the head of the tibia, two letters (X and Z) are placed to designate the axis of each bony head, beneath and above which the displaced joint has formed its abnormal axis. The dotted lines represent the leverage formed by the cylindrical surface of the tibia and thigh-bone. The arrows are placed in such a direction as the bones would take in resuming their normal position. It will readily be seen that any instrument capable of acting in the mechanical directions shown by the arrows, would accomplish not only the restoration of the joint, but extend, if contracted, the extremities of both femur and tibia.

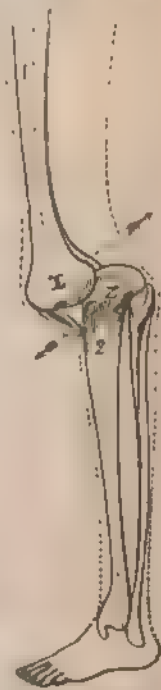

Fig. 304 — Knee-joint after Extension. Head of Tibia thrown backwards.

An additional advantage that this instrument possesses over any other with which I am acquainted, is the application of spring-power, by means of which flexion of the knee becomes an element towards the restoration of its utility.

Instead of muscular action being arrested, and atrophy of the limb being thus produced, movement is conducive to the perfect action of the apparatus; so that the patient experiences but little inconvenience from its use, all the ordinary positions assumed by the knee in walking, sitting, or standing, being preserved.

By this form of apparatus, then, three important points are secured, viz., replacement of the head of the tibia, extension of the angle of the leg, and free muscular action during the period of treatment.

In Fig. 305, A and B are two levers, composed of metal, corresponding in their direction to the perpendicular position of the thigh-bone and tibia. C and D are two axes, placed exactly coincident with the centres of the articular ends of the bones. E and F are two powerful springs, acting in opposing directions; viz., in those indicated by the arrows in Fig. 304. Thus F presses the lever B in an anterior direction, bearing the end of the tibia forward, whilst E presses the lever A in a posterior direction, bearing the end of the thigh-bone backward. As C and D are found acting above and below the actual axis of the knee-joint, they mutually influence the point formed by the apposition of the heads of the tibia and thigh-bone; and as it has already been explained that the thigh-bone really offers a fixed resistance, and the tibia

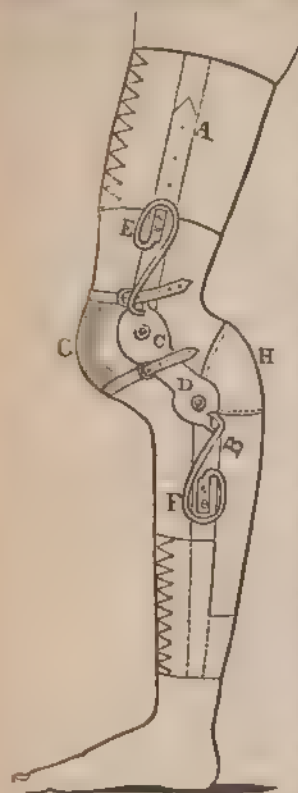

Fig. 305.—Apparatus for restoring Position after Extension of Contracted Knee-joint.

moves beneath it, the head of the latter bone is turned anteriorly in a semicircular direction consequent on the upper centre (C) being a fixed point, and the lower centre (D) rotating around it. G is an elastic knee-cap; H, a padded plate. When the ligaments are tense, there is a chance of pressing the anterior surface of the tibia against the posterior surface of the thigh-bone. This is readily obviated by having the shaft (A) made to elongate, when the centre (C), being a little lowered, pushes the lever (B) downwards, carrying the tibia with it, and thus separating the osseous surfaces of the joint.

2. The next class of cases of contracted knee that we have to consider are those in which the *Hamstrings are Contracted*, either alone or in addition to those results of chronic inflammatory action within the joint that have just been described. In these cases the hamstrings will be found to be tight; and, in proportion as the leg is extended on the thigh, they will become more tense, until at last all further extension is resisted, apparently by their traction, and not by any sudden check or stop within the joint itself.

Division of the Hamstring Tendons is in ordinary cases as simple an opera-

as any in surgery, unattended by any difficulty, provided the surgeon introduce the tenotome parallel and close to the side of the tendon to be divided, and cut in a direction from the inside or popliteal aspect towards the outside. The outer hamstring will usually be found to be the most tense, and should first be divided. In doing this, the peroneal nerve might appear to be in danger; but this may be avoided by keeping the side of the tenotome well against the inner edge of the biceps tendon, then turning the edge outwards, when passed deeply enough. The semitendinosus requires division next. The semimembranosus need not often be cut across. After the division of the tendons, tense aponeurotic bands will not unfrequently be found to stretch along one or both sides, or perhaps down the centre of the popliteal space. This may lead to the idea on the part of the surgeon that he has cut fairly cut the tendons across; but this is an error. The bands alluded to are condensed sharp-edged prolongations of the fascia lata, formed during the period of contraction of the joint by the retraction and thickening of this membranous expansion. Such condensations as these had better be left untouched, as they will readily stretch out under gradual extension, or be ruptured by forcible traction of the limb. If, on the other hand, the surgeon be tempted by their apparently superficial and safe position to proceed to their division, he may be led into a serious dilemma by being brought more readily into contact with the popliteal vessels than is desirable or safe. In these cases, the anatomical relations of parts are so much altered by the narrowing of the popliteal space, and by the projection of the head of the tibia backwards or by its lateral rotation, that the surgeon is unable to calculate with sufficient nicety the precise position of the large vessels and nerves in the neighbourhood of which he is about to act; and he may thus injure one or other of these at a time when he thinks that he is operating at a safe distance from them.

After the division of the hamstrings, the knee does not commonly come readily into the straight position, but gradual extension, by means of proper apparatus, will be required to break through or extend the adhesions within and around the joint.

Contraction with Lateral Displacement is not unfrequently met with. In these cases the knee is contracted more or less in the angular direction; but, in addition to this, the lower end of the thigh-bone is directed inwards and perhaps somewhat forwards, and the tibia is rotated outwards, carrying the foot with it. There is thus a triple deformity—angular, mesial, and rotatory. I believe the angular to be the primary deformity, and the mesial and rotatory to be secondary to this, arising partly from the efforts of the patient to walk by resting on the point of the great toe, and throwing the thigh inwards in order to effect this, and partly from the action of the biceps rotating the leg inwards.

The *Treatment* of these cases is not very satisfactory. Mere extension of the limb, whether gradual or forced, may counteract the angular deformity; but it will not only leave the other displacements ununinfluenced, but may actually increase the rotation of the leg outwards. A leg and thigh-splint, such as in Fig. 305, but having, instead of the springs, a rack and-pinion apparatus working on three centres, so as to extend the limb, abduct the knee, and rotate the leg inwards, is the only contrivance by which this deformity can be counteracted, and the limb properly restored to shape.

3. *Ossous Ankylosis of the Knee* is not of very frequent occurrence. It is usually, if not invariably, the result of traumatic inflammation of the joint. If the limb be straight no operation will be advisable; if it be bent, we

that the patient cannot put the foot to the ground, the only remedy will be the operation practised by Dr. Rhea Barton, of sawing out a wedge-shaped portion of the ankylosed bones, and then bringing the limb into the straight position. Judged by the excellent results that have followed resections of the knee-joint, such an operation is not unlikely to be attended by good success. Should there be much atrophy of the limb, with shortening of it, and possibly necrosed bone with old sinuses and occasional abscesses about the knee, amputation will place the patient in the position of most comfort.

Ankylosis of the knee in the *straight position* interferes comparatively little with the utility of the limb. It is, however, desirable, when practicable, to restore the flexibility of the joint. The possibility of doing this will depend on the degree of ankylosis. If this be osseous, or even if densely fibrous, little can be done; but if the rigidity depend chiefly on condensation of the capsule, and the deposit of plastic matter externally to the joint, much may be effected by passive motion, shampooing, douches, and friction.

Ankylosis of the knee in the *angular position forwards*, so that the leg is bent upwards upon the thigh, is of very rare occurrence. Indeed, I am acquainted with only two preparations illustrating this deformity—one in the museum of St. Thomas's Hospital, another exhibited by Mr. Adams to the Pathological Society, from a limb amputated by Dr. Grant of Canada, in which this condition occurred in a young man as the consequence of a wound of the joint some years previously.

CLUB-FOOT.—Deformities of the feet are commonly single; but not unfrequently they affect both extremities. They appear to be more frequent in boys than in girls. Four varieties of club-foot are recognised:—*Talipes Equinus*, in which the heel is elevated; *Talipes Calcaneus*, in which the anterior part of the foot is drawn up; *Talipes Varus*, in which the foot is twisted inwards; and *Talipes Valgus*, in which it is twisted outwards. These conditions may occur in the simple forms just mentioned; but most commonly talipes varus is complicated with equinus, and not unfrequently talipes valgus with calcaneus. Bonnet, of Lyons, has made a classification of talipes, according as it is occasioned by an affection of the internal or of the external popliteal nerve. When the muscles supplied by the internal popliteal are affected, we find the talipes equinus, equino-varus, and varus. When the external popliteal is affected, we have the calcaneus and valgus.

Pathological Changes.—On dissecting a foot affected by talipes, it will be seen that but little alteration has taken place in the condition of the bones. In some preparations of this kind which are in the University College Museum, these are nearly in a normal condition (Figs. 306—309). Indeed, in talipes equinus and calcaneus, they are scarcely if at all altered; but in talipes varus and valgus, if of old standing, the astragalus will generally be found atrophied, more particularly about its head, which may be somewhat twisted, and the scaphoid and cuboid bones will be seen to have undergone similar changes. The ligaments are necessarily somewhat altered in shape, being lengthened on the convexity, and shortened on the concavity of the foot, the direction of the tendons is altered, and the muscles, not only of the foot, but of the leg and thigh, are generally atrophied from disuse, so that the limb in old cases is withered and shortened; indeed, so great an incumbrance may it occasionally become under these circumstances, that amputation of the leg may be insisted on by the patient, and may with propriety be performed by the surgeon.

Talipes Equinus is characterised by elevation of the heel, and great tension of the tendo Achillis, so that the foot is extended in nearly a straight line with the leg, and the patient walks on his toes, which are placed at a right angle to the foot (Figs. 306, 307). In this deformity there is

Fig. 306.—*Talipes Equinus*.

no lateral displacement. According to Tamplin, it is never congenital. It most commonly arises from disturbance of the nervous system, during teething, or from the irritation of worms in children. In adults, as well as in children, it may come on from some disease, such as abscess in the calf of the leg, by which the gastrocnemius muscle is crippled. It is the most important, and at the same time the simplest in itself, of all the forms of club-foot; it commonly compli-

cates the other species.

The Treatment consists in dividing the tendo Achillis, and bringing the heel well down.

The tendo Achillis is best divided about an inch above its insertion into the os calcis. The patient should be laid prone; the surgeon, grasping the foot, extends it forcibly, so as to throw out the tendon in good relief, and make it tense; he then slides a tenotome beneath it, and cuts slowly through it from beneath upwards, bearing well upon the foot; as the division proceeds, he will hear the tendon cracking as its fibres are successively cut through. The division should never be made from above downwards, as the posterior tibial artery or its malleolar branches might readily be wounded.

Talipes Calcaneus is an extremely rare variety of club-foot. In it the heel is depressed, the toes and anterior part of the foot being elevated (Fig. 308); it is usually, I believe, congenital—in one case, however, that of a girl twelve years of age, it was acquired. It arises from contraction of the extensor tendons.

Treatment.—In order to bring down the foot, the tibialis anticus, the extensor communis, the extensor pollicis, and the peroneus tertius muscles, may all require to be divided as they pass over the dorsum; a straight splint should then be applied, and the foot drawn down to it. A minor degree of this affection consists in a peculiar pro-

Fig. 308.—*Talipes Calcaneus*.

jection upwards of one or two of the toes, associated with some tension of the extensor tendon: by dividing this, and keeping the foot on a flat splint, the deformity may commonly be corrected. In some cases, how-

Fig. 307.—Bones in *Talipes Equinus*.

ever, the toe is so prominent, and the contiguous ones are squeezed under it in such a manner, that the foot is completely crippled, and amputation of the displaced digit is required in order to restore the utility of the member.

Talipes Varus.—In this deformity the foot is twisted inwards, and the

Fig. 309 —Talipes Varus.

sole is contracted ; the patient walking on the outer side of the foot, where the skin covering the tarsal end of the fifth metatarsal bone often becomes excessively dense and firm, and a bursa occasionally forms (Figs. 309, 310). In most cases there is some elevation of the heel, the affection partaking somewhat of the cha-

Fig. 310 —Bones in Talipes Varus.

acter of talipes equinus. It is the most common form of congenital deformity, both feet being found similarly affected ; but it may be non-congenital, and then it is limited to one foot.

The *Treatment* consists in the successive division of the tendons of the tibialis anticus and tibialis posticus, which are the muscles principally at fault. After these have been cut across, the tendo Achillis should be divided ; but its section should be made last, as it steadies the foot, and thus facilitates the division of the tibial tendons. In most cases the plantar fascia is contracted, and requires division wherever it feels tense and projecting. In the section of the tibialis posticus tendon behind the ankle, there is much danger of wounding the posterior tibial artery, which lies close to it. The best way to avoid this vessel is, as Tamplin recommends, to puncture the sheath of the tendon with a sharp scalpel introduced directly downwards, and then to divide it in a direction forwards, away from the vessel, with a blunt tenotome. There will also be less risk of this accident occurring, if the line of the tibia be clearly felt and taken as the guide for puncturing the fascia over the tendon. Unless great care be taken in cutting through the tendo Achillis, there is also some risk of wounding the artery ; as, in bad cases of varus, these two structures lie nearly parallel to one another, the tendo Achillis being drawn out of the median line towards the inner ankle. Indeed, in one instance I have seen the posterior tibial artery punctured during the division of this tendon, or rather in an attempt to divide some tense bands that lay beneath it ; the bleeding, which was very free and in a full jet, was, however, readily stopped by pressure, no bad consequences resulting. The proper plan of treatment, when such an accident occurs, is, when the artery is merely punctured, to cut it completely across, and then to apply firm pressure, by means of a pad and bandage, over the bleeding orifice. Tamplin states that he has seen no ill effects follow this accident. If a circumscribed false aneurism form, it must be laid open, the clots turned out, and the vessel tied. No extension of the foot should be practised for some time in such cases, lest the coagulum be disturbed.

In ordinary cases of varus, after a lapse of four or five days, Scarpa's or Little's shoe, or Aveling's talivet, may be applied ; or the foot may be well

abducted by means of a wooden splint, fixed to the outer side of the leg, and provided with pegs, so placed that the toes can be drawn up, and the foot well turned out, by rollers and tapes attached to them.

Talipes Valpus—*Flat or Splay Foot*—is the antithesis to varus. In it there is a tendency in the first instance to obliteration of the arch of the instep, so that the sole becomes perfectly flattened; and, as the disease advances, a tendency to eversion of the foot usually takes place (Fig. 311).

When it has advanced to this extent, the toes and anterior part are often somewhat raised, so as to constitute the variety termed *Calcaneo-valgus*. In *talipes valgus* the ligaments of the sole of the foot, which bind the bones together so as to form the arch, are weakened and elongated, and the peroneal and extensor tendons are commonly tense. It is not so frequent a form of club-foot as the other varieties. It commonly affects only one extremity, being often met with in young adults, as the consequence of over-fatigue of the foot from long continued standing and from the habit of sliding the foot in walking, or twisting it, so as to press upon the inner side. When both feet are everted, there is usually knock-knee as well; and then this affection is met with at a much earlier period of life.

Fig. 311.—*Talipes valgus*.

Treatment.—In the earlier stages of acquired *talipes valgus* in young adults, more particularly in young women, the deformity may often be remedied by putting the patient under the influence of chloroform, forcibly drawing the foot inwards, so as to overcome the tension of the peronei muscles, fixing it in a Dupuytren's splint, and afterwards restoring the arch of the foot by a convex sole in the shoe.

In the more confirmed cases, the treatment consists in the division of the tendons of the peroneus longus and brevis, behind the outer ankle; and of that of the extensor communis on the dorsum. Scarpa's shoe may then be applied, and the arch of the foot restored by wearing a pad under the sole for some considerable time.

In *Talipes Calcaneo-valgus* the projection of the heel backwards is obliterated, and the outer side of the foot curved round towards this, so that the little toe approaches the point of the heel. It is not a congenital affection; and, as it commonly arises from a partially paralysed state of the gastrocnemius, the treatment is not very satisfactory.

CONTRACTION OF THE PLANTAR FASCIA.—In some cases, great arching of the instep and shortening of the foot will result from contraction of the plantar fascia. Here the division of the internal and middle prolongations of this structure will be necessary; after which, a Scarpa's shoe with a jointed foot piece may be used, to effect extension of the arch of the foot.

CONTRACTION OF ONE TOE is not of unfrequent occurrence. In this complaint the proximal phalanx is either on its normal level or slightly drawn up; the two distal are bent down at an acute angle, the apex of which is formed by the articulation of the first with the second. This contraction more commonly affects the second toe, is often asymmetrical in the two feet, and is frequently a source of great inconvenience, and even permanent lameness. It appears to be due to contraction of the digital prolongation of the plantar fascia, and is best remedied by dividing this subcutaneously opposite the lower part of the second phalanx, and then straightening the toe.

WEAK ANKLES not uncommonly occur in rickety children : the ligaments being relaxed, the joints appearing to be swollen, and the child being unable to walk or stand without great difficulty. Under these circumstances, attention to the state of the general health, douching with salt water, with the application of an elastic India-rubber bandage round the ankle, or the use of light iron supports, will be found most useful.

DISEASES OF REGIONS.

CHAPTER LV.

DISEASES OF THE HEAD AND NECK.

DISEASES OF THE SCALP AND SKULL.

FUNGUS OF THE DURA MATER.—Sometimes without external or apparent cause, at other times in consequence of a blow or fall, a *Fungous Tumour* grows from some part of the dura mater, usually on the top of the head or one of the parietal regions. As it increases in size, it produces absorption of the skull covering it, the bone becomes thinned and expanded, and crackles like parchment on pressure, sometimes not being raised above its proper level, but more usually being pushed up by the pressure of the growth beneath, which at last protrudes under the scalp. More usually, this perforation of the skull is gradual ; but in some cases it would appear to have been sudden, the first intimation that the patient had of disease being the presence of a tumour under the scalp. When the skull is perforated, the sharp edges of the circular opening can be distinctly felt ; and the tumour which protrudes pulsates distinctly, as may be proved both by the finger and by the eye.

Symptoms.—Symptoms of cerebral disturbance—double vision, loss of sight, deafness, or epileptic fits, with fixed pain in the head—usually precede for a considerable time the external appearance of the tumour. In some rare cases, no such symptoms have indicated the existence of intracranial disease ; and the first evidence of the disease has been the sudden protrusion of a pulsating tumour through the skull. If the tumour be compressed, egg shell crackling of the expanded and thinned cranial bones will be felt, and, if attempts be made to push it back under the bones, giddiness, syncope, and convulsions are produced. As the disease makes progress, death from paralysis and coma supervenes.

Treatment.—The result of the treatment of fungus of the dura mater is not very satisfactory ; yet, as the disease appears to be almost of necessity fatal if left to itself, something should be attempted—not, however, until the tumour has fairly appeared through the bones. The scalp covering it should be turned back by a crucial incision, and the tumour exposed. The aperture in the skull through which it is protruded may then, if necessary,

be enlarged by the use of the trephine or Hey's saw, so as to lay bare the full extent of the tumour, which must then be carefully dissected away from the dura mater.

FUNGUS OF THE SKULL may occur. At first it closely resembles the disease just described; it differs from this, however, in being devoid of pulsation, and incapable of being pushed back. It appears to spring from the diploe of the skull, and may probably be of a myeloid or encephaloid character, sometimes secondary to primary deposits of a like nature elsewhere. In other cases it appears to be simply vascular, in structure resembling the pulp of a red gooseberry or a broken-down mulberry. In a case of this kind which I had an opportunity of seeing some years ago, the growth was successfully removed by Mr. B. Phillips.

HERNIA CEREBRI, arising from wound or ulceration of the dura mater, has been already described (p. 356).

ENCEPHALOCELE, or CONGENITAL HERNIA OF THE BRAIN, is a rare malformation, usually speedily fatal. Mr. Z. Lawrence finds that, of 39 instances in which it occurred, 21 were males, 18 females; that the protrusion may vary from the size of a pea to that of a tumour exceeding the child's head; that the occiput is its chief seat,—of 79 cases, 53 being in this situation. In 6 instances, the subjects of this malformation reached an adult age; in all the remaining cases they died early, or were still born. Surgery offers little in these cases; though in one instance the protruding portion of brain was successfully sliced off, the patient surviving.

DISEASES OF THE EYE AND ITS APPENDAGES.

ENCYSTED TUMOURS OF THE EYELIDS.—Small cysts are not infrequently met with, lying between the tarsal cartilage and the conjunctiva. At first they occasion no inconvenience; but as they increase in size they cause the conjunctiva covering them to become injected, papillated, and granular, thus at last occasioning a considerable amount of irritation and lachrymation.

Treatment.—These tumours may be removed either by being dissected out, or by being obliterated by inflammation set up in them. When the tumour is to be dissected out, the eyelid must be everted, and the cyst, having been exposed by dividing the conjunctiva covering it with a fine scalpel, must be drawn forwards with a hook and removed by a few touches of the knife. This little operation is, however, at times somewhat troublesome; and in preference to it I always induce obliteration of the cyst by exciting inflammation in it. This may most conveniently be done by everting the lid, and then making a crucial puncture into the cyst with a lancet; the contents having escaped or been squeezed out, and the part well dried with a piece of lint, a pointed silver probe dipped in nitric acid should be quickly introduced through the puncture, and the inside of the cyst stirred up; and, a little sweet oil having been poured over the lid, it may be replaced. Some induration will be left in the site of the cyst for a few weeks; but, as that subsides, the tumour will be found to have disappeared.

Not unfrequently larger cysts, varying in size from a cherry to a plum stone, are met with at the outer angle of the eyebrow, extending to the eyelid or the temple. These may contain either clear fluid or atheroma, and are readily extirpated by a linear incision parallel to the fibres of the orbicularis palpebrarum.

PUNCTURE OF THE LACHRYMAL SAC.—This operation is frequently required in those cases in which, the nasal duct having become obstructed, the lachrymal sac becomes distended by the accumulation of the tears, inflames, and either threatens suppuration, or gives way so as to leave a fistulous opening

below the inner angle of the eye, through which tears often escape—the ordinary *fistula lachrymalis*. If a fistula have not already formed, the sac being merely distended, the passage through the nasal duct may sometimes be restored by the careful introduction of a very fine silver probe into it through the puncta; or the sac may be injected through the same orifice by means of one of Anel's syringes. Should these measures not prove successful, the permeability of the duct may be restored by catheterism from below; for this purpose a steel probe or sound, bent nearly to a right angle at about one inch from the extremity, should be passed into the nostril beneath the inferior turbinate bone; by a slight to-and-fro movement, the point of the instrument may be made to enter the orifice of the duct, and then, on directing the handle downwards and inwards, it will pass up along the canal into the lachrymal sac.

If these means, however, do not prove successful in restoring a passage for the tears, or should a fistula have formed, the sac may be punctured and a style passed into it from above. This operation may be performed in the following way. The patient's head being well supported on the breast of an assistant, and the lower eyelid having been put well on the stretch by traction with the finger at the outer angle, the surgeon feels for the tendo oculi, the under surface of which is the guide into the lachrymal sac. In many cases, however, owing to the swelling and induration of parts, this tendon cannot be felt; and then the guide must be the edge of the orbit below and a little to the outside of the puncture. Having ascertained this, he rests the little finger on the cheek; and, holding a strong narrow-bladed bistoury between the forefinger and thumb, with the flat of the blade parallel to the face and the edge turned outwards, he passes the point downwards and inwards well under the tendon of the orbicularis, the handle resting against the middle or outer third of the eyebrow (Fig. 312). He then, by

Fig. 312—Puncture of the Lachrymal Sac.

carrying the handle inwards and somewhat forwards until it rests against the bridge of the nose, causes the point to take a direction backwards, downwards, and slightly inwards, for about three-quarters of an inch, when the nasal duct will be fairly entered, which may be known by the bistoury supporting itself. The style may then be introduced along the blade, which should be firmly pressed inwards.

In order to avoid the puncture of the sac and the introduction of styles in the ordinary way, Bowman has introduced a new method of treatment in cases of stricture or chronic inflammation in the lachrymal canals or sac. It consists in passing a fine probe into one or both puncta—usually the lower one is sufficient; then slitting this up on its conjunctival aspect with a narrow-bladed knife, so as to open the canaliculus freely; down this a probe is then carefully passed, the stricture, if any exist, dilated or incised, and the nasal duct opened.

The performance of these operations must be accompanied by the adoption of proper local and constitutional treatment.

EXTIRPATION OF THE LACHRYMAL GLAND may be required for cancerous degeneration. This operation may be performed from the outer or from the inner side of the lid: whenever practicable, it should be done from the inner aspect. It is performed in the following way. The outer commissure of the lids having been divided as far as the edge of the orbit, the upper eyelid is everted by an assistant; the surgeon then divides the conjunctiva covering the tumour, and, fixing a hook in it, draws it forwards, and with a few careful touches of the knife divides its attachments. After the removal of the tumour the lid drops into its normal position, and the commissure is closed by a suture.

EXTIRPATION OF THE EYEBALL.—This operation may be required for cancer of the eyeball, either of an encephaloid or a melanotic character, as represented in the following drawing (Fig. 313), taken from a patient of mine affected with subconjunctival melanosis of the eye. It is also occasionally called for when, in consequence of injury or disease, one eye has become disorganised and the vision of the other is sympathetically affected, and can only be preserved by the removal of the globe that is already useless. The operation may be performed in the following way.

Fig. 313.—Melanosis of the Eye.

The surgeon, standing in front of the patient, who is recumbent, makes an incision through the outer commissure of the lids as far as the edge of the orbit. The eyelids are then well everted, and held apart by a wire speculum. The surgeon next passes a double hook into the globe and draws it well forward; then with a curved broad pair of scissors he divides the conjunctiva at its upper part, and proceeds to cut across the several muscles of the orbit, and lastly the optic nerve. Should any of the structures within the orbit now present an unhealthy or suspicious appearance, he clears them out. The hemorrhage, which is usually rather abundant, may be readily arrested by a pledget of dry lint, pressed into the orbit and retained by means of a circular bandage.

If the lachrymal gland be diseased, it must of course be removed with the eyeball. If sound, it may be left, as it atrophies and gives no trouble.

DISEASES OF THE EAR.

INFLAMMATION OF THE EXTERNAL EAR, OTITIS, or EAR-ACHE, is usually a rheumatic affection, and is characterised by intense pain, generally associated with hemicrania; a kind of combination, indeed, of inflammation and neuralgia. This pain is much increased at night, by warmth of the bed, and is generally accompanied by throbbing and noises in the ear. The *Treatment*, at first antiphlogistic, generally and locally, may advantageously, after a time, give place to quinine and iodide of potassium, with the external application of aconite. Occasionally the affection runs on to the formation of abscess in the meatus externus, attended by excessively painful throbbing. To relieve this, leeching, poulticing, and early lancing will be required.

OTORRHEA.—This is a fetid discharge of a muco-purulent character, usually occurring in strumous children, and often associated with enlarged glands under the angle of the jaw. It may be of two kinds; either proceeding simply from the mucous surfaces, and being inflammatory; or being connected with necrosis of the petrous portion of temporal bone, associated with disease and destruction of the tympanum, and necessarily of the internal

ear. In the first case, astrigent injections containing some of the chlorides in solution may advantageously be used, and will commonly arrest it. If, however, it proceed from disease of the bones, it is necessarily of a far more serious character; and, the membranes at the base of the brain becoming irritated by the extension of the morbid action to them, convulsions and death usually at last result. In some of these cases, phlebitis of the sinuses and of the cerebral veins ensues, and proves fatal.

EXTERNAL EAR.—The external ear is occasionally the seat of special affections; thus in idiots, *Hypertrophy* of this structure is sometimes met with; and in gouty subjects, *Tophi*, or *Gouty Concretions*, are occasionally deposited in it. Paget, Bruck, and Vanzetti have described a *Fibrous Tumour* that occasionally forms in the lobule of the ear from the irritation produced by piercing it, and as "one of the penalties attached to the barbarism of ear-rings." These tumours are semi-malignant, like the warty growths of cicatrices; and, after excision—their only treatment—are somewhat apt to return.

CONCRETIONS IN THE MEATUS.—We not uncommonly find that the meatus becomes blocked up by accumulations of wax, dark, indurated, and pipe-like, or forming balls and masses that lie in contact with the tympanum. These chiefly occur in individuals of the bilious-phlegmatic temperament, and are a common source of temporary deafness among young people. They not only materially impair the sense of hearing, but are very apt to give rise to noises in the head, and to crackling sensations on opening and shutting the mouth. Their presence is best ascertained by examination with a well-constructed ear-speculum; that introduced by Toynbee, of a double convex shape, is the most useful. The *Treatment* of these concretions consists in softening the wax by the introduction of a little glycerine into the ear for a few nights, and then repeatedly washing out the meatus by the injection of tepid soap and water, or water containing a little soap-liniment, thrown in with a large syringe; as the fluid regurgitates from the tympanum, it will at length bring away the dark and hardened ceruminous masses.

POLYPI are occasionally met with, situated rather deeply on one side of the meatus. They are usually hard and fleshy-looking, though sometimes soft and gelatinous, as in the nose; sometimes pediculated, but at others situated on a broad base. They produce serious inconvenience by obstructing the external ear, and require to be pulled off by means of forceps, or, if too firmly fixed for this, cut off with scissors; the surface from which they spring should then be touched with nitrate of silver, so as to prevent a recurrence of the growth.

THICKENING OF THE CUTICLE.—Occasionally the cuticle of the external ear, and that covering the tympanum, becomes thickened and indurated, assuming a dull white appearance: this condition may give rise to some amount of deafness. In these circumstances, glycerine, citrine ointment, or solution of nitrate of silver, will be extremely useful in restoring the healthy action of the integument of the part.

DEAFNESS.—It is not my intention to enter into the general pathology of the various kinds of deafness, nor to discuss its causes. It may be stated generally, however, that it may arise from obstruction of the external ear from disease, ulceration and perforation of the tympanum; from various inflammatory affections, chiefly of a subacute and chronic character, of the internal and middle ear; from paralysis of the acoustic nerve, either local or dependent on cerebral lesions; and lastly, from obstruction in the Eustachian tube, or from disease of the throat. Toynbee has especially shown that many cases of so-called "nervous" deafness, together with ringing, ringing, boiling and other noises in the head, are in reality dependent upon

chronic inflammatory affections of the internal and middle ear; and that the treatment best adapted for their cure consists in constitutional and local means of an alterative and antiphlogistic character.

DISEASES OF THE NOSE AND CHEEKS.

EPISTAXIS, or bleeding from the nose, is very common in children and in young people about the age of puberty, more particularly in girls, antecedently to the menstrual period; it may either be of an active or passive character, but is most usually dependent on congestion of the mucous membrane. But in the adult it is more serious, and it may then be associated with and dependent on two very opposite conditions—either on a state of plethora with tendency to cerebral congestion, or on an anæmic and cachectic state, in which the blood is thin, and does not coagulate readily. In the first condition, when occurring in the young and plethoric, the epistaxis is often a salutary relief to the system. But when occurring in cachectic and anæmic people, more particularly in persons advanced in years, it becomes of very serious moment; and in such circumstances the loss of blood may be so continuous and copious that, unless active means be adopted, a fatal termination may ensue, the hemorrhage being truly arterial. The most dangerous forms of epistaxis do not occur in the young and plethoric, but rather in middle-aged or elderly people of feeble constitutions.

Treatment.—In young people, otherwise healthy, and in the slighter cases, epistaxis may commonly be arrested by the employment of ordinary domestic means, such as the application of cold to the nape of the neck and forehead; and its return may be prevented by the use of purgatives or attention to the proper regulation of the menstrual function.

In plethoric adults the flow should not be too suddenly checked. Should it prove very abundant, dry cupping between the shoulders, and the application of an ice-bag to the forehead, with rest, will be required.

In anæmic and cachectic subjects, and in old people, the hemorrhage is often attended by dangerous consequences, and requires the use of active measures for its suppression. In these cases the following plan should be adopted. The head should be raised, an ice-bag applied to the forehead, complete rest and quietude enjoined, and gallic acid in ten-grain doses, or half-drachm doses of the tincture of ergot, administered at frequent intervals. Should the bleeding still be profuse and continuous, the interior of the nose may be spunged out with a solution of perchloride of iron or tannin. If this do not suffice, it will become necessary to plug one or both nostrils. This is best done by means of a plug of prepared sponge, having a quill or a piece of gum catheter passed through it for breathing purposes, and soaked in a solution of perchloride of iron.

Should, however, the hemorrhage still continue, the blood forcing its way backwards into the throat, or perhaps being swallowed, the posterior nares require to be plugged as well. This is best done by carrying a long piece of strong whip-cord along the floor of the nose through the posterior nares into the pharynx, by means of Bellocq's sound (Fig. 314), or, if this be not at hand, by threading the cord through an elastic catheter, and carrying this into the pharynx, then seizing the cord as it appears behind the soft palate, and drawing it forwards into the mouth, at the same time that the catheter is taken out of the nostril. In this way the string will pass through the nose, round the back of the soft palate, into and then out of the mouth (Fig. 315). To the centre of the piece of string that hangs out between the lips, a plug of lint, of about the size of the thumb, or better still, a piece of

compressed sponge, should be firmly tied; this is then drawn up into the posterior nares by pulling on the end of the ligature that hangs from the

Fig. 314.—Bellucq's Snare.

Fig. 315.—Plugging the Nares.

nose, being guided in its passage behind the palate by the fingers introduced into the mouth. When the bleeding has ceased, it may readily be withdrawn by means of the string that hangs out of the mouth. As the epistaxis is very apt to recur, it is a wise precaution when the plug is removed from behind the palate to leave a loop of string in the nose and mouth, which may be knotted and fixed by a slip of plaster behind the ear. In this way the plug may, if occasion occur, be readily replaced without the necessity of re-introducing the sound or catheter through the nose, which is often a troublesome operation.

CHRONIC THICKENING OF THE SCHNEIDERIAN MEMBRANE.—The mucous membrane of the nose is not unfrequently chronically inflamed, especially in strumous children; that portion of the membrane covering the turbinate bones becoming thick, soft, and vascular, and projecting like a broad fringe from their surface. It is usually of a bright red colour, and covered with mucus. This swelling at all times produces snuffling and a peculiar intonation of voice, but increases in wet weather, and then may become so great as seriously to obstruct the breathing.

The *Treatment* consists in attention to the general health; more especially to the eradication of the strumous diathesis. Much benefit may also be derived from the local application or injection of astringents, as a strong solution of the nitrate of silver applied by means of a camel's hair brush, and sulphate of zinc and oak-bark lotions snuffed up, or injected by means of a proper syringe. In many instances, when this disease occurs in strumous children, change of air will effect the greatest amount of benefit.

ABSCESS occasionally forms either on the mucous membrane or on the septum, and thus may lead to necrosis of the cartilages and bones, separation of these, flattening of the nose, depression of its bridge, and great deformity. These various forms of abscess, followed by necrosis, are commonly syphilitic, and then are associated with ulcers and a foul and fetid discharge, which has a tendency to cake upon their surface, forming dark and ragged crusts, and constituting the different kinds of *Ozena*. The septum may be the seat of chronic ulcerations consequent upon the irritation of decayed

path, producing disease of the antrum, and escape of morbid secretion from the into the cavity of the nose.

The *Treatment* of these conditions must be conducted by the local application of nitrate of silver, black wash, and the chlorinated lotions; the general treatment consists usually in the administration of the dilute mineral acids, iodide of potassium, and sarsaparilla.

ULCERS and FISTULES, of a less serious character, though very painful and chronic, often occur at the angle of the ala and septum, or between the ala and tip. Their *Treatment* consists in touching them from time to time with nitrate of silver, or in the application every night of white precipitate or strychnine ointment; at the same time that the general health is attended to, cachexy removed, and the strength restored, by the administration of iron, bark, and sarsaparilla.

NECROSIS not unfrequently occurs in the loose bony structures lying in the nasal fossæ or in the nasal bones themselves. In these cases the septum nasi participates in the morbid action, and commonly separates or is perforated.

Necrosis may occur in these situations either as the result of syphilis, the action of mercury, or from external injury. I have, however, seen cases, more particularly in women and children, which were not referrible to any of these causes, or indeed to any other external exciting cause, and in which scrofula was probably the occasion of the disease.

The presence of the necrosis may be suspected from the great fetor that infects the breath—the characteristic odour of dead bone being emitted, but in an excessive degree; and the existence of necrosis may always be positively determined by exploration of the nasal cavities with a probe.

The *Treatment* is simple, and must be conducted on ordinary medical and surgical principles. If the general health be impaired, or if the disease be specific, appropriate alterative constitutional treatment must be adopted. The fetor may be lessened by the injection or snuffing up of disinfecting liquids, more particularly the chlorides and permanganates. So soon as the bone is loosened, it must be extracted with polypus forceps, coming away in soft black crumbling, offensive masses. There is often abundant hemorrhage after this extraction, but I have never had serious trouble given in these cases; plugging may possibly be required if cold do not arrest the bleeding.

LIPOMA is a chronic hypertrophy of the cutaneous and subcutaneous structures, and of the cellular tissue of the nose, forming a large reddish-blue, vascular-looking, soft, tremulous, and lobulated mass, enveloping the end of the nose, and producing excessive deformity of it. There are all degrees of this disease, from mere clubbing of the end of the organ, to the formation of a set of pendulous lobular tumours attached to it. The sebaceous glands and crypts appear to be the structures chiefly implicated in this disease. The patient's appearance may be greatly improved by the removal of these growths. This may be done readily enough by making an incision down the mesial line to the alar cartilages, and then dissecting the lipoma off these on each side; especial care, however, being taken in doing this not to encroach upon the nostril. This is best avoided by directing an assistant to keep his finger in it while the dissection is being prosecuted, so that he may warn the surgeon of the too near approach of the knife. The surface is then left to granulate and cicatrize.

LUPUS and EPITHELIAL CANCER.—The nose is frequently the seat of Lupus and various forms of Epithelial Cancer, many of the deformities of this feature being referrible to this affection; indeed, lupus may be looked

upon as almost specially affecting this organ, destroying one or both alae, the columna, or perhaps the whole of the nose. The consideration of the nature and treatment of these affections in this situation presents nothing special; but that of the cure of the deformities induced by them, which is full of interest to the surgeon, will be considered in detail when we speak of the plastic operations that are practised on the face.

POLYPUS.—Tumours of very different structures and composition are met with in the nostrils; and to all of these which possess the common characters of being pendulous and blocking up these passages, the term *Polypus* is given. Thus surgeons commonly speak of the *Benign*, the *Soft*, the *Gelatinous* or *Mucous Polyp*, as well as the *Sarcomatous* or *Fleshy*, and the *Malignant Polyp*. The term, however, should properly be confined to a soft and pendulous mucous growth; the fleshy and malignant polypi being mere varieties of fibrous or encephaloid tumours, springing from the bones in the nasal fossae, or from the ethmoidal and sphenoidal cells.

The true *Mucous Nasal Polyp* is a soft, moist, gelatinous tumour, of a greyish-yellow colour when lodged in the nasal fossae; but when it descends into the anterior nares, or beyond them, and is exposed to the air, it becomes of a reddish-brown or purple tint, and somewhat shrivelled on the surface. It is usually lobulated, pedunculated, or bottle-shaped; and not very vascular except at the root, where it is permeated by largish thin-walled vessels that bleed freely on the slightest touch. In structure it is homogeneous, and composed of the elements of mucous membrane, covered by tessellated and ciliated epithelium, the cilia of which may often be seen under the microscope in active movement after the removal of the growth. The tumour may grow from any points of the surface of the turbinate and ethmoid bones, and has indeed occasionally, though very rarely, been observed to project into the nose from the frontal sinuses and antrum. Most frequently it grows from the inferior spongy bone towards the outer side of the nostril, sometimes from the roof of the nares, but never from the septum.

The polypi are usually numerous and of all sizes; as they increase they commonly extend forwards into the anterior nares, but, when large, they may be seen to reach into the posterior fauces, hanging down behind the palate.

Symptoms.—The symptoms occasioned by the presence of nasal polypi depend on their interference with respiration and speech, and on the visual changes which they occasion. The respiration through the affected nostril is impeded, the patient being unable to blow through it when directed to do so, and his speech is thick and nasal. There are snuffling and mucous discharge from the nostril: and all these symptoms are worse in damp than in dry weather. On examining the interior of the nose, by opening the nostril widely with the forceps or nasal speculum (Fig. 316), and then directing the patient to blow down, the lower end of the polyp may be distinctly seen, and if large, will descend on a level with or even beyond the nasal aperture. By the introduction of a probe, the size and extent of the tumour, together with the position of its pedicle, may be readily

ascertained. As it grows, it impresses changes on the shape of neighbouring bones, producing expansion and flattening of the nose; it induces caries of

Fig. 316.—Nasal Speculum.

the spongy bones; and, interfering with the flow of tears down the nasal duct, occasions a watery state of the eyes, which, together with the change of shape in the features, and the peculiar character of voice and respiration, enables the surgeon at once to recognise the nature of his patient's disease. Polypi chiefly occur in young adults after the age of puberty; but they are not unfrequently met with at later periods of life.

Diagnosis.—1. Mucous nasal polypi may be distinguished from chronic thickening of the mucous membrane covering the spongy bones by the absence in the latter of any pedunculated growth around which a probe can be passed, together with the florid red character of the thickened membrane, and the fact that the subjects of this thickening are almost invariably strumous children. 2. In *abscess of the septum*, the history of the case, and the fact of the polyp never being attached to this part of the nose, will establish the diagnosis. 3. There is a peculiar malformation, consisting in a *deviation of the septum* to one side, that may at first be a little puzzling; but here the examination of both nostrils, and the discovery of a depression of one side of the septum corresponding to the projection on the other, will reveal the true nature of the case. 4. The *fibrous and malignant tumours* of the nostril will be found to differ sufficiently in consistence and appearance from the ordinary polypi to prevent their being confounded with them in many cases; yet in some instances much care will be required in coming to a definite opinion as to their true nature.

Treatment.—The spontaneous separation and expulsion of nasal polypi is of rare occurrence. I have, however, seen one case in which, after the assiduous use of chloride of zinc injections, a very copious discharge of large sloughy polypoid masses took place from one nostril which had been blocked up by them for many months previously, and from which they had even descended into the pharynx.

Nasal polypi may generally be most readily removed by avulsion with forceps; occasionally, but rarely, when they are very large, with a broad base, and especially when they extend into the throat, they require the application of the ligature. In removing these growths by the *forceps*, instruments of good length but very slender construction should be used, —those generally sold are too thick; the interior of the blades should be properly serrated, and have a longitudinal groove, so that the root of the tumour may be tightly grasped. The patient should be made to sit on rather a low chair; and, as there is generally a good deal of bleeding, a towel should be pinned over his clothes, and a basin placed before him to receive the blood and expectorated matters. The surgeon then, having ascertained by the introduction of a probe, or by means of the blades of the forceps, the situation of the pedicle of the polyp, grasps this firmly and pulls it off with a twisting movement of the hand. He proceeds in this manner, twisting off rather than pulling away polyp after polyp, until the whole of the nostril is cleared, which may be ascertained by examination and by directing the patient to compress the sound and to blow through the affected side of the nose. The bleeding, which is often very free, stops on the application of cold water. At about the end of a fortnight the patient should be examined again, as it not unfrequently happens that small polypi, which had been prevented from descending into the nares by the presence of the larger ones, now come down and require removal. These procedures must be had recourse to from time to time, until all tendency to fresh formations of this kind has ceased.

The *ligature* is chiefly required for those polypi that pass into the pharynx through the posterior nares. They may best be tied by passing a loop of

strong whipcord, by means of a double cannula, through the nose; and then, after expanding the noose round the tumour in the throat and making it grasp its pedicle, knotting it tightly. In some instances the polypus attains a great size, producing absorption of the nasal bones, and of the nasal process of the superior maxilla. In such cases, it may be necessary in order to extract them, to slit up the nose, and possibly clip away with forceps the osseous surface from which they spring.

When the tumour, more especially if fibrous or fibro-plastic, hangs down in the pharynx behind the soft palate, its pedicle may be ligatured by conveying a thread through the nostril by means of a Belloeq's sound, and attaching to this a loop of silver wire, which, as it is withdrawn through the nostril, embraces the base of the tumour. The noose may then be tightened by twisting up the ends of the wire, or by running a silver cannula along them.

FIBROUS TUMOUR.—The intranasal fibrous tumour (sarcomatous or fleshy polypus) is usually attached to the posterior part of the nasal septum, descending to the pharynx. It is globular, smooth, firm, and has little disposition to bleed or ulcerate. It may grow to a large size, extending into the throat, and perhaps finding its way from the nose into situations where it is little expected. Thus it has been met with in the pterygo-maxillary fossa, and has been known to pass into the orbit through a hole in its inner wall.

MALIGNANT TUMOUR (sometimes called malignant polypus), either encephaloid, or of a fibro-plastic or simply recurrent character, occasionally forms in the nostrils. It grows rapidly, with great expansion of the bones, much discharge, fetor, and bleeding, the hemorrhage being often excessive. It attacks children and persons advanced in life; extends into the pharynx behind the soft palate; and after a time has a tendency to press against, absorb, and protrude through the nasal or lachrymal bones, speedily destroying life by hemorrhage, cachexy, or secondary deposits. In such cases the surgeon may make an attempt to extract the growth in the ordinary way through the nostril; or this may even be slit up in order that the attachment of the growth may be more fairly reached; or, should the tumour protrude into the pharynx behind the soft palate, it may be extirpated from that situation. It is, however, seldom that anything very effectual or permanent can be done by operation; and it should be borne in mind, that some of the malignant growths which project into the nostrils take their origin from inside the cranium, or from the sphenoidal cells, and that the nasal portion is only the external protrusion, as it were, of a deeply-seated tumour.

CALCULI are occasionally met with in the nasal fossae, where they simulate foreign bodies; and here extraction may be practised with a pair of forceps. But sometimes these *rhinoliths* are situated under the mucous membrane. In two cases I have dissected round calcareous bodies of this kind, of about the size of cherry-stones, from under the mucous membrane of the ala of the nostril in children.

THE FRONTAL SINUSES, though rarely, are occasionally the seat of disease. *Abscess* may form here, with much pain and expansion, and possibly caries of their anterior wall, attended by the local signs of inflammation and by danger of concomitant inflammation of the membranes of the brain. In such circumstances it may be proper for the surgeon to consider the advisability of removing by a small trephine the anterior wall of the sinus, and thus giving exit to the retained pus. There are a few cases recorded in surgical writings, of Polypus springing from these sinuses, and finding their way down

into the nose after producing expansion of it and much inconvenience. Here likewise the propriety of trephining and so extracting the morbid mass would have to be considered.

TUMOURS AND ULCERS OF THE CHEEKS.—The cheeks are occasionally the seat of *Encysted Tumours* and *Cancerous Growths*, either springing from their inner surface, or taking their origin as *Lupoid Ulcers* on the outside. The *Encysted Tumours* in this situation may readily be removed by a little simple dissection. If they be attached to, or lie close under, the mucous membrane of the mouth, they may be dissected out from within, without interfering with the cutaneous structures. *Canceroid Ulcers and Tumours*, such as represented in Fig. 317, seldom admit of operative interference.

SALIVARY FISTULA.—One of the most troublesome surgical affections situated in the cheek is a *Salivary Fistula*, occurring in consequence of injury, abscess, or operation, by which the parotid duct has been opened, so as to cause a trickling of saliva through the external aperture made into it. If the fistulous opening be recent, the lips of the external wound may be brought together and made to close, while the internal aperture is free. If it be of old date, a seton composed of a few threads may be passed into the fistula from the inside of the mouth, so as to allow the saliva to find its way along this, whilst union of the external orifice is attained by paring its edges and bringing it together with hare-lip pins. My colleague, Mr. Marshall, has succeeded in closing an aperture of this kind by restoring the canal by means of a wire heated by galvanism, and then causing the external orifice to contract.

Fig. 317.—Canceroid Ulcer of Cheek.

DISEASES OF THE LIPS.

CONGENITAL MALFORMATION OF THE LIPS is of common occurrence. *Congenital Contraction*, or even complete closure of the orifice of the mouth, has been met with at birth: such a condition must be remedied according to circumstances by the skill of the surgeon. By far the most common malformation, however, is the condition termed *Hare-lip*, which will be noticed in detail in the chapter on the Plastic Surgery of the Face and Mouth.

HYERTROPHY to a great extent occasionally occurs in either or both lips. It is often of an oedematous character, being kept up by the irritation of fissures or cracks; if so, these must be cured, when the size of the lip will gradually diminish. Sometimes, however, it becomes permanent, continuing after the cure of the fissure; under these circumstances it may be necessary to excise an elliptical portion of the mucous membrane of the lip in a horizontal direction, and then to bring the edges together by means of sutures or pins.

ULCERATION is not unfrequently met with on the prolabium, frequently of a simple character, though chronic. It is frequently dependent on a disordered state of the digestive organs. It will commonly yield to the application of nitrate of silver, to proper constitutional treatment having for its object the improvement of the digestion, and in very chronic cases to the administration of the preparations of arsenic.

ENCYSTED AND ERECTILE TUMOURS.—The lips may be the seat of encysted and erectile tumours, requiring extirpation by the knife or ligature. In dealing with these, the surgeon must be guided by the circumstances of the individual case; but he should, if possible, avoid cutting through the whole thickness of the lip; and, if compelled to do so, he must act as will be described in speaking of cancer of this region. These growths more frequently occur on the lower lip.

Encysted Tumours are usually small and transparent, with thin walls, containing a glairy straw-coloured fluid. These should always be dissected out; mere excision of a portion of the wall being followed by recurrence of the disease.

Erectile Tumours of the lip are usually of an active character, and may either be excised, if of moderate extent and implicating the whole thickness of the lip; or, if of large size and projecting from the mucous surface, they may be safely ligatured (p. 688). I have had under my care several cases of *Nævus* of the upper lip, implicating the whole substance of the part, and have successfully removed them by the repeated application of potassæ cum calce.

MALIGNANT DISEASES OF THE LIPS.—Not unfrequently *Warty Growths* and various forms of *Epithelioma* and *Canceroid Diseases* appear upon the lips. These affections are not removable by therapeutic means, and require surgical interference.

Epithelioma of the lip either commences as a warty growth, which gradually ulcerates like the ordinary forms of tubercular lupus; or it begins as an indurated crack or fissure, the edges of which have a tendency to spread. The submaxillary glands tend to become involved: and the disease may eventually prove fatal by the pain, exhaustion, and constitutional irritation induced by them. *Epithelioma* almost invariably occurs in men, affects the lower lip, and is met with after the middle period of life. Of fourteen cases in which I have operated, seven were above sixty, and four between fifty and sixty years of age; in one case only did the disease occur under thirty. This disease is at first entirely local, often being induced by some irritation, as by a rugged broken tooth, or by smoking a clay-pipe; and when removed it does not, I believe, very commonly return. At least, of the very many cases that have been operated upon at the University College Hospital, I have only known one patient return with a recurrence of the disease, and I do not recollect any case of secondary affection of this description to have applied to that institution after having been operated on in other hospitals; I cannot, therefore, but come to the conclusion that the operation for epithelioma of the lip frequently cures the patient permanently of disease.

When the glands under the jaw are enlarged in this disease, it is a question whether an operation should be done; but I think decidedly that extirpation of the disease and removal of the enlarged glands (provided that the surrounding soft parts be not involved) should be practised if the patient be in a good state of health, as he will thus be placed in a more favourable condition than before the operation, and will have a better chance of prolongation of life.

Operation.—When once the true nature of the disease has been ascertained, the operation should be performed with as little delay as possible, but, before it is done, it is well that any very prominent or broken tooth should be removed, and the tartar cleaned away from the incisors. The operation requires to be somewhat modified, according to the situation and extent of the affection (Fig. 318). If this be tolerably limited, a V-shaped

cut, extending widely round it, and carried sufficiently low to include any indurated prolongation of the absorbents, should be practised; the edges of

Fig. 318.—Epithelioma of Lower Lip:
Lines of Incision

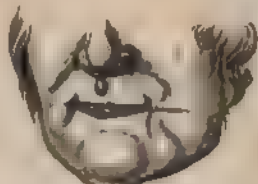

Fig. 319.—Lip after Removal of
Epithelioma.

the cut should then be brought together by two hare-lip pins with a twisted suture, as in the case of a simple hare-lip. When the disease occupies a considerable longitudinal extent, but does not dip down very deeply, a slice of the lip should be shaved off, including the whole of the morbid structure; and it is often surprising, under these circumstances, to observe how the tissues of the lip will speedily rise to their natural level, thus preventing any material deformity from being left (Fig. 319). In some cases the disease occupies a square surface, and then it is necessary to excise a portion of the lip; when this is done, a considerable gap is left, requiring to be filled by some plastic operation of the kind that will be considered in a subsequent chapter (LVIII.), which may be most conveniently done at the time when the excision is performed.

DISEASES OF THE PAROTID GLAND.

PAROTITIS, or **MUMPS**, is a common affection, especially in children, though it not unfrequently occurs in adults. It arises usually from cold and wet, and is frequently infectious. Both sides of the neck are usually affected, and the swelling, stiffness, and pain are often considerable, though it very rarely happens that suppuration occurs, unless it be in the lymphatic glands of the neighbourhood. Metastasis, though of rare occurrence, has been described as occasionally happening to the testicle or breast.

The *Treatment* of this affection is simple. If it be severe, the application of hot fomentations and leeches, the administration of saline purgatives, and, when the affection is on the decline, frictions with camphorated oil, will hasten its resolution.

TUMOURS.—Tumours of the parotid gland itself are not so frequent as morbid growths situated upon it or in its vicinity; yet occasionally they consist in an actual transformation of its structure. The tumours met with in this region may be simple or malignant. When simple, they are usually of a *fibrous* nature and often *encysted*; they are hard, deeply attached, but moveable on careful manipulation; round, and of very great size, becoming even as large as a cocoa-nut (Fig. 320); the skin covering them is thin but not ad-

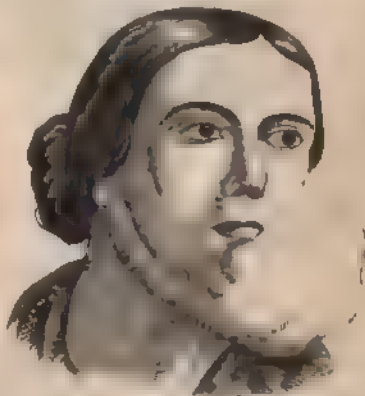

Fig. 320.—Fibrous Tumour of Parotid too
large for Removal.

herent, and not unfrequently a network of veins covers the mass. These growths frequently send prolongations under the ramus of the lower jaw, and then occupy the whole of the space between its angle and the mastoid process; when firmly bound down, they involve the blood-vessels and nerves

Fig. 321.—Tumour of Parotid

in this important region, coming into relation with the styloid process and its muscles, and even pressing upon the pharynx, as was the case with the patient from whom the preceding cut (Fig. 320) was taken. In consequence of the large size that these tumours may attain, they have a tendency to produce atrophy of the parotid, and often, by interfering with the cerebral circulation, occasion various congestive symptoms about the brain. Besides the fibrous, various other simple tumours, such as fatty, enchondromatous, and encysted, occur in the parotid region. These present nothing remarkable in their course here. In some cases the parotid may undergo cancerous infiltration, the tumour then presenting the characters and running the course of the ordinary forms of malignant disease.

Fig. 322.—Tumour of Parotid Back View.

These present nothing remarkable in their course here. In some cases the parotid may undergo cancerous infiltration, the tumour then presenting the characters and running the course of the ordinary forms of malignant disease.

Diagnosis.—It is of great importance to effect the diagnosis between the non-malignant and the malignant varieties of tumours in the parotid region. In the fibrous, fibro-plastic, fibro-cellular, and enchondromatous tumour, there is always mobility; and, although the attachments may be deep, the skin is not involved to any extent. The outline of the mass is usually well defined, square, and somewhat lobulated. The progress of the growth is very slow, often occupying many years before it attains any considerable bulk, as in the annexed cuts (Figs. 321, 322), representing a tumour of sixteen years' standing, which I excised. In the scirrhus

growth there is no mobility, but the mass is solidly fixed; its outline is ill defined, the skin soon assumes a reddish-purple colour, is brawny, and presents the usual characters indicative of subjacent malignant action.

When these tumours are *medullary*, they grow with considerable rapidity, feel soft and pulpy, and are rounded and ill-defined in their outline, especially under the ear and by the ramus of the jaw.

Treatment.—In the treatment of these tumours, extirpation is necessarily the only course that can be adopted; and this in my opinion should not be attempted if the disease be malignant; for, as it would be impossible to remove its deeper attachments, the growth to a certainty would speedily return. Even if the disease be of a simple character, care must be taken that every lobule and prolongation be extirpated; for, if any be left, however small, it will without doubt become the nucleus of a new tumour. In removing tumours in this situation, the superficial incisions should be free, and either longitudinal or crucial, so that the whole mass may be fairly exposed. It is not wise to remove integument, however redundant this may appear to be, unless it have undergone infiltration, incorporation with the tumour, or change of structure; and even then as little as possible should be taken away. The fibrous or aponeurotic investments of the tumour must be fairly opened, and the edge of the knife must then be directed against it, and the dissection carried on from below upwards, or from behind forwards, so that one division of the blood-vessels supplying it may be sufficient. After the tumour has been well loosened by the division of investing fasciæ and structures (and it is surprising how moveable it often becomes after this has been done, though it may previously appear to have incorporated somewhat solidly with the subjacent tissues), it should be taken hold of by the hand or a large double hook, and drawn well forwards whilst the deep dissection is being carried on. In prosecuting this, the surgeon must particularly guard against wounding the temporo-maxillary artery and the portio dura nerve, which are especially exposed to injury. In some cases the division of these, especially of the artery, cannot be avoided, as they are incorporated in the mass that is undergoing removal. The hemorrhage would then of course be abundant, but may usually be immediately arrested by the ligature of the divided artery; indeed, in most cases the bleeding is profuse, owing to the unavoidable section of nutrient vessels and of large subcutaneous veins, but may generally be readily arrested by ligature and pressure. In most instances, however, by keeping the edge of the knife carefully against the tumour and by drawing it well forward, so as to loosen it in its cellular bed at each stroke of the scalpel, removal of the morbid mass may be effected without the division of any important vessel or nerve. It is of more consequence to avoid a wound of the portio dura or of the chief branches of the pes anserinus, than even of the temporo-maxillary artery; as persistent and incurable paralysis of the jaw would result from such an injury. Injury to this nerve is best avoided by dissecting out the tumour by incisions parallel to its main trunk and chief branches, and especially by drawing the mass well forward, and directing the knife towards it. After the extirpation of some small fibrous or encysted tumours in the substance of the parotid, there is often a great tendency to copious secondary hemorrhage, requiring pressure, or even the application of the actual cautery, for its arrest.

If the tumour, though non-malignant, have been allowed to attain an enormous size, developing at its deeper attachments as well as superficially, with large lobes lying behind and under the ramus of the jaw, in close relation with the pharynx, the internal carotid, and jugular vein, it would not be prudent to attempt its removal.

Excision of the Parotid Gland itself is occasionally spoken of, but is very rarely if ever done. I believe that in most, if not all, the cases in which

it is stated that complete removal of this gland has been accomplished, tumours overlying and compressing it have been mistaken for it. It is evident that a diseased parotid could not be removed without the division of the external carotid artery and facial nerve.

TUMOURS OF THE NECK.

Besides tumours in the parotid region, *Fatty, Fibrous, Glandular, and Encysted Growths* are not unfrequently met with in the *Submaxillary Space*, and in the *Triangles of the Neck*. In these situations they may occasionally attain a considerable size, though they seldom extend very deeply, being superficial to the deep fascia. Hence, when the integuments and superficial structures covering such a growth are divided, it may be insulated with sufficient facility, its fixity being in a great measure due to its being bound down by the investing fascia, rather than to its having contracted deep adhesions. Occasionally, though rarely, a slowly growing tumour develops deeply in the anterior triangle of the neck, lying between the sterno-mastoid, the trachea, and the pharynx, possibly even under the carotid sheath, with the artery pushed on one side, or even running over the anterior convexity of the growth. In such cases, the question of removal requires to be approached with the utmost caution. If the tumour be moveable above the vessels, it may generally be taken out; if it lie below the sheath, even though not fixed to the spine, its extirpation is not practicable. Before determining upon the removal of a tumour situated in one of the triangles of the neck, it is indeed always very necessary that a diagnosis be effected of its nature, and that some opinion be formed of the probable extent of its deep attachments.

The first point to ascertain is, whether it be simple or malignant. If simple, it will usually have been many years in growing; it will be hard but not stony, lobulated or somewhat square-shaped; the patient's general health being good. It will generally be found to be moveable, though not perhaps to any great extent, and will present no sign of incorporation with neighbouring structures; the fibres of the platysma will not appear to spread over it, and the sterno-mastoid muscle may be traced to one side of or below it. Under such circumstances, removal of the tumour may be undertaken by any surgeon possessing a fair share of anatomical knowledge and manual skill, with every prospect of success. But if the tumour be of stony hardness, have implicated the skin, and be immovable, the whole head being moved on any attempt at drawing it aside; if it be ill-defined under the jaw and ear, or rapidly growing, soft and pulpy to the feel, deeply seated under the angle of the jaw, evidently below the platysma and deep fascia of the neck, and possibly beneath the sterno-mastoid, then no attempt at extirpation should be undertaken, as the mass could either not be removed with safety, or, if it were by any possibility extirpated, then already existing contamination of the neighbouring parts would certainly lead to a speedy recurrence of the disease. In removing *submaxillary tumours*, a free superficial incision nearly parallel to the margin of the lower jaw, but below this, will usually allow ready extirpation of the mass. In these operations the facial artery is generally sufficiently under cover of the bone to escape injury, but there may be, and usually is, free venous hemorrhage.

HYDROCELE OF THE NECK.—A peculiar cystic tumour, hydrocele of the neck, has been described by Maunoir and Phillips. The disease usually appears in the posterior inferior triangle, forming a rounded tumour, smooth, tense, and elastic, unilocular in some cases, multilocular in others; filled with a yellow or chocolate-coloured sero-albuminous fluid. It may attain

so large a size as to interfere with deglutition and respiration. The largest I have seen was of the size of an orange. The skin covering this tumour is not discoloured, in some cases of natural thickness, in others thin and expanded, so as to give a bladder-like appearance to the growth.

The *Treatment* of this tumour consists in tapping, when complete collapse of the cyst takes place; which, however, will soon fill again. A permanent cure may be effected by injection with iodine, or by passing a seton across.

ENLARGEMENT OF THE LYMPHATIC GLANDS of the neck, terminating either in chronic induration or in abscess, is of such common occurrence as to constitute perhaps the most frequent form of glandular enlargement. The tumours thus formed present nothing peculiar in their progress or treatment when occurring in this situation; except that when abscess forms it should be opened early by a small incision, and in such a direction, corresponding to the natural folds of the skin, as to leave as little scarring as possible.

BRONCHOCELE.

The thyroid gland is subject to various chronic enlargements which commonly go by the name of *Bronchocele*. These may be divided into three distinct forms.

1. **SIMPLE HYPERTROPHY.**—The thyroid gland may be simply hypertrophied, and may then attain a very considerable size; in some cases forming an immense lobulated tumour on the forepart of the neck, such as is met with in various districts of this country and of the continent, in which the disease is endemic. In the majority of instances, however, the tumour is of but very moderate size, commencing at first as a mere fulness and uniform or rounded enlargement of the isthmus, or of one of the lateral lobes of the thyroid gland, and gradually increasing, until perhaps, by the pressure of the growth confined between the sterno-mastoid muscle and the deep structures of the neck, respiration and deglutition become seriously affected. There is a remarkable connection between tumours of the thyroid gland of this kind, and a general anæmic condition of the system. In London nothing is more common than to find a certain degree of bronchocele in pale and bloodless women and girls; indeed so frequent is the coincidence that it is impossible not to regard it in the light of cause and effect. Great prominence of the eyeballs is frequently associated with these conditions. In practice we constantly observe this triple pathological sequence, viz., anæmia, exophthalmos, and bronchocele; and the connection of these has been commented on by Graves, Basedow, Sichel, White Cooper, Aran, Begbie, and numerous other authors.

2. **CYSTIC BRONCHOCELE** is owing to the development of cystic tumours in the thyroid gland, either associated with, or occurring independently of, general hypertrophy of it. These cysts, which may be single or numerous, usually contain a dark, bloody-looking fluid, and have often cauliflower-like excrescences projecting into their interior.

3. **PULSATING BRONCHOCELE** is occasionally met with. The pulsation, which is excentric and distensile, is synchronous with the heart's action, and evidently due to the vascular character of the tumour itself. This form of bronchocele is sometimes conjoined with the cystic; when it is confined to one lobe only, care must be taken not to confound the beatings with carotid aneurism; a mistake which I have known to occur, and the diagnosis of which has been adverted to at page 629.

TREATMENT.—The treatment of bronchocele must vary according to the size and character of the tumour. When small, and associated with anæmia, and of comparatively recent formation, it is best treated by improving the

general condition of the patient by the administration of iron internally, especially the iodide, with the external application of iodine or of iodide of lead ointment. Indeed, in the soft bronchocele occurring in anæmic exophthalmic females, iron is of the utmost service, and acts almost as a specific.

In bronchoceles of large size, hard, and unconnected with anæmia, the chief reliance is to be placed on the free and continuous use of iodine internally as well as externally. Iodide of lead and compound iodine ointment may be used with advantage. It has been recommended by Dr. Mout that thebimiodide of mercury ointment (16 gra. to the ounce) should be well rubbed in for several days; and then, the tumour being covered with it, the patient should be exposed to the strong heat of a mid-day summer sun. This method of treatment, which is said to have been extremely successful in India, has not been tried in this country to a sufficient extent to enable an opinion to be formed of its merits. In some instances pressure has been of use, especially in conjunction with the iodine inunctions; though it is not so easy to apply this means, and any considerable degree of it can necessarily not be borne, on account of the increased difficulty of respiration that is thus occasioned. In fact, the compression exercised upon the tumour by the sterno-mastoid muscle in some of these cases is occasionally so considerable, that it becomes necessary to divide its tendon subcutaneously, in order to relieve the trachea from the constriction to which it is subjected. When the tumour is chiefly cystic, the fluid contents may be drawn off by tapping, and an endeavour may be made to cause the cysts to close by inducing inflammation in them by the injection of tincture of iodine. When bronchocele is very large, its absorption cannot, I think, be expected to take place by these or any other means; and the question then arises as to the propriety of having recourse to operative interference. *Excision of the tumour* is seldom to be thought of; the disease, even though of large size, not being detrimental to life. The vascularity of the tumour is so great, and the arterial supply that it receives from both sets of thyroid arteries so abundant, that any attempt at extirpation must generally be attended by such profuse hemorrhage as necessarily to prevent the completion of the operation. Cases have, it is true, occurred to Roux and others, in which large bronchoceles have been successfully extirpated; but these operations must be looked upon as altogether the exception in the treatment of the disease; and instances are certainly not often met with, in which a surgeon would think it proper to undertake so serious a procedure for an affection that is not necessarily mortal. I have more than once been tempted to remove large pendulous pedunculated bronchoceles, but close examination has satisfied me in all such cases that the neck of the tumour was so vascular, containing large arterial and venous branches, and so intimately connected with the sheath of the carotid, stretching under the sterno-mastoid, which was expanded over it, that no operation could be safely undertaken. In the event of its being thought desirable to operate, the better plan would be, after exposing the tumour, to enucleate it as much as possible with the handle of the scalpel, ligaturing carefully all the vessels divided as they were cut.

Ligature of the thyroid arteries has been practised by some surgeons, with, it is stated, a certain degree of success. The difficulties and danger of the operation, the uncertainty of its results, and the readiness with which the arterial supply would be forwarded to the tumour from other sources, have caused it to be but little resorted to by surgeons of the present day. In one case of pulsating bronchocele in which I had recourse to this treat-

ment, no benefit resulted from it. The introduction of a *seton* across the tumour is occasionally attended by beneficial results. This operation, however, is not unaccompanied by danger; a patient in the neighbourhood of London, on whom it was being performed a few years ago, lost his life by the puncture of a vein at the root of the neck, into which air was spontaneously admitted. *Injection of perchloride of iron* by means of the syringe figured at p. 683, is likely to be of service in some cases of very vascular and pulsating bronchocele. In one instance of the kind in which I employed it, although much local inflammation and deep-seated suppuration was induced by it, the patient was in the end materially benefited.

CHAPTER LVI.

DISEASES OF THE JAWS AND THEIR APPENDAGES.

DISEASES OF THE GUMS AND ALVEOLAR PROCESSES.

ABSCESS OF THE GUMS is of very frequent occurrence, from the irritation of decayed teeth. Here a free and early incision should be made; which, by giving exit to the pus, will afford immediate relief.

SPONGY AND SLOUGHY ULCERATION OF THE GUMS will occur as the result of constitutional cachexy induced in any way—by mercury, malaria, syphilis, &c. It is best treated by tonics, in conjunction with the chlorate of potash and mineral acids internally. If it spread actively, escharotics, such as hydrochloric acid or creasote, may be advantageously applied. If it do not make much progress, a solution of nitrate of silver, with chlorinated or tannin gargles, will be useful.

EPULIS is a tumour springing from the periostum and edge of the alveolus, and implicating the osseous walls: it grows up between and loosens the neighbouring teeth, which it displaces and envelops in its structure. It is of two kinds; *simple* and *malignant*. The *Simple Epulis* is a fibrous tumour; the *Malignant* is usually myeloid—if the term “malignant” can be applied to that form of tumour; but it is also occasionally cancerous.

Epulis is most frequently met with in the lower jaw. I have, however, seen several instances of it springing from the alveolus of the upper jaw. It appears chiefly to be occasioned by the irritation of decayed stumps, and hence is more frequently met with in connection with the molar than with the incisor teeth. Although this disease has occasionally been met with in children, it seldom occurs before the adult age, and then may be developed at any—even up to an advanced—period of life. It is seen then as often among females as males. A fibrous epulis appears as a red, smooth, and lobulated tumour, at first hard and semi-elastic, like the ordinary structure of the gum, but after a time softening by disintegration, and ulcerating on the surface, with a purulent or sanious discharge. The fibrous variety appears simply to be a circumscribed and rapidly-growing hypertrophy of the gum.

Treatment.—The treatment of epulis consists in the removal of the whole

Fig. 322.—Epulis of lower jaw.

of the mass and of that portion of the alveolus from which it springs. As it evinces a great tendency to reproduction, it must not simply be shaved off the bones, but a portion of the osseous structure must be removed as well; unless this point be attended to, the growth will to a certainty be reproduced. In all ordinary cases of simple epulis, this may be done from the inside of the mouth without the necessity of making any incisions through the cheek. In very large epuloid masses, more particularly of the myeloid variety, and extending towards the ramus, it may be necessary either to carry an incision from the angle of the mouth downwards and outwards, or to dissect up the cheek from the bone, and thus expose the disease fully. In performing the operation, the first thing to be done is to extract a tooth contiguous to and on each side of the tumour; a cut must then be made with a saw through the alveoli of the teeth that have been removed, down to a level with the base of the growth. In doing this, care must be taken not to cut too near the remaining teeth, lest the alveoli be opened and their support lost. If the tumour be large, it may be necessary to saw deeply, but the base of the lower jaw should, whenever practicable, be left intact, the whole of its substance not being sawn through, so that, though a considerable portion of bone be removed, yet the length of the jaw may be preserved. For this purpose Hey's saw should not be used, as it is a niggling instrument, difficult to manage in this situation; but a straight and stiff-backed saw, with as deep a blade as the mouth will conveniently admit, will be found most useful (Fig. 233). The epulis, included between two vertical cuts, may now, if small, be removed with cross-cutting forceps, and the bleeding stopped by placing a plug in the wound and compressing it against the teeth of the upper jaw by means of a bandage passed under the chin. If the epulis be large, a horizontal cut should be made along the bone about midway between the alveolus and the base, by means of a Hey's saw; and, after the bone has been penetrated to a sufficient depth, the blade of the cross-cutting forceps may be fixed in this cut, and the diseased part then removed. Should there be a spouting dental artery, it may be necessary to apply a red-hot wire, or the perchloride of iron, in order to arrest its bleeding. The cut surface will speedily granulate; and the cavity fills up with fibrous tissue. The operation for the removal of epulis is a very safe one. Of 28 cases collected by Hutchinson from different London Hospitals, one was fatal; and that one from pyæmia.

Malignant Epulis.—Cancerous ulcers and fungous fibro-plastic growths from the alveolar processes, *malignant epulis*, as they are called, occur in the same way as the last; but they are soft, purplish, very vascular, grow rapidly, and are speedily reproduced after removal; they principally, so far as my observation goes, occur in males advanced in life. The same operation requires to be practised for these diseases as for the simple epulis, and, as there is usually much hemorrhage following their removal, a red hot iron must be applied to the bleeding surface. If a malignant epulis be of very large size, it may be necessary to remove a portion of the whole thickness of the bone, through an external incision, as will be described in the section on Excision of the Lower Jaw (p. 876).

NECROSIS OF THE JAWS is commonly the effect of blows, of salivation by mercury, of syphilis, of fever, or of exposure to the fumes of phosphorus. I have, however, seen the disease occur idiopathically in otherwise healthy subjects, without any assignable cause. In this way I have seen the whole of the alveolar process of the upper jaw exfoliate in a young lady, otherwise perfectly healthy; and I have several times had occasion to remove large portions of the lower jaw—in one case more than half of the bone—for necrosis

that was not referrible to any of the causes mentioned above, or indeed to any assignable reason. The disease begins with deeply seated pain resembling inveterate tooth-ache, which nothing will allay; the gums become swollen; the teeth are loosened, and eventually drop out. Before they do so, however, pus usually wells up through the alveoli. Abscesses form outside the mouth and under the angles of the jaw—having fistulous openings through which bare bone is reached by the probe. The general health suffers greatly in these cases, more so than in necrosis generally, doubtless in consequence of the patient swallowing some of the pus from the dead bone.

Necrosis of the jaws, arising from the inhalations of the fumes of phosphorus during the manufacture of lucifer matches, first noticed by Lortner of Vienna, has been especially described by Von Bibra and Geist, who had abundant opportunities of observing the disease at the large manufactures at Nuremberg. This *Lucifer match disease* has of late years also been observed in many cases in this country. It consists in necrosis of the jaws, and is attended by the symptoms just described, but in a severer degree and an acute form. Both jaws are equally liable to be affected; but commonly one only at a time is diseased, and the whole of the bone may die and be separated. Thus of 51 cases observed by Von Bibra, both jaws were affected in 5 instances only—the upper alone in 21 cases, the lower in 25. It appears that workmen having sound teeth are not easily if at all influenced by the fumes; but, if any tooth become carious, then the effect of the fumes will eventually manifest itself by the induction of necrosis, the action extending probably through the carious tooth into the interior of the alveolus.

Treatment.—The treatment of necrosis of the jaws presents nothing special. The removal of the sequestra should be effected as far as practicable through the interior of the mouth, by free incisions through the gums.

In the upper jaw, where the necrosis seldom extends beyond the alveolar border or the palatal process, this may always readily be done.

In the lower jaw, the question as to whether the dead bone should be extracted through the inside of the mouth, or by incision from without through the cheek, will be determined partly by the position of the sinus and partly by the situation and extent of the bone affected. This may in a great measure be ascertained by the situation of the sinus leading down to it. If these be in the cheek, or in the side of the neck, or under the angle of the jaw, it is usually an indication that, if the whole of the corresponding sinus or body of the bone be not involved, the posterior and outer parts are certainly affected; and, under these circumstances, extraction of the sequestrum is best effected by opening up the sinus parallel to the line of the jaw, and removing the necrosed bone in the usual way. The incisions for this purpose need not usually be very extensive. If the operation be delayed, in accordance with those principles that guide us in the management of necrosed bone generally, until the sequestrum is quite loose, it may usually be readily extracted, in whole or in pieces, through an opening that will leave but a small cicatrix. By such operations as these, the whole of the lower jaw has been extracted piecemeal at intervals in a state of necrosis, first on one and then on the other side. *Cornelius* has removed the whole of the necrosed lower jaw at one operation, dissecting first one and then the other condyle in the usual way.

If, however, there be no external abscess or sinus—if the gum have been loosened and perforated, with a ragged portion of sequestrum protruding through it into the cavity of the mouth, then no external incision will be

required, but the dead bone may be readily removed from within the mouth. Large portions of the jaw may thus be removed. I have taken away the whole of one ramus with its processes entire through the gum, without any external incision: and in a negro, the whole of the bone in a state of necrosis has thus been removed in separate pieces, by Perry, through the inside of the mouth.

The amount of regeneration of bone will depend greatly upon the state of the periostum before the removal of the sequestra. If this be healthy, and if new bone have already formed prior to operation, a very perfect reproduction of the portions of jaw removed may take place. Should no new bone have formed before the operation, a dense fibroid cicatricial structure will replace the removed bone.

DISEASES OF THE ANTRUM AND UPPER JAW.

Our present knowledge of diseases of the jaws, and of the operative procedures necessary for their removal, is chiefly due to the labours of Gensoul and of Liston. O'Shaughnessy also, who appears to have had many opportunities of witnessing these affections amongst the natives of India, has added much to our acquaintance with their pathology and treatment.

DROPSY OF THE ANTRUM, from accumulation of glairy mucus like the contents of a ranula or ganglion within this cavity, occasionally occurs. As the aperture leading from this cavity into the nose is a little above its floor, there may be a natural tendency for the fluid secreted here to accumulate to some extent before it is discharged; and if this aperture be from any cause blocked up, the secretion may increase to so great a degree as to occasion serious inconvenience by its outward pressure. In such cases the accumulation of fluid has been known after a time to expand and absorb the osseous walls of the cavity, so as to constitute a true cystic disease, and in this way the floor of the orbit or the roof of the mouth may be caused to bulge, the nasal cavity may be encroached upon, and the cheek rendered round and prominent—an indolent semi-elastic tumour forming in it and protruding it outwards, and giving rise to the egg-shell or parchment-like crackling on pressure.

Treatment.—Catheterism of the antrum may be practised in these cases by passing a curved probe along the side of the nostril between the superior and middle turbinate bones; where, in the middle meatus, about its centre, the aperture leading into the sinus may be felt. Should this treatment not succeed, the antrum must be opened from without: this is done by dissecting up the cheek from the gum, and thus making an opening into the cavity of the antrum with a strong pair of scissors or a perforator, through its most expanded and thinnest part, and leaving a plug of lint in the aperture, so as to allow the discharge to escape freely. The shape of the cheek may be restored by the gradual pressure of a spring pad or double-headed roller.

SUPPURATION may take place in the antrum. It is usually excited by the irritation of a carious molar tooth, or by some injury of the face, and occasions perhaps much throbbing or lancinating pain. The pus, as it forms, will sometimes overflow, as it were, into the nose through the aperture into the middle fossa, and then may keep up constant irritation, with much fetor in the nostrils; in other cases, it drains through the socket of a tooth into the mouth; and in other instances again, its exit being prevented, it gives rise to enlargement of the cheek, the soft parts of which become brawny and inflamed, and the bones expanded, so that at last they are thinned to such an extent that, as in dropsy of the cavity, they crackle when pressed upon. Any portion of the wall of the cavity—the orbital, buccal, palatal, or

nasal—may thus be expanded and fluctuation be felt through it; and, the lachrymal duct being commonly obstructed, the eye on the affected side becomes watery.

Treatment.—The treatment of this condition consists in the extraction of any carious tooth seated in the neighbourhood of the antrum; or, if the teeth be all sound, in the removal of the second molar, the fangs of which come into close relation to, and frequently perforate the bottom of, the cavity. In this way an exit should be given to the matter; but as it will not discharge itself sufficiently freely, the antrum must be opened through the alveolus, or through the canine fossa under the cheek, provided it be much expanded in this situation, so that its cavity can be easily reached. The perforation into the antrum may readily be made, or the socket of the tooth enlarged, by means of a triangular antrum-perforator, such as here represented (Fig. 324). As the matter drains away, the cavity will gradually contract, and the deformity thus be removed. It is well not to attempt to perforate in the site of teeth that have been extracted for some length of time, as here the bone becomes unduly consolidated, and I have consequently seen failures in reaching the cavity occur. The matter that is discharged is often very offensive, or it may be thick and pasty from the absorption of its watery parts. After the aperture has been made, the cavity should be syringed out with tepid water, and its shape gradually restored by pressure.

Fig. 324.—Tri-
angular An-
trum-perfor-
ator.

Tumours of various kinds spring from the upper jaw, taking their origin either from the surface of the superior maxillary or malar bones, from the interior of the antrum, or from the pterygo-maxillary fossa.

Those that grow from the *Surface of the Bone*, are either some of the various forms of *Epidis* that spring from its alveolar border, and must be treated as already described; or they are *Exostoses* growing from the outer surface of the bone, projecting perhaps up into the orbit, and requiring removal with the saw, bone-nippers, or gouge. In doing this, care must be taken not to destroy the nasal process of the bone, lest the lachrymal sac be opened.

The tumours that spring from the *Malar Bone*, from the *Cavity of the Antrum*, or from the *Posterior Part of the Upper Jaw*, are of very various kinds: fibrous, recurring fibroid, cartilaginous, osseous, fatty, fibro-plastic, erectile, and encephaloid growths may all be met with in this situation. In the Museum of University College, which is very rich in specimens of these tumours, most of the above-named varieties will be found. The *Fibrous Tumour* is perhaps the most common; it principally occurs in elderly people, and may attain very considerable bulk. The *Encephaloid* comes next in order of frequency; and the *Osseous*, *Enchondromatous*, and *Myeloid* occur, but are extremely rare. The osseous tumours are remarkable as occasionally appearing to set up a spontaneous attempt at elimination, by necrosis taking place in them.

Situation and Symptoms.—Encephaloid, myeloid, and osseous tumours occasionally spring from the surface of the malar bone, pushing forward the cheek, spreading into the mouth, and involving, with greater or less rapidity, according to their malignancy, the soft structures of the face and the lymphatic glands under the jaw. They are usually rapid in growth, irregular in outline, and only secondarily implicate the superior maxilla and neighbouring cavities. The various growths that are connected with, or

spring from, the mucous membrane of the antrum expand and dilate the walls of this cavity, pressing them, and giving rise to a considerable protrusion of the face. The tumour thus formed is oval, slightly lobed perhaps, more especially if fibrous in character. As it increases in size, it encroaches on the nasal cavities lying in the vicinity of the antrum. It presses on the palate, causing considerable swelling in the roof of the mouth, on the alveolar processes and teeth, giving rise to irregular protrusion. It may encroach upon the orbit, occasioning stilted vision, and impairment of vision. As the tumour enlarges, it stretches back into the pharynx, interfering with deglutition, and occasions sometimes severe epistaxis. In the early stage, and of a lloid character, obstruction of the nasal fossa will be the earliest sign, leading to the suspicion of polypus. As the disease is observed speedily to become involved, the glands of the maxillary absorbent glands enlarged.

Diagnosis.—In the diagnosis of these tumours, the following points are to be attended to:—1, to distinguish them from other tumours; 2, to determine whether the growth be simple or compound; 3, to ascertain its primary seat.

1. In making the diagnosis from *fluid accumulations*, the history of the case, and the uniform enlargement of the tumour projecting externally beyond any part of the face, lead the surgeon to determine that it is not of a solid character. This is not sufficient; and it becomes necessary to resort to exploratory puncture by means of the perforator, through the thinned and expanded parts already indicated. This is necessary in cases of doubt; for it has happened even to the most experienced that, after making incisions through the cheek with the tumour, the bones were found to be expanded and the operation had been undertaken, consequently, the operation had been undertaken.

2. In determining whether the growth be of a solid or fluid character, the surgeon will experience much difficulty, if the cavity of the antrum; but when once it has penetrated its walls, this point is easily solved. Whilst the tumour is within the antrum, much light may, however, be thrown upon the rapidity of its growth; the great point there is to suspect that it is malignant. Yet, the signs are of value, too much importance must not be placed upon them as a general rule, fibrous and cartilaginous tumours grow more rapidly than the malignant, yet it may happen that the malignant grows more rapidly in a short space of time. With regard to the value of the signs in a diagnostic point of view, that, as a general rule, simple tumours are more common in young, whilst the malignant forms of the disease are more common with at the middle or advanced periods of life. In a diagnostic point of view, to examine the condition of the glands. When the disease is malignant, they become enlarged at a very early period. In a case under my care of a tumour, whilst still in the antrum, was detected being a long chain of indurated lymphatic glands in the lower jaw, where they had become secondary.

where the bones had been perforated by the growth. When once a malignant tumour has passed beyond the cavity of the antrum, and is thus freed from the pressure of its walls, it grows with great rapidity. Insinuating itself extensively amongst the bones of the face and skull, it creeps through the foramina and fissures, encroaches greatly on the nasal cavity and orbit, implicates the integuments of the cheek and the soft structures within the mouth, and throws out sprouting masses in these several situations, which present all the characters of the true malignant fungus.

3. A point of very great importance in relation to operative interference is to determine the *primary seat of the tumour*; whether it spring from the cavity of the antrum, from the malar bone, or from behind the superior maxilla in the spheno-maxillary or pterygo-maxillary fissure. In the former case, the nasal or the palatal walls of the antrum are expanded, and the line of teeth is rendered irregular. When the tumour primarily springs from the malar bone, it pushes forward the cheek into a somewhat conical prominence, and dips down into the mouth between the gums and the soft structures of the face. It does not involve the orbit or palate, or alter the hue of the teeth, but rather spreads over the bones, and involves the covering soft parts by continuity of tissue, without any definite anatomical disposition. As the tumour increases in size it will implicate the anterior wall of the antrum, and thus secondarily project into that cavity.

When the disease develops primarily *behind the superior maxilla*, that bone will be found to be simply pushed bodily forwards, there being little if any deformity in its outline, the line of teeth not being displaced, nor the walls of the antrum—palatal, nasal, or orbital—expanded. Yet it must be borne in mind that the difficulty of diagnosis is greatly increased by the fact that a tumour, though not originating in the antrum, may pass into the orbit through the spheno-maxillary fissure, and may make its way forwards amongst the bones of the face, partly by creeping through, and partly by absorbing and displacing them.

Treatment.—In the treatment of tumour of the antrum, nothing can be done except to extirpate the growth; and it is consequently of great importance to distinguish those forms of the disease in which an operation can be undertaken with safety, and with a fair chance of success, from those in which none should be performed. When the tumour, springing from the antrum, is of a simple character, the disease should be removed, together with the whole of the superior maxilla; the tumour, whatever size it has attained, being generally encysted, and the bones expanded around it; so that it is well bounded, and does not implicate neighbouring parts. Here, as Liston justly observes, no nibbling or grubbing operations should be done, but free excision of the whole mass practised. When the tumour springs from the spheno-maxillary or pterygo-maxillary fissure, pushing the bones of the side of the face forwards, I think it is doubtful whether the surgeon ought to interfere, as the base of the skull may be implicated to such an extent that the patient may die a few hours after the operation, as I saw happen in a case of Liston's. When once a malignant growth of this part has passed beyond the osseous boundaries of the antrum, unpleating the soft structures of the cheek, with enlargement of the submaxillary glands, I do not think that it is wise or prudent to interfere with it by operation; as infiltration will have taken place more widely than the knife can reach, and speedy recurrence must of necessity ensue. So long as it is contained within this cavity, where indeed it is often impossible to ascertain, until after removal, the true nature of the affection, it may be excised, provided the glands in the neck be not greatly enlarged. If they be much implicated,

even though the walls of the antrum be not perforated, I think it is safer not to interfere, as a cure by operative procedure must be hopeless. Whenever the soft structures of the cheek are involved so as to require partial excision with the tumour, no operation should be performed; as the disease will probably have become constitutional, cannot be completely extirpated, and will speedily recur in the cicatrix. When the upper jaw on both sides is affected, as sometimes, though rarely, has happened, it is clear that the tumour cannot be removed.

EXCISION OF THE UPPER JAW.—The operation of excision of the upper jaw together with the malar bone for tumour of the antrum, was first proposed by Lizars in 1826; though Gensoul of Lyons was the first surgeon by whom the operation was actually performed, in May, 1829. Extirpation of the superior maxilla, though a serious, is not a very dangerous operation. Of 17 cases, collected by Hutchinson, in which it has been practised in the London Hospitals, it was successful in 14; and of 16 cases (10 of total and 6 of partial resection) performed by Esmarch, 13 were successful (*viz.*, 8 of the former and 5 of the latter). It may conveniently be done in the following way. The central incisor tooth on the diseased side having been extracted, the point of a bistoury should be entered opposite the external angular process of the frontal bone, and carried with a semicircular sweep into the angle of the mouth. From the upper end of this incision, a cut about one inch in length may be carried along the zygoma. Another incision is made from the nasal process of the superior maxillary bone, down to the side of the nose, round the ala, which it detaches, and through the centre of the upper lip into the mouth. The flap thus formed is dissected upwards until the margin of the orbit is reached: the soft parts are then carefully separated from the floor of this cavity, and the infraorbital nerve is dissected out and drawn upwards by a curved copper spatula, which protects it and the globe of the eye. The next step in the operation consists in the division of the bones. This may best be done with strong cutting pliers; the zygoma should be first cut across, the external orbital angle next divided, and then the internal angle cut through by putting one blade of the forceps into the nostril and the other into the orbit. The palatal arch must next be cut across by notching it deeply with a Hey's or a narrow-bladed saw, and then, passing the pliers into the mouth and nose, cutting through the line of the groove and the alveolus of the incisor that had been extracted. The whole mass having had its osseous connections separated, is depressed, drawn forwards, and readily removed by breaking down adhesions with the finger, or by the division of a few remaining soft parts with the bistoury. In the early stage of the operation, during the incisions through the cheek, there is often a good deal of hemorrhage; this may be arrested by pressure, or by the ligation of any vessels, such as the facial, or transverse facial, that bleed with great activity, and, if necessary, by the application of the actual cautery to the bones. However much the soft parts may have been stretched, no skin should ever be removed, as it will all eventually contract. In the later stage of the operation, after the removal of the tumour, there is not so much hemorrhage as might be expected; though some branches of the internal maxillary artery will require ligation. By such an operation as this, the whole of the superior maxillary and malar bones may, if necessary, be removed, and the large cavity that is left between the eye and mouth, having some lint introduced into the bottom so as to support the parts in the orbit and the cheek, may be allowed to granulate; the cheek being replaced and retained *in situ* by a few points of twisted suture evenly introduced through the line of incision in it, and in the upper lip. After cicatrization a coun-

hence, the deformity resulting from such a procedure will be far less than might at first be anticipated.

In some cases, the malar bone and floor of the orbit will be found to be sound. When this is the case they should both be left; and with this view, after the cheek has been turned up, as just described, a deep groove should be made with a narrow straight-backed saw below the orbit, directly across from the nasal process of the maxillary and the outer edge of the malar bone. The removal of the growth may now be effected by cutting through the nasal process with the forceps, and then applying the instrument to the horizontal groove made below the orbit, after which the palatal arch may be divided as already directed.

Fergusson has in some cases succeeded in removing tumours of considerable magnitude by a single incision through the cheek, from the angle of the mouth upwards and outwards; and in other cases by slitting open the upper lip in the mesial line, and then carrying the knife along the side of the base of the columna into the nostrile; by which simple incision, this distinguished surgeon has shown, sufficient relaxation of parts can be obtained to excise the greater portion of the superior maxillary bone.

DISEASES OF THE LOWER JAW.

Tumours not unfrequently spring from the lower jaw. Like those in the superior maxilla, they may either be simple or malignant. Amongst the simple, we most commonly find the *Fibro-cystic*. *Fibrous* tumours are also occasionally met with, and more rarely *Oseous* and *Enchondromatous* growths. The malignant tumours are principally of an *Encephaloid* character. These various growths frequently occur in early and middle life, and usually spring from the diploe between the two tables of which the bone is composed. They project into the mouth and on the side of the neck, forming large rounded uniform, or imperfectly lobed masses. Occasionally malignant diseases spring from the neighbourhood of the bone, and, without invading its structure, envelope it so as to give rise to an appearance of morbid implication of it.

In the *Cystic* and *Fibro-cystic Tumours* of the jaw, the growth is expanded into cysts, having more or less solid matter intermixed, partaking of the character of spulis. These cysts are of various degrees of thickness; some being thin and membranous, others having the walls partly composed of fibrous tissue, and others again having expanded bony lamellae largely entering into their composition, so that on pressure they occasionally communicate the semi-crepitant sensations peculiar to the cystic expansions of the osseous structure. The fluid contained in these cysts is a viscid liquid, usually semi-transparent, yellowish, or bloody.

Diagnosis.—In the lower, as in the upper jaw, it is of great importance to diagnose the simple from the malignant affections; as in the latter form of disease an operation is rarely justifiable, the soft tissues around the bone being usually implicated to such an extent as not to admit of removal, and consequently of the full and complete extirpation of the disease. The malignant tumours may generally be readily detected by the rapidity of their growth, by their pulpy or elastic character, and by infiltration of neighbouring parts, with implication of the submaxillary glands.

Treatment.—The treatment of tumour of the lower jaw depends in a great measure upon the character of the growth. In cystic tumour of moderate size, with thin walls and but little deposit of fibrous tissue around the cysts, the best mode of treatment consists in cutting down on the expanded portion of bone, opening the cyst by means of the antrum-perforator, small trephine,

or cutting pliers, according to its size and the thickness of its walls ; letting out the fluid contained within ; and then, by introducing a plug of lint, causing the cavity to granulate from the bottom, and gradually to contract. When the cysts are so large that they have destroyed the integrity of the bone, or when they are associated with a large quantity of fibrous tissue, so as to constitute true fibro-cystic tumours, excision of the diseased bone must be practised. This, also, is the only plan of treatment that can be had recourse to in other affections of this bone.

EXCISION OF THE LOWER JAW.—The operation of excision of a portion of the lower jaw for tumour of that bone was first performed by Dr. Deadrick of Tennessee, in 1810, and not as is generally but erroneously supposed, by Dupuytren. As the growths for which this operation is performed are usually situated between the symphysis and the angle of the bone, seldom extending beyond the middle line, the operation is generally limited to one side of the face. In some instances, however, the tumour may encroach so far that it may be necessary to remove more than the half of the bone ; and in other cases, again, though of very rare occurrence, the whole of the bone has been disarticulated.

When the tumour is of moderate size, and is situated about *midway between the symphysis and angle* of the jaw, it may be reached by making a semilunar incision of sufficient length under the lower edge of the bone, and carrying the anterior extremity of it well forward upon the chin, but not dividing, if possible, the lower lip, nor cutting into the angle of the mouth ; then dissecting up the flap thus formed, and carrying the knife cautiously along the inner side of the jaw, so as to detach the mucous membrane of the mouth and the mylo-hyoid muscle to a sufficient extent. In doing thus the hemorrhage is often very profuse : the bleeding from the facial artery is particularly forcible, the blood being thrown in a larger and stronger jet than would seem probable from the size of the vessel. This hemorrhage should be at once controlled by the application of ligatures to both ends of the bleeding artery, and to any other points from which it is more than usually abundant. Unless this be done, the after-steps of the operation will be rendered much more obscure and difficult. One of the teeth on each side of the tumour having been previously drawn, the jaw must now be deeply notched through their alveoli into its base with a narrow strong-backed saw, and cut through with pliers, or completely divided with the saw. After the fragment of diseased bone, with the attached tumour, has been removed, and all bleeding vessels have been secured, the flap of cheek should be laid down smoothly, and retained *in situ* by means of hare-lip pins. Occasionally the dental artery in the cut jaw gives trouble ; the hemorrhage from this source may be checked by the application of a piece of solid perchloride of iron. The patient must be fed with slops which should be sucked in through a tube. At a later period, when cicatrization is well advanced, the teeth should be tied together with strong silver wire ; or a silver cap should be fitted upon the teeth of the two portions of bone that are left, and attached by an elastic spring to another silver cap put on those of the upper jaw, so as to prevent the displacement that would otherwise occur in the smaller fragment. Union takes place after a time by fibrous tissue, which becomes sufficiently dense to make the jaw strong and useful.

In those cases in which the tumour *encroaches upon the angle and ramus* of the jaw, it is usually better to remove the bone at the articulation on the affected side, for, if the articular end including the coronoid process be left, it will be displaced forwards and upwards by the action of the temporal and external pterygoid muscles, and be a source of much inconvenience and ulti-

tation to the patient, unattended by any corresponding utility. In these cases, the removal of one lateral half of the jaw will consequently be required, and the operation may be performed in the following way. The point of a strong bistoury or scalpel should be entered immediately behind the articulation, carried down the posterior margin of the ramus behind the angle, and under the body of the bone beyond the anterior limits of the tumour, where it must slope gradually upwards, terminating at some distance from the lips, which should not be encroached upon; the convex flap thus formed is dissected up, and the facial artery and any other branches requiring ligature tied. The knife is then carried behind the jaw in front of the tumour, and, one of the incisor teeth having been extracted before the operation commenced, a saw should be applied to the bone in this situation, and its section finished by means of the cutting-pliers; the surgeon then dissects under and around it; in this situation a scalpel, curved on the flat, will be found useful, the edge of the knife being kept close to the bone and tumour. When he has cleared the tumour and ramus, he depresses the body of the bone forcibly with his left hand, in order more readily to divide the attachment of the temporal muscle to the coronoid process. This having been done, the only part left is the disarticulation, which is best effected by opening the joint from the front, whilst the bone is well depressed and twisted somewhat outwards, the edge of the knife being kept close to its neck, scraping the bone so as, if possible, to avoid wounding the internal maxillary artery, when, any remaining attachments having been cut through, the disarticulation is effected. In depressing the bone to reach the temporal muscle and the joint, care must be taken not to use too much force, lest it happen that the ramus give way, having been weakened by the disease; this accident would produce a good deal of trouble in removing the fragment left behind, which can only be done by seizing it with necrosis forceps, thus dragging it forwards, and then dividing the muscle and capsule. Should the internal maxillary artery have been divided, it must be ligatured, or the termination of the external carotid, where the vessel divides into the temporal and internal maxillary, tied: any other branches that bleed will necessarily also require the ligature. The cavity, having been lightly filled with lint, should then be left to granulate; the cheek being laid down and attached along the line of incision by hare-lip pins and twisted sutures. A kind of fibrous tissue forms in place of the jaw that has been removed, and comparatively little deformity results. When the disease of the bone extends *beyond the symphysis*, a thick ligature should be passed through the end of the tongue, which must be drawn forwards by an assistant, lest on the division of the insertion of its muscles into the lower jaw it be forcibly retracted into the pharynx, and thus threaten or even occasion suffocation, as has happened to surgeons of eminence both in France and in America.

For necrosis of the lower jaw, and the operations for it, see p. 868.

CHAPTER LVII.

DISEASES OF THE MOUTH AND THROAT.

DISEASES OF THE TONGUE.

TONGUE-TIE.—Infants and even adults are said to be *tongue-tied*, when the frænum linguae is shorter than usual, causing the end of the tongue to be depressed and fixed, so that it cannot be protruded beyond the incisors. If this malformation be considerable, suckling and distinct articulation may be interfered with; and then division of the fold becomes necessary, which may readily be done by snipping it across with a pair of round-ended scissors. In this operation, the risk of wounding the ravine arteries that is sometimes spoken of, may be avoided by keeping the point of the scissors downwards towards the floor of the mouth.

PROLAPSUS OF THE TONGUE has occasionally been met with, either as a congenital or an acquired condition; it has been described by Lassus and Crosse as consisting either in a want of power in the retractor muscles, or in hypertrophy of the organ. In this condition, the tongue lolls out of the mouth, is greatly swollen, of a purplish colour, but somewhat dry, with constant dribbling of saliva. If the swelling have existed for a long time, it may give rise to deformity of the teeth, and of the alveolus of the lower jaw, which is pushed forwards. In the *Treatment* of this affection, little can be done unless it be excessive and permanent, when excision of a portion of the tongue by knife or ligature may be required. In children, the ligature would certainly be the safest, as excision might be followed by abundant hemorrhage, not very easy to arrest.

GLOSSITIS is a rare affection, more particularly when it occurs idiopathically; most commonly it results from profuse and injudicious salivation. In this disease the tongue is greatly infiltrated with serum and blood, becoming immensely swollen, so as to hang out of the mouth, with profuse salivation and inability on the part of the patient to swallow or speak, with perhaps a threatening of suffocation.

The *Treatment* is as simple as it is efficient; it consists in making a long and free incision along the dorsum of the tongue on each side of the raphe, which gives free and immediate relief by the escape of blood and infiltrated fluids. I have seen a patient, who was nearly suffocated by the immense size of his tongue, relieved at once, and get nearly well in the course of a few hours by such incisions. Purgatives, especially of a saline character, are also useful; but these cannot be administered until after the swelling has been relieved in the way just mentioned.

ABSCESS OF THE TONGUE, though rare, occasionally occurs. I have seen several instances of it. The abscess forms a small deeply seated elastic but firm tumour, which sometimes feels slightly moveable and presents no superficial discoloration. A boy was brought to me some time ago with an elastic tumour of slow growth, and of about the size of a small plum, situated deeply in the centre of the tongue; on puncturing it, about half an ounce of healthy pus was let out, after which the cyst speedily closed.

NEVUS and **ANEURISM BY ANASTOMOSIS** is but rarely seen in the tongue, and when met with would require to be treated on the same principles that guide us in the management of that disease elsewhere. A very

remarkable instance of an erectile tumour of a nævoid character affecting the tongue came under my care, in which the whole of the free extremity of the organ was implicated in the morbid growth, presenting a thin club-shaped end, which protruded between the teeth and lips of the patient, a girl about three years old. In this case Mr. Image, of Bury St. Edmunds, had very judiciously arrested the activity of the disease, and had produced consolidation of the mass by the introduction of setons, which were worn for some months; and, when the child subsequently came under my care, the chief inconvenience that existed resulted from interference with speech, and the deformity occasioned by the hypertrophied and elongated organ. By means of the *écorseur* I removed all the redundant tissues, and so reduced the tongue to its normal length and breadth.

MORBID CHANGES OF THE EPIDERMIC COVERING of the tongue sometimes occur: amongst the most remarkable of these is *Psoriasis*. In this affection the tongue is indurated, shrivelled, and dry, having cracks upon its surface, with patches of a dead-white colour, and irregular in shape, varying in size from that of a split-pea to an inch in diameter; this condition, exactly resembling psoriasis of the palms of the hands, may occur with or without scaly disease of the general integument. I have seen it in both conditions, and have always found it a most difficult affection to treat. The preparations of arsenic with Plummer's pill and sarsaparilla, have, however, appeared to afford the best results. In some instances it is evidently of syphilitic origin; and then it requires to be treated on the general principles that guide us in the management of the constitutional forms of that disease.

The surface of the tongue occasionally assumes a *Glazed and Warty Character*, as if covered with a layer of boiled sago; the mucous membrane being cedematous, elevated, and papillated, but at the same time glassy and semi-transparent, and without induration. This condition, which usually arises from syphilis, requires the constitutional treatment of that disease.

FISSURES OR CRACKS not uncommonly appear upon the side of the tongue, usually opposite the molar teeth, sometimes dependent on irritation of stumps, but not unfrequently on dyspepsia. These cracks may in some depraved states of the constitution extend rapidly, eroding away a considerable portion of the side of the organ in a short time, so as to leave a large and deep sloughy cavity with much dusky inflammation around it, with great fetor of the breath, and a copious discharge of saliva, which trickles out of the corners of the mouth; the patient being usually destroyed in from three to six months, by the irritation of the discharges, the inability to take food, and the supervention of hemorrhage.

Treatment.—This disease, which is a combination of sloughing and ulceration, is best treated in the early stages by the application of leeches beneath the jaw, and the use of chlorinated gargles, with a moderately antiphlogistic regimen; as it advances, the internal administration of arsenic is useful in some cases, with the application of the balsam of Peru, either pure or diluted with the yolk of egg, and the employment of gargles composed of the chlorides and the tincture of myrrh.

SYPHILITIC TUBERCLE is not unfrequently met with in the tongue, as one of the advanced symptoms of constitutional syphilis, forming an indurated irregularly circumscribed mass, of a round shape, situated deeply in the substance of the organ, or towards the centre of the tip. The surface covering the tubercle is of a dusky red or coppery colour; it rarely runs on to ulceration, though rhagades and fissures occasionally form around it; there is no fetid discharge, and no destruction of the organ.

The *Treatment* consists in the administration of small doses of bichloride of mercury in sarsaparilla, under which the tubercle will rapidly disappear.

CANCEROUS AND CANCEROID DISEASES.—These affections usually commence as epithelioma with tubercles, or fissures, more rarely as scirrhus in a solid mass in the body of the organ; most commonly the disease is situated at the sides, but occasionally the tip is affected. If it appear as a tubercle or warty growth, it is usually flat, indurated, and of a purplish-red colour, gradually running into ulceration; if with a fissure, thus from the commencement has an indurated base, a foul surface, and an everted edge. As the ulceration extends, a chasm with ragged sides, a sloughy surface that cannot be cleansed, and a widely indurated base, gradually form; there is great fetor of the breath, profuse salivation, and, as the disease progresses, implication of the mucous membrane and of the structures of the floor of the mouth, and of the submaxillary or sublingual glands, takes place. The lymphatic glands under the jaw usually become involved at an early period, but I have known the disease to exist for a year or two without their becoming implicated. Cachexy at last supervenes, and the patient dies from the conjoined effects of exhaustion, irritation, and poisoning of the system. In the majority of instances, the disease assumes an *Epithelial* form, but tumours of the tongue may occasionally occur, presenting all the characters of *Scirrhus*. In one instance I have seen cancer of the tongue assume a truly *Encephaloid* character: it was a case in which the disease had twice been removed, and, recurring a third time, assumed the character of a large soft fungating growth, with rapid implication of the floor of the mouth and maxillary glands, death speedily occurring from exhaustion.

Diagnosis.—The diagnosis of these various forms of disease of the tongue is important. The *foul and sloughing ulcer* may be distinguished from all others by the rapidity of its progress, its eroding action, and the absence of all induration at its base. *Syphilitic ulceration*, with an indurated base, commonly closely resembles cancer of the tongue; so closely, indeed, that it is only with great difficulty that the diagnosis can be effected. This, however, may generally be accomplished after a time by observing that the syphilitic ulcer is elongated, irregular, and does not rapidly extend, while the cancerous ulcer is of a circular shape, has eroded edges, and spreads with considerable rapidity. The influence also of treatment will after a time throw light upon the nature of the disease; and the scrapings of the cancerous ulcer, when examined under the microscope, will always reveal its true character.

The diagnosis between the *syphilitic* and the *cancerous tubercle* is most important; here the duration of the disease and the co-existence of constitutional syphilis must be taken into account. It is also of much moment to attend to the situation of the tumour; the syphilitic tubercle being almost invariably met with deeply in the substance of the organ, whilst the cancerous growth is commonly seated at its edges or tip.

Treatment.—In the treatment of cancer of the tongue, therapeutic means are utterly useless. No measures hold out any chance of recovery to the patient, except the removal of the diseased structure; and this it is by no means easy to accomplish, as the cancerous infiltration extends much further than at first appears; passing deeply between the muscular fasciculi into the root of the tongue. This may be effected by either the ligature or the knife. No operation is of any use unless it be carried very wide of the disease, and it should be done as early as possible, before glandular or constitutional infection has come on.

When the free anterior portion only of the tongue is diseased, or when it

is only superficially affected at its back part, the morbid structure may readily and safely be excised; the hemorrhage that ensues, though abundant at the time, usually ceases of itself, or may be arrested by the ligature of the bleeding points, and by the introduction of ice into the mouth. When the organ is more extensively diseased, it has been proposed to divide the lower jaw, and thus to get a view of the whole of the tongue, and to remove as much as proper, treating afterwards the section in the bone as a fracture of it. When, however, the tongue is very deeply diseased, excision is objectionable, as the hemorrhage that follows may be so considerable as to be stopped with difficulty, and, indeed, to require the application of the actual cautery for its arrest. In these deep cancerous affections of the tongue, also, there is usually great enlargement of the submaxillary glands, with infiltration of the floor of the mouth and of the neighbouring soft parts to such an extent as to render it impossible with safety or advantage to excise the diseased mass.

Ligature is the plan to which recourse is usually had; and it is indeed, except where the tip is alone involved, preferable to excision. But, though there is no risk of hemorrhage when this means is used, it is not without objection, on account of the painful nature of the process and its tediousness. Hilton has removed the first objection by proposing and practising section of the gustatory nerve prior to the application of the ligatures. This operation may be done by drawing the tongue forwards and dividing the mucous membrane and submucous tissue vertically for three-quarters of an inch, opposite the molar teeth, over the hyo-glossus muscle, and across the upper portion of the sublingual gland; much venous bleeding usually occurs, which embarrasses the search for the nerve, yet with a little dissection this may be exposed and divided, when sensation will cease in the whole of that portion of the tongue which is anterior to the line of incision. By means of the ligature any portion of the tongue, however deeply seated, may be securely strangled. For the purposes of this operation strong thick saddler's whipcord is the best, as it does not readily cut through the soft and brittle tissue of the organ, which will be the case if the small compressed cord usually sold by the instrument-makers be used.

In removing cancer of the tongue by ligature, the patient should be conveniently seated opposite a strong light. The surgeon then passes a stout doubled silk thread through the tip of the tongue, near the raphe, but somewhat to the side on which he is about to operate; by means of this thread, an assistant draws the organ out of the mouth and keeps it under control; a wooden wedge is next placed between the teeth of the upper and lower jaws, on the side opposite to that on which the operation is to be performed, and the ligature is then passed by means of an ordinary *nævus-needle*, or, what is often more convenient, a corkscrew needle curved on the side as well as to the point (Fig. 325). In many cases, the plan

Fig. 325.—Corkscrew Needle.

described for ligaturing flat *nævi* will be found the most convenient mode of passing the whipcord round the cancer of the tongue (Fig. 326). In whatever way the ligatures are applied, care should always be taken to pass

them through the healthy tissue of the organ wide of the disease, and they should then be tied very tightly, so as to strangle the mass effectually. Great swelling of the tongue, followed by profuse salivation and some

Fig. 326.—Ligature applied to Cancer of Tongue.

fetor of the breath, attend this operation: but the mass, if properly constricted, will slough away in a few days, leaving a large gap that readily fills by granulation. When the disease exists so far back in the tongue that it cannot readily be reached from the

mouth, Cloquet, Arnott, and others have successfully strangled it by making an incision in the hyoid region, between the genio-hyoid muscles, forcing the ligatures by means of long needles through the base of the tongue, and then drawing them tight through the aperture in the neck, so as effectually to constrict the diseased mass.

Regnoli has successfully extirpated large portions of the tongue for cancerous disease of the back of the organ, by making an incision of a semi-lunar shape, along the line of the lower jaw from one angle of the bone to the other; thus opening into the cavity of the mouth through its floor, then making a vertical cut through the centre of this, from the hyoid bone forwards, clearing the parts by a little dissection, and drawing the tongue through the opening down upon the anterior part of the neck, where the diseased structures may be ligatured or excised (Fig. 327). The wound is

Fig. 327.—Regnoli's Operation for removing Cancer of the Tongue.

then closed and united in the usual manner. By this means the surgeon can reach portions of the organ that cannot be got at in any other way. If more space be required, a vertical incision may be made through the centre of the lower lip down to the hyoid bone, the symphysis of the lower jaw cut through with a chain-saw, the mylo-hyoid muscles separated, the tendinous attachment of the genio-hyoid and genio-hyo-glossi muscles divided, and the larynx drawn forwards, when the whole of the organ down to its hyoid attachments will be exposed, and may be removed by the knife or *écarateur*.

This operation, which has hitherto proved fatal in this country, has been successfully performed in two

instances by Fiddes of Jamaica, who has in this way removed the tongue close to the hyoid bone. By dividing and ligaturing the lingual artery, first on one side and then on the other, all dangerous hemorrhage was avoided. After recovery, the patients were found to possess a fair amount of articulation.

The *Ecraseur* has been successfully used by Chassaignac in removing tumours of the tongue that could not otherwise be extirpated. In such

Operations two or more instruments are commonly required, which, as *Thomassinac* represents (Fig. 328), must be passed through the substance of the tongue in opposite directions, so as to isolate and detach the diseased portion of the organ.

In removing large portions of the tongue by means of the *écraseur*, the instrument should be worked very slowly, in order that time may be given for the vessels to contract; but, even with this precaution, hemorrhage will usually occur from the larger arteries to such an extent as to require the application of the ligature.

When, however, the floor of the mouth is implicated in the morbid action, nothing should, I think, be attempted; as it is impossible to extirpate the whole of the disease, and partial removal of it will only be followed by rapid recurrence and increased activity of development. I do not think that slight enlargement of the submaxillary glands should be any bar to the operation, provided the disease be limited, and the constitution good. If enlarged, the glands may be excised together with the disease of the tongue; or, if they be not of very considerable size, they may be left, when they will perhaps subside without the necessity of operation, as their enlargement may probably be dependent upon simple irritation; should they continue indurated, they may readily be removed at a subsequent period.

ENCYSTED, FATTY, and EREMITAL TUMOURS are met with in the tongue, and underneath it in the floor of the mouth.

They require extirpation by the ligature, or enucleation with the handle of the scalpel or fingers, according to their situation and size; and for these irregular operations no special directions can be given. In removing such tumours as these, when situated under or by the side of the tongue, the knife must necessarily be used with much caution. It must, however, be borne in mind that, if these growths cannot be reached from the inside of the mouth, they may be got at by incision through the mylo-hyoid region, where there is but a slight thickness of soft parts between the surface and the floor of the mouth.

Ranula is perhaps the most remarkable of the buccal tumours. This disease occurs under two forms.

1. A globular swelling, semi-transparent, evidently containing fluid, and often attaining the size of a walnut or a pigeon's egg, situated under the tongue, pushes this organ upwards and backwards, and consequently interferes with deglutition and speech (Fig. 329). The walls of the cyst are usually thin, with small vessels ramifying on them; its contents are glairy and serous. This form of *ranula* is usually said to be a dilatation of *Wharton's duct*; but it certainly appears to me that there is no proof of

Fig. 328.—*Écraseur* applied to Cancer of Tongue.

Fig. 329.—*Ranula*.

the disease being of this nature, and, indeed, it is not very easy to understand how so small a duct can be dilated to so large a size as is occasionally attained by these tumours, which seem, in some cases at least, rather to consist of distinct cystic formations, such as commonly occur in connection with other secreting glands.

The *Treatment* of this form of ranula consists either in passing a seton through its walls, so that contraction may take place on this; or else in the excision of a large portion of the anterior wall of the cyst, the remainder contracting, until it at last becomes obliterated.

2. Besides the ordinary form of ranula, an encysted tumour, partaking of this character, is occasionally met with, lying above the mylo-hyoid muscle, between it and the buccal mucous membrane. It projects, however, more distinctly into the neck than into the mouth, and thus forms a large tumour under the angle and body of the lower jaw, soft or elastic, and semi-fluctuating, occupying, perhaps, all the space between the lower jaw and the hyoid bone on one side. It attains the size of an orange. In a case of this kind in a lad of twenty, under my care, the contents of the tumour, which closely resembled cream-cheese in character, were found to be composed of well-formed epithelial scales and much fatty matter.

Treatment.—Such tumours are best treated by making a free opening into them from the mouth, squeezing or spooning out their contents, stuffing the cavity with lint, and allowing it to granulate and contract. If an attempt be made to extirpate them from without, the profuse and perhaps dangerous hemorrhage, the firmness with which the cyst-wall is incorporated with surrounding parts, and the danger attendant on the free use of the knife in the neighbourhood of such important parts as lie between the mylo-hyoid muscle and the base of the tongue, will render such an operation not only unsatisfactory, but hazardous.

DISEASES OF THE UVULA AND TONSILS.

ELONGATION OF THE UVULA.—The uvula occasionally, becoming elongated and hanging down into the pharynx, so as to touch the epiglottis and sensitive mucous membrane in its neighbourhood, gives rise to great irritation

of the fauces, and to a tickling or spasmodic cough, which can only be cured by removing the pendulous body. This little operation may be readily done by seizing the end of the uvula with a pair of polypus-forceps, and snipping it across near the root with a long pair of scissors. It is better not to remove the whole of the uvula. If this be done, throat-irritation is apt to continue. I have been most satisfied with the result of those cases, in which a stump from a quarter to the third of an inch in length has been left. For some years I have been in the habit of using a pair of "vulsellum-scissors" (Fig. 330),

Fig. 330.—Vulsellum Scissors.

Fig. 331.—Polypus Forceps.

which I have had constructed for the purpose, by which the uvula is cut off at the same moment that it is seized, thus rendering the operation easier.

and less irritating to the patient. A very ingenious instrument of American invention, consisting of a pair of forceps and scissors combined, may be employed with the same view; viz., by closing the handles of this instrument the uvula is first seized, and is then immediately cut across (Fig. 331).

TONSILLITIS.—The tonsils are not unfrequently the seat of disease, becoming inflamed or permanently enlarged. When inflamed, they become swollen and red, with much pain in the side of the neck and ear, increased by any attempt at swallowing; there is usually rather a profuse secretion of saliva, and a good deal of swelling under the angles of the jaws; the tongue is much coated with thick pasty mucus, and the voice is thick and nasal. The *Treatment* consists in the application of leeches under the jaw, of fomentations, the inhalation of the steam of hot water, and low diet, which need scarcely be enforced, on account of the difficulty and pain in swallowing. If the mouth can be opened, much relief may be given by scarifying the tonsils with a probe-pointed bistoury; and, if abscess form, it should be opened early, which may most readily be done with a gum-lancet.

HYPERTROPHY OF THE TONSILS.—The tonsils often become chronically indurated and enlarged, sometimes as the result of repeated attacks of inflammation of these parts, but in the majority of instances independently of any inflammatory mischief; though, when once enlarged, these organs are constantly liable to inflammatory attacks. Hypertrophy of the tonsils most commonly occurs as a strumous disease in scrofulous children, who have a tendency to congestion of the mucous membrane of the nose, and to enlargement of the lymphatic glands of the neck. In such cases as these the enlargement of the tonsils may gradually subside as the child grows older and stronger; and I think it well not to be in too great a hurry to excise the tonsils in young children, but rather to adopt a course of constitutional treatment with the view to the improvement of the general health and strength, by means that are ordinarily had recourse to in the management of strumous affections; the internal use of iron and the local application of the tincture of iodine or of nitrate of silver being occasionally serviceable. In the majority of instances, however, the disease will not be influenced by any therapeutic means that may be adopted: and as the enlargement, continuing or increasing, gives rise to difficulty in respiration, and thus interferes with the due arterialisation of the blood in the lungs, and impairs the child's speech, it becomes necessary to remove the projecting portion of the enlarged growth. This may most conveniently be done by means of the ordinary tonsil-guillotine; the ring of the instrument being passed over the tumour, the cutting blade is pushed forwards, and thus a slice of the projecting part of the growth is removed. In some cases not a little difficulty is experienced in getting the tonsil fairly into the ring of the

Fig. 332.—Tonsil guillotine, with Prang.

instrument, more particularly if the child be unruly; this may be obviated by drawing it through with a vulsellum or double hook, and indeed in some

of the machines sold for the purpose a kind of prong is attached, which, being fixed into the tonsil, draws it forwards before it is sliced off (Fig. 332). In performing this operation, especially in children, it is most convenient for the surgeon to stand behind the patient, as he can thus look better into the mouth, and has more command over the head. Should a guillotine not be at hand, the tonsil may be removed by seizing it with a vulsellum, drawing it forwards, and then taking off a slice with a probe-pointed bistoury, the base of the blade of which should be wrapped round with a piece of plaster, to prevent its wounding the tongue. In excising the tonsil in this way, care must be taken to cut downwards and inwards towards the mesial line, and on no account to turn the edge of the knife outwards, lest the internal carotid artery be endangered. The hemorrhage that follows this operation is usually very trifling; but I have known it to be sufficiently abundant to endanger the patient's life. In such cases, ice and gallic acid will usually arrest the bleeding. In one case to which I was called, I found a gargle of spirits of turpentine suspended in mucilage effectual after all other means had failed.

DISEASES OF THE PHARYNX.

INFLAMMATION OF THE PHARYNX of a diffuse erysipelatous character, with low fever, not unfrequently occurs; it is best treated by the application of a strong solution of nitrate of silver, the use of emollient gargles, and the internal administration of ammonia, with bark, stimulants, and support. If it have a tendency to run into sloughing action, the internal administration of the mineral acids, with bark and stimulants, the nitrate of silver lotion and chlorinated gargles are useful. Sometimes abscess forms in the substance of the velum, and then requires to be opened with the knife that is delineated at page 419.

ABSCESS occasionally forms in the cellular tissue behind the pharynx, the posterior wall of which is consequently pushed forwards so as to occlude the posterior nares, giving rise to a peculiar nasal intonation of voice; it also may interfere with breathing by pressing upon the upper part of the larynx. This kind of abscess is often connected with disease of the bones at the base of the skull, or of the upper cervical vertebrae. In many cases, if left to itself, it would burst through the mucous membrane into the mouth; but in others it comes forwards under the sterno-mastoid muscles into the forepart of the neck. By exploring the pharynx with the finger, which may readily be done, tension and fluctuation through its posterior wall may easily be made out.

In these cases the *Treatment* simply consists in letting out the matter by puncturing the tense membrane covering it. This may be done by means of a sharp-pointed bistoury properly protected, or the ordinary abscess-knife. The pus let out is usually offensive, even though the bones be not affected.

TUMOURS are occasionally met with in the postpharyngeal cellular tissue, giving rise to the same swelling, difficulty in respiration and deglutition, and lateral projection, as occur in abscess of this region. These growths are mostly *cancerous*, and speedily prove fatal. *Polyps* in the pharynx usually come down from the nasal cavities, but sometimes spring from the inside of this canal on one or other of its margins. They are usually, when truly pharyngeal, of a malignant character, and grow with great rapidity. The uses of the part are necessarily interfered with, and death may eventually result from obstruction to deglutition and respiration. *Epilethoma* of the pharynx has occasionally been met with. This form of the disease, which is of rare occurrence, does not differ from similar growths elsewhere.

STRICTURE OF THE ŒSOPHAGUS.

All diseases of the œsophagus have a tendency to constrict and eventually to occlude its passage, and hence are commonly described as *Strictures* of it. In some instances the constriction of the œsophagus may be of a purely *nervous* or *spasmodic* character; but in the majority of instances it is the result either of fibrous or cancerous degeneration of the walls of the canal, and is then termed the *organic* stricture. The simple non-malignant or fibrous stricture in most instances eventually degenerates into epithelioma, and hence appears to be more rare than it in reality is, as it is seldom met with after death in its undegenerated form. Scirrhus and œncephaloid growths may, though rarely, develop in and around the œsophagus.

The great feature of œsophageal stricture is difficulty of deglutition; but dysphagia may arise from many causes besides œsophageal stricture. Hence its diagnosis is in the highest degree important.

CONDITIONS PRODUCING DYSPHAGIA INDEPENDENTLY OF STRICTURE.—

There are at least eight different conditions met with in the neck and chest capable of giving rise to dysphagia by compressing the œsophagus, independently of any stricture of that canal.

1. *Tumours connected with the Pharynx.*—Putting out of consideration tumours of the tonsils, which would always be readily discovered, *polypus* of the pharynx may hang down and offer obstruction to the passage of food. In all polypoid growths connected with the pharynx (which are exceedingly rare) the nature, connections, &c., of the growth may be made out by drawing the tongue well forward, keeping it fixed with the tongue-spatula, and passing the finger well down behind the root of the organ; the pharynx can thus be explored, even below the root of the epiglottis, without much difficulty. Abscess may exist between the posterior wall of the pharynx and the spine, possibly arising from caries of the cervical vertebrae; or a *postpharyngeal tumour*, as, for instance, a carcinomatous growth, may be developed from the bodies of the vertebrae, and push the pharynx forwards. The eye is often deceived in these cases, failing to detect the existence of an enlargement at the back of the pharynx; but the finger readily recognises it. In the case of abscess there is fluctuation, and the dysphagia will be removed by opening the abscess and letting out the contents; and the solid or semi-solid and soft, or other feel of a tumour in this situation will lead to a very probable guess as to its nature.

2. *Morbid Conditions of the Larynx.*—Œdema about the back of the epiglottis, or chronic œdema, ulceration, and thickening of mucous membrane there, or œdema about the rima glottidis, may give rise to a tendency for liquids to pass into the air-passages, and thus occasion a serious impediment in swallowing, the difficulty being attended with a feeling of spasm and suffocation. By passing the finger down behind the root of the tongue, the state of parts can often be felt; but the combination of dysphagia with a suffocative fit, and these probably associated with laryngeal cough, are the chief points to be attended to in the diagnosis.

3. *Tumours in the Neck outside the Œsophagus.*—Enlarged glands or a carotid aneurism, developing posteriorly, as has been known to occur with the internal carotid artery; or a tumour connected with the thyroid body, tightly bound down by the sterno-mastoid and fascia, may, by pressing on the œsophagus, give rise to dysphagia. In all cases where that symptom is complained of, the neck should be examined carefully for tumours, which will

generally be very readily detected, especially where the difficulty has existed for some time, and the person has become much emaciated from deficient nourishment.

4. *Aneurism of the Innominate Artery.*—When this disease has risen into the root of the neck it is easily recognisable; but in certain cases it develops first in a direction backwards, and then one of the earliest symptoms is dysphagia. Indeed, the patient may suffer but little from any other symptom, and may apply to the surgeon for relief from it alone, quite unconscious of the existence of any serious disease. The diagnosis will be effected by careful attention to the symptoms described at pp. 619—21. In such a case, much danger might be incurred by at once putting an instrument into the œsophagus, under the impression that stricture existed; for the point of the bougie, or whatever instrument might be used, might perforate the sac of the aneurism, and so give rise to instant death.

5. *Aneurism of the Aorta*, whether of the fusiform or sacculated variety, may give rise to difficulty of deglutition by pressure on the gullet. In this case, also, there is great danger of the aneurismal sac being pierced by an instrument passed down for the purpose of ascertaining the existence of stricture. The presence of the symptoms of intrathoracic aneurism, described at pp. 616—7, will determine the diagnosis.

6. *Intrathoracic Tumours*, such as enlarged bronchial glands, cancerous and other tumours, may be developed from the thoracic spine into the posterior mediastinum, and so compress the œsophagus. In such cases the diagnosis is very difficult. It is difficult enough to determine the existence of a tumour, but still more so to distinguish it from an aneurism undergoing consolidation; but dulness on percussion, and dyspnoea with dysphagia, together with fixed pain in or to one side of the spine, with neuralgia down the arms or up the side of the head, and a varicose condition of the superficial veins of the chest, are the signs on which we place our chief reliance in diagnosing the existence of a tumour. Indeed, in the diagnosis of aneurism of the aorta and of mediastinal tumour, I look upon the combination of dyspnoea with dysphagia, and fixed wearing pain between the shoulders, as of the greatest importance.

7. *Dislocation of the Sternal End of the Clavicle Backwards*, whether merely a simple dislocation, or produced in consequence of excessive curvature of the spine, may give rise to difficulty of deglutition. Of the latter kind there is at least one case on record, which is narrated by Sir Astley Cooper, in which the sternal end of the clavicle by its pressure so obstructed the passage of food, that the patient was brought into a condition of extreme danger. The surgeon, under whose care the patient was, very skilfully and creditably sawed through and detached the sternal end of the clavicle, and thus relieved his patient from the imminent danger in which she was placed.

8. *Impaction of a Foreign Body in the Gullet*—If a man swallow such a thing as a piece of mutton bone, or the settings of artificial teeth, it generally lies across the gullet in such a manner as to be easily felt by the surgeon on passing a probang; but there are other cases in which a foreign body becomes so lodged in the canal as to escape detection and removal. Some years ago I was requested to see a patient who was said to have swallowed a piece of gutta-percha. He had, it appeared, in consequence of having lost several teeth, endeavoured to construct an artificial masticatory apparatus for himself, which had become loose, and he had accidentally swallowed it. A few days afterwards, finding that deglutition continued difficult, he consulted a very able surgeon, who carefully examined him; but, not detecting any foreign body, he considered that the piece of gutta-

percha had passed into the stomach, and that the oesophagus had been scraped by it in its passage down. Inability to swallow solids came on. I saw him months afterwards. The question then was whether the foreign body was still impacted in the oesophagus, or whether the symptoms arose from damage inflicted on that tube. I examined the oesophagus most carefully, but failed, as other surgeons had previously done, to discover the existence of any foreign body. I thought that the oesophagus had been injured in some way, and that probably epithelioma was developing itself, and would, sooner or later, prove fatal. One day, while at dinner, the patient suddenly vomited a large quantity of blood, and fell down dead. On examination after death, we found that the piece of gutta-percha had formed for itself a bed in the wall of the oesophagus, lying parallel with the inside of the tube, and that the ulceration of the mucous membrane caused by its presence had opened some oesophageal vessel—which, we could not ascertain (it was not, however, either the carotid artery or the jugular vein); thus giving rise to the copious and sudden hemorrhage which had caused the patient's death. The surface of the gutta-percha which looked into the oesophagus, being constantly covered and smoothed over by mucus, and being protected, as it were, by a rim of swollen mucous membrane all around it, had allowed the probe to pass easily without its presence being detected.

These, so far as my experience goes, are the eight conditions which are likely to simulate stricture of the oesophagus; and such are the points to be attended to in the diagnosis of these affections from each other. With regard to their diagnosis from stricture, the process is rather a negative than an affirmative one, proving the absence of tumour, aneurism, &c. The conclusion that the difficulty in deglutition can arise from no other cause than stricture is arrived at by a process of exclusion; and the situation and extent of the stricture are ascertained by exploration with a gum-elastic catheter or bougie.

FORMS OF STRICTURE.—There are three forms of this affection which it is necessary to distinguish from each other, inasmuch as they differ greatly in the mode of treatment, and in the ultimate result. These are—1. *Hysterical or Spasmodic Stricture*; 2. *Fibrous Stricture*; 3. *Carcinomatous Stricture*.

1. *Hysterical or Spasmodic Stricture* is met with chiefly in young females under twenty-five, though it may occur in much older persons of the hysterical temperament. The stricture is generally high up in the pharynx, rather than in the oesophagus; being produced by the contraction of the constrictor muscles of the pharynx. The dysphagia is intermittent; when the patient's mind is allowed to dwell long on the affection, and she becomes anxious about it, then the difficulty is greatly increased; whilst at other times, when her thoughts are diverted from it, food passes easily. It will be found also, in these cases, that on attempting to pass a probing or large bougie, its progress will at first be resisted, but, by patiently and gently pressing down upon the stricture, the instrument will soon pass easily.

2. *Fibrous Stricture.*—There are two kinds of organic stricture of the oesophagus—namely, the simple and the malignant—between which the diagnosis is often very difficult; because strictures originally fibrous sometimes degenerate into or assume a malignant form; while others sometimes become fibrous from the first, and others, again, are originally carcinomatous. Generally, on passing an instrument, we find that in the simple or fibrous stricture it passes smoothly, and gives no sensation of roughness, no feeling of lacerating its way, or as if it were passing over an ulcerated surface, no blood follows its withdrawal, and the patient does not bring up pus, or vomit

and blood, though there may be copious mucous discharge. There is no material enlargement in the neck, no swelling of the cervical glands, no sign of the cancerous cachexia.

3. *Carcinomatous Stricture*.—In the malignant or carcinomatous stricture the instrument seems to pass over a rough and ulcerated surface, its introduction is followed by blood, and the patient coughs up blood, or blood and pus, mixed often with shreds of tissue—conditions all indicating a loss of substance (Fig. 333). There is, also, generally, an ovoid or elongated swelling at the root of the neck; the neighbouring glands may be affected; there may be cancerous tumours elsewhere; and the symptoms of the cancerous cachexia may be present. A fibrous stricture may, however, and very commonly does, degenerate into a malignant one—into epithelioma, though, perhaps, not into scirrhus or encephaloid.

Fig. 333.—Carcinomatous Stricture.

CAUSES.—The causes of stricture of the oesophagus are very obscure, indeed inappreciable in the majority of cases. The occurrence of the *hysterical stricture* may, in some cases, be traced to the irritation of a fragment of food, or some pointed body, as a fish-bone, lodging in the throat of a female predisposed to nervous complaints. The *simple fibrous stricture*, when it occurs, may be referred to the cauterisation of the interior of the oesophagus by the accidental or suicidal swallowing of some corrosive liquid, acid or alkaline, by which

the mucous membrane is destroyed, charred as it were, and a cicatrix as of a burn forms. The special causes of cancer of the oesophagus are not known.

TREATMENT.—The treatment of the stricture of the oesophagus will depend upon its nature. In the *hysterical variety*, the occasional introduction of a full-sized oesophagus-bougie, the application of belladonna to the neck, and antihysterical treatment generally, iron, aloetics, douches, and diverting the patient's mind from her malady, are the means to be employed. In such cases, Dr. Garrod has very advantageously employed large doses of *assafoetida*.

The treatment of *organic stricture* is more difficult. In it care should be taken that the patient is principally kept upon nutritious slops, or upon meat that has been well chopped up, as larger fragments are apt to become impacted at the seat of constriction. The difficulty in deglutition will, however, gradually increase, the patient being unable to swallow solids, then being reduced to pulpy food, and at last to liquid. After a time he will not even be able to swallow these; and then it becomes necessary for the surgeon to feed him by the introduction of a gum-elastic catheter through the stricture, and the injection of a sufficient quantity of liquid or semi-pultaceous nourishment into the stomach twice a day. After a few weeks, the irritation induced by the repeated introduction of the catheter will render its passage more and more difficult, until at last it becomes impossible to get it through the constriction. The patient may still be kept alive for some weeks by nutritive enemata, but at last dies of exhaustion and starvation. Even in cancerous stricture of the oesophagus, death seldom occurs by secondary deposits, or by constitutional contamination, but in the way just pointed out.

Such is the miserable course and termination of an organic stricture of the oesophagus. But the question now presents itself, can nothing be done to cure or even to arrest this disease?

The *Palliative Treatment* that is usually adopted in these cases consists in the introduction of bougies, and an attempt to thus dilate the stricture exactly as in the case of a constriction in the urethra. In introducing bougies into the strictured part of the oesophagus, there is, however, often a good deal of difficulty in getting the point of the instrument into the narrowed portion of the canal. This is more particularly the case when the constriction commences suddenly; the oesophagus, as is frequently the case, being dilated into a pouch like sac above it, in which the food is apt to lodge, and the end of the instrument to be arrested, and at the bottom of which a narrow orifice exists, leading into the lower portion of the canal. In these cases much patience and care may be required in overcoming the difficulty. Besides the ordinary dilatation by gradually increasing the size of the instruments used, I have in some cases seen temporary benefit result from the use of a catheter, surrounded by a tube of vulcanized India-rubber, which admitted of dilatation by the injection of water or air when introduced through the stricture; or from the employment of a tubular instrument, by passing a long small-sized bougie through the constriction, and then slipping a gum-elastic catheter with a rounded terminal aperture over it. It is needless to observe that, in the treatment of stricture of the oesophagus with bougies, no force should be used, lest the walls of the canal be perforated.

From these means temporary relief may result in some cases; but can an oesophageal stricture be thus cured? I believe not. If fibrous stricture occurred, as in the urethra, a cure might possibly be effected. But this form of oesophageal constriction, if ever met with, must be excessively rare; and if the disease can be made out to be cancerous, but little good, and most probably much harm, will result from the irritation of dilating instruments. We may, therefore, employ dilatation as a means of temporary benefit, but not with the hope of effecting a cure. Should the stricture at last become so tight as no longer to allow the catheter to be passed, and food to be thus injected into the stomach, the patient must inevitably die of inanition, unless kept alive by nutritive enemata. By these means I have known life prolonged, by a frail tenure it is true, for many weeks. In such cases it is an interesting physiological fact that, although the patients may continue to be moderately well nourished, and do not feel the pangs of hunger, they suffer excessively from thirst.

Has surgery no resource in those cases in which the stricture has become impermeable, and in which neither food can be swallowed nor a catheter passed, and in which, consequently, the most miserable death, that by starvation, is impending? In such cases it has been proposed by Sédillot to open the stomach by an incision through the abdominal walls, and thus directly introduce food into the organ. This operation has been practised several times by Sédillot, Fenger of Copenhagen, Cooper, Forster, and others. Sédillot, who has given it the name of *Gastrostomy*, lays down the following rules for its performance.

Operation.—The patient lying on his back, the surgeon, who stands on the right side, makes a crucial incision, each limb of which is about one inch and a half in length, on the left side of the mesial line of the abdomen, two fingers' breadth to the inner side of the costal cartilages, and about one third nearer to the ensiform cartilage than to the umbilicus; having previously satisfied himself by percussion and palpation that the liver is not in his way. The dissection is carried through the abdominal wall, and the peritoneum is opened. The surgeon then feels with the left index finger for the left border of the liver; by following this upwards, the stomach is reached. This organ is then seized with forceps, drawn forwards, and examined, so that its

identity may be established. By means of three or four points of suture, the anterior wall of the organ is then fixed to the edges of the aperture in the integuments, and an opening is made into it about midway between its two extremities, and a little above the lower margin. Nutritive injections must not be made into the artificial opening for the first few days; not, in fact, until consolidation of the wall of the stomach to the parietal peritoneum has been secured, and a fistulous opening thus fairly established. This must be kept patent by properly adapted silver tubes, through which the nutritive injections are to be made.

The value of this operation has as yet to be determined by experience. In no case in which it has hitherto been done has it succeeded in adding much, if anything, to the prolongation of life. In reasoning upon it, two objections present themselves. First, there is the great and immediate danger of destroying life outright by the induction of peritonitis; though it is by no means impossible that the tendency to abdominal inflammation may be lessened by the previous starvation of the patient. But supposing this risk to be overcome, what is gained by the artificial opening? It is true that through it the patient might be nourished; but, as every idiopathic stricture of the œsophagus is either from the first of a cancerous character, or eventually assumes a malignant action, of what advantage is it to endeavour to prolong a precarious existence, which must in a few weeks or months be cut short by the unchecked progress of a malignant disease? Would not the immediate danger of the operation much more than counteract all good to be eventually derived from it?

There is, however, one class of œsophageal strictures which are of the most obstinate character, and rapidly fatal by simple occlusion of the tube, without any tendency to malignancy. These are the constrictions that result from the swallowing of corrosive liquids, whether acid or alkaline. In such cases as these, in which speedy death by starvation is inevitable, I think that recourse might with propriety be had to the operation of gastrostomy.

DISEASES OF THE LARYNX.

LARYNGITIS.—Inflammation of the larynx principally occurs in adults, from exposure to cold, to the infection of erysipelas, or to the general occasioning causes of the low forms of inflammation. It differs essentially from the croup of children, which is attended by an albuminous exudation, and spreads downwards into the bronchi; whilst in laryngitis, there is no effusion of plastic matter, and the disease is confined to the larynx itself. Laryngitis may not only be of an acute or chronic kind, but it likewise presents two distinct varieties, according to the parts affected, the cause from which it arises, and the condition of constitution in which it occurs: in one, the true *Acute Laryngitis*, the inflammation is chiefly seated in the mucous membrane and cartilages; in the other, the *Edematous Laryngitis*, the affection chiefly occurs in the submucous cellular tissue, within and around the larynx.

In all inflammatory affections of the larynx, whether acute or chronic, there is great danger to life; the rima glottidis, that narrow chink through which all the air destined for respiration must enter, becomes readily occluded, and asphyxia consequently results. This may happen either by the swelling of the lips of the glottis, from the effusion of plastic matter within or upon them, or by the occurrence of spasm in the larynx; indeed, there is always more or less spasm conjoined with all the inflammatory affections of this part of the air-tube; and this spasm, being superadded to already existing mechanical occlusion, commonly proves fatal. These laryngeal spasms do not at first recur oftener than at intervals of half an hour or

an hour ; but as the disease advances they become more frequent, and in any one of them the patient may be carried off. It is of importance to bear in mind that death may occur in these cases, although a considerable portion of the cavity of the larynx continue free. Thus Cheyne states that there are always in croup at least three-eighths of the cavity of the larynx open for the transmission of air ; and that death must consequently result from some other cause than mere mechanical obstruction. This freedom from permanent occlusion commonly occurs in cases of laryngitis ; and the immediate cause of death in the majority of instances appears to be spasm, conjoined with defective arterialisation of the blood, which, becoming dark and poisonous, causes congestion of the lungs or brain, and thus low pneumonia and convulsions.

ACUTE LARYNGITIS.—The *Symptoms* are those of local inflammatory action of an acute kind, conjoined with those of interference with the proper admission of air to the lungs. The cartilages and the mucous membrane are the parts principally inflamed, and but little effusion takes place under the mucous membrane ; hence the symptoms are not always indicative of such early or intense interference with respiration, as is met with in the oedematous form of the disease. In acute laryngitis there are pain and tenderness on pressing upon the larynx, more especially about the pomum Adami. The voice at first is harsh and rough, then stridulous or sonorous ; and deglutition becomes difficult. The difficulty in swallowing is often at first the most prominent symptom, and continues throughout ; dyspnoea, often of a spasmodic character, then appears, the lips becoming livid, the features pale and bedewed with perspiration, the eyes watery and bloodshot, and the respiratory muscles being called into violent action ; the nostrils are dilated ; gasping efforts at breathing, and sudden fits of increased difficulty in inspiring, come on ; at the same time the pulse becomes feeble, though it continues rapid ; and, unless efficiently relieved, the patient will speedily sink. When it proves fatal, the acute usually runs into the oedematous form of laryngitis.

Treatment.—The treatment should be actively antiphlogistic. No time must be lost, otherwise the patient will fall into a hopeless state of asphyxia. Free blood-letting, the application of an abundant supply of leeches to the larynx, and the administration of calomel in large doses, with antimonials, must be employed. If, notwithstanding the administration of these remedies, the difficulty in respiration continue to increase, the windpipe must be opened before the lungs and brain become irretrievably engorged. It is no easy matter to determine when it is no longer prudent to trust to active antiphlogistic treatment, and when recourse should be had to operation ; indeed, the determination of this point may be considered as one of the nicest questions in surgery. As a general rule it may be stated that if, notwithstanding the antiphlogistic means above indicated, the dyspnoea become gradually more urgent, and the paroxysms of spasmodic difficulty of breathing more frequent and severe, then no time should be lost in the performance of the operation, for however short a period the disease may have existed. I can truly say that I have seen several cases lost by delaying the performance of this operation, but never one by opening the windpipe too early. Indeed, if the opening be even made somewhat early, I do not think that much if any harm results, as the larynx is thereby set at ease ; and, on the laryngitis being subdued by the continuance of proper treatment, the aperture, which has simply served as a breathing-hole, may be allowed to close by granulation.

(**OEDEMATOUS LARYNGITIS** is seated chiefly, if not entirely, in the submu-

cous cellular tissue, and frequently comes on in the course of chronic affections of the larynx. It may, however, be of a distinctly erysipelatous character, occurring as the result of exposure to infection, or to atmospheric vicissitudes. In fact, in many cases it appears to be at times epidemic, and in its pathological conditions resembles closely phlegmonous erysipelas of the part; the mucous membrane becoming red, pulpy, and swollen, and the cellular tissue lying beneath it infiltrated with semi-puriform plastic matter. In this form of the disease, the fauces are reddened, dusky, and swollen; there is much and early dyspnoea; the voice becomes hoarse, rough, and speedily extinct; deglutition becomes very difficult; and, on passing the finger over the back of the tongue, the epiglottis will be felt rigid and turgid. There may be some degree of tenderness about the larynx; but the local symptoms, which are less acute, are attended by a greater amount of dyspnoea than in the acute form of laryngitis. In oedematous laryngitis there is also a good deal of spasm associated with the local turgescence. The spasms sometimes come on early, and carry off the patient at once, and are very apt to be brought on by speaking or swallowing; but as the disease advances, the dyspnoea may become more continuous, with great restlessness, a quick, small pulse, and convulsive breathing, the countenance being pale, sunken, and clammy, and the eye dull. Stupor at length supervenes, and speedily terminates in death.

The oedematous infiltration in this form of laryngitis is principally confined to the submucous cellular tissue around the epiglottis, at the margin of the glottis, and to that which lies at the back of the thyroid cartilage. In these situations the tissue is distended with sero-plastic fluid, of an opalescent appearance, so as almost completely to occlude the rima glottidis (Fig. 334).

It is a pathological fact of much importance, that this effusion never extends below the true vocal cords, being limited at this point by the direct adhesion of the mucous membrane to the subjacent fibrous tissue, without the intervention of any cellular membrane.

Fig. 334.—Oedema of the Glottis.

Diagnosis.—It is of great importance to make the diagnosis between the two forms of laryngitis. In the acute variety of the disease, antiphlogistic treatment is of great moment; in the oedematous form it is comparatively useless, for here effusion sets in early, and nothing is left for the surgeon but to open the air-passages, so as to give the patient breathing-room, whilst the disease is being subdued. In making the diagnosis, the epidemic character of the affection, the absence of much pain in the larynx, and the dusky-red and swollen fauces, point to the oedematous variety. Then, also, the effect of antiphlogistic treatment should be taken into account. If, after its active employment, no alleviation of the symptoms occur, it is only reasonable to suppose that the obstruction to breathing is owing rather to a purely mechanical obstacle than to simple inflammation.

Treatment.—The treatment of oedematous laryngitis must be antiphlogistic, though the constitution will not usually bear any very active measures. Leeching under the jaws and over the larynx, the administration of antimonials and salines, will be especially serviceable. In many cases, scarification with a hernia-knife or probe-pointed bistoury about the root of the epiglottis, the sides of the glottis, and the back of the thyroid cartilage, will be found the most ready means of unloading the infiltrated mucous

membrane. In these cases, however, it is especially necessary to open the windpipe before it is too late, and the lungs have become engorged. After the proper employment of the means that have been indicated and their failure, the less delay there is in opening the air-passages through the crico-thyroid membrane, the better. The surgeon should not wait until extreme and continuous dyspnoea has set in; this may never occur, the difficulty in breathing being rather spasmodic than continuous, and in one of the spasms of dyspnoea life may suddenly become extinct. The lungs also may become fatally congested, if the difficulty in breathing be allowed to continue too long. The operation adds but little to the patient's danger, but the increased risk is immense if it be delayed to an advanced period. Not unfrequently this operation is delayed until too late; there is, I think, more risk of doing this than of opening the windpipe too early. When once dyspnoea with laryngeal spasm has fairly set in, every moment is precious, and the patient may at any time be carried off by the recurrence of the spasmodic seizures. The patient does not die gradually asphyxiated, but is suddenly seized with a spasm that terminates his existence.

If the oedematous laryngitis become chronic, sloughing and putrid suppuration of the submucous cellular tissue may occur, as in phlegmonous erysipelas of other parts of the body, and the patient may die partly from asphyxia and partly from typhoid symptoms, with putridity of the breath and mouth. In these cases the administration of stimulants and tonics, more particularly port wine and bark, with free sponging of the part with a strong solution of nitrate of silver, will be urgently required.

CHRONIC LARYNGITIS.—The larynx is liable to various chronic diseases of a serious character, some of which are incurable, leaving a permanent impairment of voice, or alteration in the use of the larynx. These affections present great variety; and, as many of them are attended by loss of voice, they are included under the general term of *Aphonia*. In many cases this affection results simply from cold in relaxed and debilitated subjects, or after long exercise of the voice in persons not accustomed to public speaking. This affection commonly occurs amongst clergymen, and hence is familiarly known as the *Clergyman's Sore Throat*; it is also of frequent occurrence amongst singers, but may be met with among all classes of the community. Aphonia commonly appears to depend upon chronic inflammation of the mucous membrane of the rima glottidis, but is more especially dependent on disease of that extensive mucous surface which stretches from the base of the epiglottis over the back of the thyroid cartilage. In many instances it may also extend into the interior of the larynx, and at last may implicate the vocal cords. In all these situations the membrane is reddened and inflamed, ulcerated at points, and secreting a thin and acrid mucus. In other instances again, the disease implicates the soft palate, the back of the nares, and the neighbouring parts; and in these cases the morbidly inflamed surfaces will be seen to secrete a thick puriform fluid, which usually hangs in a broad streak down one side of the posterior wall of the pharynx.

Symptoms.—The symptoms of this chronic irritation of the mucous membrane in these situations consist of habitual tickling or spasmodic cough, a veiled or hoarse character of voice with, perhaps, at last, complete extinction of it, so that it cannot be raised above a whisper; at the same time there is usually a feeling as if there were some constant cause of irritation in the throat, attended by a desire to cough up and expectorate. As the disease advances, the expectoration becomes more and more puriform, the cough increases, the patient emaciates, is affected with night-sweats, and at last

sinks from what is called *Laryngeal Phthisis*. The neighbouring parts of the pharynx are affected so severe, though they may eventually become diseased downwards.

Diagnosis.—These affections are very frequently bronchitis or catarrhal attacks. From the first by the absence of all auscultatory signs in the pharynx will prevent the disease from being catarrh. This examination, however, requires that a full view may be gained of all the parts engaged is best obtained by means of the laryngoscope brought into view by seating the patient and depressing the root of the tongue at the same time by means of a proper tongue-depressor or spatula to inspire. In order to examine the mucous membrane of the pharynx, and in the neighbourhood of the posterior, may be raised by any convenient instrument.

Treatment.—The treatment of the various diseases of the mucous membrane of the pharynx and larynx is the topical application of a solution of the nitrate of silver almost be looked upon as specific in these diseases.

The practice of treating chronic disease of the throat with a strong solution of the nitrate of silver is by many years ago it was employed by Sir C. Bell and is now applied the solution in these cases by means of a piece of whalebone. Of late years this practice has been recommended by the profession by Trousseau, and especially Horace Green and J. Warren.

Of the great value of this treatment in laryngeal disease, I believe it to be almost impossible to doubt. In chronic inflammatory or ulcerative affections of the throat, to a satisfactory termination by any other means, that is the simplest and most effectual, consists in the application of a proper spatula, and then passing a throat-spatula piece of this material firmly attached to a curved

Fig. 335.—Probang for applying Nitrate of Silver.

and saturated with a solution of nitrate of silver, diseased, so that the liquid may be applied to the surfaces. This solution should vary in strength from one drachm of the salt to an ounce of distilled water; the latter strength will be most useful. This plan of treatment has been practised of late years in this country, and with considerable success in a number of cases. Some of its advocates, however, have objected to this way of disease that is visibly seated in the trachea, as the action extends down the trachea into the bronchi, and it is difficult to follow it in these situations. They accordingly recommend a probang between and beyond the vocal cords, and passing out the interior of the larynx and the lower part of the trachea, applying the caustic solution to them, as if this way could be adopted with as little difficulty as passing the

cannot believe, however, that this practice, though commonly spoken about and professedly employed, is ever in reality carried out. Any one acquainted with the physiology of the larynx knows how acutely sensitive it is, and how it resists the introduction of any foreign body by the most violently spasmodic fits of coughing, in its normal state; and any surgeon who has seen the effects resulting from the fair and complete inhalation of a drop or two of solution of nitrate of silver in a morbid and irritable condition of the tube, must feel sure that no sponge saturated with a solution of this nature could ever have been thrust down between and beyond the vocal cords.

On inquiring into the evidence on which is founded the doctrine of the passage of the sponge-probing through and beyond the vocal cords, I have failed to discover that any of a positive character exists; and, so far as I can gather from the writings of its supporters, it would appear that the reasons from which it is inferred that the instrument thus passes may be arranged under the following heads:—

1. The Sensations of the Patient.
2. The Sensations of the Surgeon.
3. The Analogy afforded by the Introduction of Tubes for the purpose of Artificial Respiration, and by the Inhalation of Foreign Bodies.

These different conditions we must examine somewhat in detail.

1. *Sensations of the Patient.*—The exquisite degree of sensibility possessed by the larynx need not be dwelt upon here. Porter, in his admirable work *On the Surgical Pathology of the Larynx and Trachea*, very justly says, "It (the larynx) is placed as an outwork to protect the important organ of respiration, and rejects vehemently, and with spasmodic violence, every substance that can by possibility prove offensive or injurious." Many years ago, Magendie showed that this was the most sensitive part of the respiratory tube; and in the year 1843 I published in the *Medical Gazette* a series of experiments, which demonstrated the same fact. Since then, I have had repeated opportunities of verifying the correctness of these observations in the human subject in cases of cut-throat and aërial fistula, in which, by means of probes introduced through the artificial opening, I have tested the extreme sensibility of the larynx as compared with other parts of the air-passages, and have often observed the spasmodic irritation and great distress suffered by the patient when its mucous membrane is touched from within; and this, even though the part is no longer subservient to the purposes of respiration, and the sensation of asphyxia is not experienced, which would otherwise be induced, and which would greatly aggravate the distress.

If a long bent probe, or a gum-elastic catheter, be passed over the back of the tongue, two classes of sensations will be elicited, according to the part that is touched. If the instrument be directed down the pharynx, and altogether behind the larynx, into the œsophagus, as in the introduction of the stomach-pump tube, the patient will experience some little distress, which is easily quieted. The face will become slightly congested, and the eyes, perhaps, somewhat suffused, with a disposition to cough, a slight feeling of choking, and some constriction about the chest. All these sensations, however, are transitory. These symptoms may be termed *pharyngeal*.

If, on the other hand, the probe or tube be bent *forwards*, so as to touch the lips of the glottis, and more particularly if an attempt be made to push it on into the larynx, then a widely different train of symptoms will be induced. The patient suffers extreme distress and anxiety; there are great sensation of constriction about the chest and throat, spasmodic difficulty in

breathing, and an inability to speak; the countenance becomes much congested and livid; the eyes protrude, and stream with tears; he stands and gropes wildly with his hands, and is pacified with great difficulty. As the attack goes off, there are deep, sobbing inspirations, and catches in breathing. These symptoms, which are analogous to those induced by irritation of the inside of the larynx through an aerial fistula, may be termed *laryngeal*.

The first class of symptoms is produced by the application of an irritant to the mucous membrane of the pharynx; the second, by irritation of the larynx. Their severity will, in a great measure, depend upon the nature of the irritant applied. They will necessarily be far more severe when a sponge soaked in a caustic solution is thrust down the throat, than when a smooth and unirritating gum-elastic tube is passed.

Both these classes of symptoms are commonly met with after the application of the throat-probang. When the *pharyngeal* symptoms occur, there can be little doubt that no sponge saturated with a strong solution of nitrate of silver has penetrated into the glottis. But is not the case different when the *laryngeal* symptoms are fully developed? Must these not, when existing in their full intensity, be taken as evidence of the introduction of the sponge-probang through the glottis? To this I have no hesitation in answering in the negative. I have repeatedly brought on these symptoms in the most marked degree, without the use of a sponge at all, or the introduction of any solid body into the larynx. In fact, if a drop of a strong solution of the nitrate of silver be fairly inspired into the larynx, the most intense distress and appearance of impending asphyxia will be induced. I once saw this well exemplified at the hospital, whilst applying a strong solution of nitrate of silver, by means of lint wrapped round a probe, to a syphilitic ulcer on the soft palate, altogether away from the larynx; a drop was accidentally inhaled, when the patient was suddenly seized with one of the most intense attacks of laryngeal spasm that I have ever seen; for a few moments she appeared to be about to die asphyxiated, and had all the laryngeal symptoms above described fully marked.

In many cases I am in the habit of applying the solution of the nitrate of silver by means of a strong glass tube, bent nearly at right angles about an inch from one extremity. A few drops of the solution are introduced into the bent end of the tube; and this is passed over the back of the patient's tongue, so as to overhang the glottis, the other end having been closed by the pressure of the finger. The patient, having previously emptied his chest, is then told to take a deep breath; and, at the moment of doing this, the finger being removed from the tube, the solution contained at its bent end is inhaled fairly into the larynx; and, when so applied, it will produce the symptoms already described.

Thus, then, we may conclude that, when the *pharyngeal* symptoms exist alone, the sponge cannot have passed into the true air-passages; and that the *laryngeal* symptoms, however intense they may be, afford no evidence more than the inhalation of a drop or two of the caustic solution into the glottis.

2. *Sensations of the Surgeon.*—That little reliance can be placed on the mere sense of touch in many explorations of the mucous canals, is well known to surgeons. It often happens, for instance, that in the attempt to relieve retention of urine from enlarged prostate, the catheter is supposed to be in the bladder, when it has only reached the dilated sinus of the urethra; so also, in passing a bougie up the rectum, that the instrument appears to have entered the sigmoid flexure, when, in reality, it has curled back upon

itself. Those practitioners, however, who believe in the possibility of passing the sponge-probang beyond the vocal cords, rely much on the sensations communicated by its passage through this narrowed portion of the larynx. They say that, in passing the instrument to the proper depth, a certain sense of obstruction is felt; against this, which is believed to be seated in the vocal cords, the sponge is firmly pressed for a moment, when the obstacle yields, and the instrument passes onwards into the air-tubes. On the withdrawal of the probang, the same feeling of constriction is experienced by the sponge being drawn up against the cords. These sensations are undoubtedly experienced. I have many times felt them myself, and, had I judged by them alone, could have been almost certain that I had passed the instrument between and below the vocal cords, and this belief would have been strengthened by the circumstance that in many of the instances in which this constriction was felt the *laryngeal* symptoms were manifested. I soon found, however, that this was by no means uniformly the case, but that it not unfrequently happened that the *pharyngeal* symptoms only were induced; and that consequently, in accordance with what I believed to be the proper state of sensibility of the larynx, the interior of that tube could not have been traversed by the caustic sponge. Since, also, the same sensation was often experienced in the introduction of bougies and tubes into the œsophagus and stomach, it was clear that it could have nothing to do with their progress through the larynx; and I was led to conclude that it was occasioned by the passage of the instrument through that narrowed portion of the end of the pharynx, or the beginning of the œsophagus, where the cartilages of the larynx, projecting backwards, give rise to a certain amount of constriction, compressing the gullet, as it were, against the spine. Here the instrument meets with some obstruction, which is partly mechanical and partly occasioned by spasm of the constrictors of the pharynx; on this being overcome, it passes on with a sudden slip, again to meet with a degree of constriction on being withdrawn.

In numerous experiments on this point which I have made on the dead body, I have very frequently found that the instrument had passed into the œsophagus, when, from the sensation it gave, those who had introduced it felt confident that it had entered the air-passages. In fact, the shape of the sponge-probang, as it is always sold (Fig. 335), is such that it cannot be made to enter the larynx, and to pass beyond the vocal cords in the dead body, by means of those manipulations which are alone admissible in the living patient, and without the employment of a considerable degree of force. A probang with a short curve, such as those that are uniformly employed, has a natural tendency to take the direct passage, as it were, down the œsophagus, instead of turning forwards to enter the larynx. When the curve is much increased, as in an ordinary catheter, the sponge may, during life, be passed between the lips of the glottis; but it cannot even then be made to pass between and below the vocal cords, in consequence of the curve being too large to be admitted into the diameter of the trachea. The evidence of the New York Academy Commission fully warrants this statement; for the reporters remark that, notwithstanding the most persevering efforts with the whalebone slightly bent, as used by Dr. Green, and with patients who quietly submitted to the test of experiment, the results were entirely negative. In no instance did it enter the trachea. In two instances, with the whalebone curved like a common catheter, the sponge was thought to have entered the larynx; but with repeated attempts it could not be forced between the vocal cords, and the suffocation was so great that it was necessary to withdraw the instrument.

The fallacy of the sensations of the surgeon is well illustrated in the following extract from the report of the Commission of the New York Academy:—"We witnessed in cases 11 and 21 the fallacy of Dr. Green's opinion as to the success of his experiment, though based on so large an experience. In both instances, whilst positive that he had successfully passed the instrument (an elastic tube) into the trachea, the patient *came through the tube*, and thus demonstrated his error."

From these observations, then, I would conclude that the sensations of the surgeon afford no reliable evidence as to the course taken by the instrument.

3. *Analogy afforded by the Introduction of Tubes for the purpose of Artificial Respiration, and by the occasional Inhalation of Foreign Bodies.* Does any such analogy really exist? I think not. It seems to me that a very different degree of irritation would be set up by the introduction of a smooth, well-oiled tube of small calibre, through which the patient can breathe, and from which consequently there is no risk of suffocation, and the passage of a caustic sponge, which not only would stimulate the patient violently, but would necessarily induce temporary asphyxia by mechanically blocking up the air-passage, that no analogy can be drawn from the one case to the other. To do so, seems about as reasonable as to infer that because a gum-elastic or silver catheter may be passed along the urethra therefore a whalebone rod, tipped with a sponge soaked in a caustic liquid, might also be introduced into the bladder.

With regard to the introduction of foreign bodies into the larynx, it appears to me that there is no analogy whatever between this accident and the passage of the caustic sponge. In the one case, the parts are taken by surprise, the foreign body being accidentally sucked into the chest by a rush of air, during inspiration, through an open glottis. In the other case the patient is prepared for what is about to take place, involuntarily and instinctively resists, and, holding his breath, keeps the glottis closed.

But, setting aside this question of analogy, which is of little moment, the introduction of tubes, even into the larynx, so very easy and simple as certain a procedure as some writers seem to suppose it to be! On the dead body, undoubtedly nothing is easier than to pass a catheter into the larynx and down into either bronchus; but is it so in the living? That excellent surgeon, Porter of Dublin, when speaking of the introduction of Desault's tubes through the rima glottidis, in cases of cut-throat, says: "Awkward and reiterated attempts produce inconceivable distress; and, even when performed with the utmost dexterity, it must unavoidably excite cough and restlessness." And again: "Every time the instrument touches the larynx the patient becomes anxious and restless; he tosses himself about, and coughs convulsively; and each motion, whilst it increases his own distress, renders the performance of the operation more difficult. . . . Can such a patient endure the irritation that a few moments' unsuccessful poking at the rima glottidis will inevitably occasion?" The truth of these remarks may be acquiesced in by every surgeon who has ever attempted the operation there described.

On this point, the evidence of the New York Academy Commission is peculiarly valuable. That Commission, in its inquiry, employed two tubes of the size of No. 10 catheter: one, selected by Dr. Green, was slightly bent at its extremity, and was one of the kind employed by him in his practice. The other consisted of a catheter, with a wire stylette, bent with a curve, the segment of a circle six inches in diameter. This tube does not appear to be used in practice, but was employed for the purpose of comparison. It

result of the experiments with these tubes was, that Dr. Green (who was the only one that employed it) failed in passing the tube with the *small* curve in thirty-five out of thirty-eight trials, or in about ninety-two per cent. of the cases, and that the tube with the *large* curve was passed in eight cases out of thirteen; whilst the sponge-probang failed in every case (eighteen) in which it was tried.

"From these experiments it would appear that the instrument best adapted to succeed in catheterism of the air-passages is the tube having a large curve; whilst the least adapted to enter the trachea is the sponge-probang."

In the course of these experiments a point of much interest was elicited by the Commission,—viz., that a patient might blow out a lighted candle, or collapse and inflate a bladder attached to its free extremity, through the tube, even though it had never entered the trachea, but had been purposely passed into the œsophagus. This observation I have more than once confirmed at the hospital in the treatment of stricture of the œsophagus: for, on introducing a catheter through the stricture, air is sometimes sucked into the stomach, and then expelled through the catheter with sufficient force to blow out a lighted candle, by the action of the abdominal muscles alone.

On this third point, then, I think we are warranted in the conclusions, that there is not sufficient analogy between the introduction of the sponge-probang and that of a catheter tube into the larynx, to lead us to suppose the passage of the former instrument possible, because that of the latter is occasionally practicable; that the introduction even of a tube of the same shape as the sponge-probang is an operation of extreme difficulty, failing in far the greater proportion of cases in which it has been attempted, and that the introduction of foreign bodies into the larynx is effected under totally different conditions from that in which the sponge is attempted to be passed.

Finally, I think that we are fully justified in adopting the conclusion of the Commission of the New York Academy, that there is no reliable evidence that the sponge-probang has ever been passed through and beyond the vocal cords.

Inhalation of the nitrate of silver in powder is most conveniently done by mixing it, in proper proportions, with some innocuous impalpable powder, such as ground and dried sugar. The strength may vary, from one part of the nitrate of silver to twelve, sixteen, or twenty of the sugar. A small quantity of the powder so prepared should be put into the end of a thick glass tube, which has been bent nearly at right angles, about one inch from its extremity. The surgeon, placing his finger over the orifice of the straight part of the tube, carries the bent end behind the tongue, over the epiglottis; he then directs the patient to make a sudden inspiration, and at the moment of his doing so takes away his thumb, so as to allow the powder to be drawn out of the tube and into the air-passages along with the current of inspired air. In this way the nitrate of silver may, in some cases, be very conveniently applied to the whole of the affected mucous surfaces without the irritation produced by the friction of the sponge.

Injection of the solution of nitrate of silver may easily be done by means

Fig. 336.—Laryngeal Syringe

the instrument that is here delineated (Fig. 336), and which I have had

constructed for this purpose. It consists of a rod and, and having a small piston moving in it with its lower surface. The instrument is charged by dipping the rod and then drawing back the piston-rod. It is then used either between the lips of the glottis, and the flux passages or upon the inflamed surfaces in a more direct manner, pushing down the piston and compressing the fluid. In the *laryngeal syringe* the nitrate of silver can be applied to the pharynx, without irritating the tender mucous membrane; and, by applying its nozzle to the glottis, the fluid may be readily thrown down into the larynx with the greatest certainty and ease. In those cases where it is necessary to apply the solution of the nitrate of silver to the inflamed surfaces, using this simple instrument to the ordinary syringe, which upon a tender mucous surface may be a source of irritation, the mucous membrane behind the velum, or the epiglottis, the solution may readily be applied to the end of the instrument upwards, and then injected into the affected surfaces.

In whatever way the caustic is used, its application should be repeated about every second or third day, in order to insure its effect. In some instances, however, advantages may be obtained by using others, again, a longer interval is required than in the first.

RESULTS OF CHRONIC LARYNGITIS.—In the chronic disease of the larynx, the mucous membrane is covered with *Plastic Deposits*, which also form upon its surface, and at last run into *Ulceration*, with a mucous and muco-puriform discharge. These diseases have their origin, and, after continuing for some length of time, lead to dyspnoea, cough, shortness of breath, a pale, pasty, and swollen face, with suffused eyes and constant distress. In these circumstances there is a constant tendency to the supervening of the chronic laryngeal disease; and, if not relieved, proves fatal by the induction of oedema of the glottis with great rapidity.

Necrosis of the Cartilages of the Larynx not only presents more advanced forms of this affection, attended with constitutional and local, of the so-called *Laryngeal* exudation of large quantities of fetid puriform blood, and occasionally containing masses of the cartilage. In many cases *Abscesses* form outside the larynx, causing irritation and distress open externally; and not only with to such an extent, as to undermine and destroy the tissues of the anterior part of the neck, but, when the necrosed patches of cartilage, they give rise to the formation of which bubbles of air escape during respiration.

Treatment.—In the treatment of these more advanced forms, the daily application of nitrate of silver will be found to be of great service. It should be freely applied to or injected upon the inflamed surfaces, within the lips of the glottis, and more especially upon the mucous tissue which is extended over the back of the larynx, which is commonly the seat of much chronic irritation of the muco-puriform discharge. At the same time, the use of bichloride of mercury with care should be attended to.

great service, more particularly in those cases in which the disease is of a syphilitic character; the patient being kept in a regulated temperature, not allowed to exert his voice, and avoiding all laborious exertion. Whenever acute inflammation supervenes in these cases, with a tendency to œdema about the glottis, the patient should be narrowly watched, as he may readily be carried off by the sudden swelling of the lips of the rima, or by the super-vention of apœam. In cases of this kind, the air passages may require to be opened to allow respiration to be carried on; and this operation must not be delayed until such time as the patient falls into an asphyxial condition.

NERVOUS AFFECTIONS OF THE LARYNX occur both in children and in adults. In *children*, the affection, commonly called *Spasmodic Croup*, comes on suddenly and runs its course with great rapidity. The child is seized, often without previous warning, with difficulty in breathing, uses violent efforts to inspire, becomes black in the face and convulsed, and may die before anything can be done for his relief. In other instances he gapes and gasps a few times, and eventually recovers himself with a long deep-drawn whooping inspiration. In cases of this kind, the *Treatment* at the time of the fits consists in dashing cold water in the face, in exposing the body to a current of cold air, and in using friction to the extremities. If asphyxia occur, artificial respiration must be kept up either through an opening made in the windpipe or by the mouth.

In the *adult*, these spasmodic affections of the larynx may come on either from pure hysteria, or from irritation of the laryngeal nerves by the pressure of tumours or aneurisms upon them. In other instances they arise from the presence of some local inflammatory mischief about the glottis. In the hysterical form of the affection the ordinary remedies for hysteria, together with cold douches, will be of essential service. In some cases, however, the obstruction to respiration is so great, that the surgeon may almost think it necessary to have recourse to operation. When the disease arises from irritation to the trunks of the nerves, such a procedure is seldom justifiable, as the occasioning cause is usually in itself of a fatal character.

TUMOURS OR POLYPI occasionally form in the larynx. They are commonly granular, or small cauliflower-looking bodies, though they occasionally attain the size of a hazel nut. In structure they are usually epithelial, occasionally fibrous, and eventually may become canceroid (Fig. 337). They necessarily produce aphonia, interfere with respiration, and at last may give rise to asphyxia by obstructing the cavity of the larynx.

These tumours, which formerly could neither be recognised with certainty during life, nor treated effectually, have often of late not only had their existence demonstrated by means of the laryngoscope, but have been removed by Dr. Walker of Peterborough and Dr. Gibb, in this country, and by M. Moura-Bouroullou in Paris. Dr. Gibb, in cases of this kind, has succeeded in passing a loop of silver wire round the bases of two such growths, lying just within the true vocal cords, and then detaching them by drawing the wires through a steel cannula, and so tightening the loop. This ingenious operation has been performed several times with the aid of the laryngoscope. Dr. Gibb tells me, that the operation is much facilitated by first administering full doses of the bromide of ammonium, which has the property of suspending the sensibility of the pharyngeal mucous membrane.

Fig. 337.—Epithelioma in Larynx.

CHAPTER LVIII.

PLASTIC SURGERY OF THE FACE AND MOUTH.

By *Plastic or Reparative Surgery* is meant the performance of operations for the repair of deficiencies in structure, whether resulting from injury, from disease, or from malformation.

It has been long known that parts of the body may retain their vitality sufficiently to become again adherent, when attached but by a very narrow tongue of tissue to the part from which they have been all but separated. This has often been observed in cases of injuries of the face and fingers, portions of which have been nearly completely severed, and yet have united again on being replaced. But there are even a sufficient number of cases on record to show that certain parts, when completely separated, may, after being replaced, again become adherent. The most remarkable instances of this kind are those which are related by Dr. Hoffacher, and attested by Chelius and Velpeau. Dr. Hoffacher was officially appointed to attend a surgeon at the duels which were at one time frequent amongst the students at Heidelberg; and, as at these encounters broad-swords were used, he had an opportunity of seeing a considerable number of incised wounds, and has related no fewer than sixteen cases in which portions of the nose, lips, or chin had been sliced off, and, being put on again, contracted adhesions. Amongst the most remarkable of these, is a case in which the end of the nose was sliced off by a cut with the broadsword, and fell under a chest of drawers; it was not found for some time, but on being recovered and washed, was stitched on, and became firmly attached. In another instance, a dog that was in the room snapped up the detached portion of the organ as it fell to the ground, but the nose, being immediately taken out of the animal's mouth and put on again, became firmly fixed!

In order that union should take place between parts that have been separated completely or nearly so, and the rest of the body, it is necessary that they be soft and vascular, and more especially that their structure be of a homogeneous character, such as is met with in the tissues of the face; where no very large bloodvessels, nerves, tendons, or bone are found. It is the same in plastic operations, which succeed best under similar conditions of tissue, and which are conducted on the same principle as an attempt at union in a partially severed structure.

It is principally for deformities and loss of the nose and lip that plastic operations are of much service; they may, however, occasionally be had recourse to in other situations, as about the cheeks and eyelids, but seldom with an equal amount of success. Reference has already been made (p. 412) to the performance of plastic operations on the perineum. In the practice of this very interesting branch of surgery, there is much opportunity for the display of manual dexterity. On this, indeed, almost the whole success of the operation depends; and a vast deal may be done in apparently the most unpromising cases by management, skill, and patience. In these operative procedures the names of Serres, Dieffenbach, Liston, Fergusson, Sedillot, B. Langenbeck, and Jobert, deservedly take the first rank.

In performing the various plastic operations, four methods have been employed. In the first, the flap of skin that is intended to repair the lost structure is transplanted from a distant part, as the arm. This operation

which was introduced by the Italian surgeon, Tagliacotius, and hence commonly called by his name, has in a great measure fallen into disuse, on account of the difficulty of its execution, and the great uncertainty of obtaining a successful result. The second plan consists in transplanting the reparative structure from some part in the neighbourhood of the organ to be repaired; the skin from the forehead, for instance, being used for the formation of a new nose; that from the chin for the restoration of a lost lip. This procedure, which seems first to have been adopted by the natives of India in restoring the loss of the nose, is the method that is most commonly employed in this country in plastic operations on the face. The third method consists in loosening the skin by a process of subcutaneous section to some distance around the part to be repaired, and then drawing it forwards with or without incision through its substance. This gliding operation is chiefly practised for the closure of fistulous openings. The fourth method is employed in cases where an abnormal fissure exists in a part. It consists in bringing together and uniting the edges of the fissure, after having pared them evenly, so as to expose their vascular surfaces.

Union in plastic operations is affected by primary adhesion between the raw surfaces which are brought into contact. Should, however, this mode of union fail from any accidental circumstance, the surgeon need not despair; as the parts may unite by adhesive inflammation, or even through the medium of granulation, in a very satisfactory and complete manner.

For proper union to be effected, it is necessary that the edges be cleanly and evenly cut, so as to adjust themselves accurately to one another. This may often be most skilfully effected by making the incision in the part that is to receive the flap somewhat oblique or bevelled, thus securing a more accurate adaptation of the edges.

After the flap has been formed and the part in which it is to be transplanted properly pared, the operation should be delayed a few minutes until all bleeding has ceased. This is of much importance, as the interposition of a layer of coagulated blood will materially interfere with union.

In bringing the parts into apposition, great care must be taken that no undue traction or constriction be exercised, lest their circulation be interfered with, and their vitality be endangered.

The parts may be maintained in apposition by sutures, collodion, or the application of a strip of isinglass plaster. The sutures should be as fine as possible, introduced with a small needle, and knotted on the sound parts. Occasionally, as in hare-lip, pins may advantageously be used. In some instances, instead of sutures, a small spring-forceps (Fig. 53), termed a *serrefine*, may be employed, but most generally interrupted sutures are the best. The use of collodion, where applicable, is of great advantage in plastic surgery, as it not only secures adhesion, but, by excluding the air, lessens the chance of suppuration.

For a plastic procedure to succeed, it is absolutely necessary that no morbid action be going on in the seat of operation; and not only that none be actually in progress, but that all have ceased for some considerable time. This is more particularly the case when the deformity for the remedying of which it is practised has resulted from syphilitic or cancerous ulceration. In both cases it is necessary to see that the constitution is sound, as well as that all local disease has been eradicated; otherwise the irritation of the operation might set it up again, and the new flap might be invaded and destroyed. From want of this precaution, I have more than once seen disappointment result. When an operation, as on the nose or lip, is performed for cancerous disease, ablation of the morbid part may be done at the moment

of operating—the affection being a local one; when for struma or syphilis the disease is constitutional, and care must be taken that all morbid action has thoroughly and completely ceased. As a general rule, plastic operations practised for the repair of mutilations from injury, or of congenital deficiencies, are more successful than those that are performed after disease.

No routine system of treatment should be adopted; but a few days of rest, good diet, and a dose or two of aperient medicine, may be prescribed before the operation is proceeded with. In the after-treatment of the case, a nourishing but unstimulating regimen should be observed.

PLASTIC SURGERY OF THE EYELIDS.

BLEPHAROPLASTY, or the operation by which the eyelids are repaired, is occasionally required for loss of substance—the result of wounds, cicatrices, or operations. It is less satisfactory in its results than most of the other plastic procedures about the face; yet it may, in some cases, improve materially the patient's appearance.

When the upper eyelid requires repair, the flap is taken from the forehead; when it is the lower lid, from the cheek or temple. This operation may be performed either by the gliding method, or by twisting a flap into its new situation. By the gliding method, a triangular flap is cut and partially detached (Fig. 338 a), and then drawn gently

Fig. 338.—Operation for Repair of Eyelid. (a) Gliding Method; (b) Twisting Method.

forwards until it corresponds to and fills up the gap that requires repair, when it is there fixed by a few points of suture. When the twisting method is employed, an oval flap is detached (Fig. 338 b), except its pedicle, and twisted down, to be planted on the raw surface.

Occasionally neither of these methods is applicable; and then the procedure, that was successfully adopted in a case of which the annexed cut (Fig. 339) is a representation, may be adopted. Here there was a deep and

Fig. 339.—Lower Eyelid deformed by Cicatrix.

Fig. 340.—Lower Eyelid after Operation.

hard cicatrix across the lower eyelid, causing eversion of its outer portion, and adhesion of the inner part to the ball of the eye. After dividing the adhesions and removing the cicatrix, I made a semilunar incision so as to dissect up the eyelid, and then fixed it by points of suture in its new situation, where it became firmly adherent (Fig. 340).

Operations of various kinds are frequently performed on the eyelids, which are truly of a plastic character.

SYMBLEPHARON.—In symblepharon, or adhesion between the lid and the eye-ball, the adherent portion of lid may be included between V-shaped incisions and removed, and the edges of the cuts brought together (Fig. 341 a).

EPICANTHIA.—In epicanthis, or projection of the nasal fold of the eyelids, an elliptical portion may be removed parallel to the nose, and the edges of the incision brought together with sutures.

PTOSIS.—In ptosis, or drooping of the upper eyelid, an oval portion of the lid may be raised horizontally, and removed so as to leave an oval gap (Fig. 341 b); the edges of which being brought together will lessen the depth of the lid, and thus diminish the deformity.

ENTROPION.—In entropion, or inversion of the eyelid, the same operation may be practised, and thus, by the contraction of the cicatrix, the tendency to its turning inwards lessened. But various other procedures are at times required in order to remedy this deformity. Thus a vertical instead of a transverse flap may be removed; or Crampton's plan may be followed, which consists in making a vertical incision through the whole thickness of the lid, near each angle (Fig. 342 a), and then removing a transverse fold of the skin, bringing the edges of that wound together in the usual way. This operation is chiefly applicable when the tarsal cartilage is contracted and, as it were, shortened. Lastly, when the tarsal cartilage is much contracted and inverted, the whole edge of the lid may be removed by passing a Beer's spatula between it and the ball, and then cutting upon it.

ECTROPION.—In ectropion, or eversion, the lid may be well everted, and a portion of the conjunctiva raised with a pair of forceps and snipped off. This operation, however, seldom succeeds; and it is usually better to remove a wedge-shaped portion of the lid, of a size proportioned to the amount of eversion; or Dieffenbach's method may be tried, which consists in making a transverse incision through the lid down to the conjunctiva, seizing this, drawing it forwards until the lid is restored to its proper shape, then removing the projecting fold, and bringing the edges of the incision together in the usual way (Fig. 342 b).

PLASTIC SURGERY OF THE NOSE.

RHINOPLASTIC OPERATIONS occasionally require to be performed for the restoration of the form of the nasal organ, which has been destroyed by injury or disease. This branch of plastic surgery has long received much attention, and has been reduced to distinct rules. Either the entire nose, or a portion, may demand operation.

COLUMNA.—When the columna and a portion of the septum are destroyed, a large gap is left at the nasal aperture; and, the nose becoming flattened in consequence of its tip falling in, great deformity necessarily results. The upper lip also, losing that amount of support which it receives from the columna, becomes pendulous, projecting, and thickened at the end, thus adding to the disfigurement. The restoration of the columna is effected from this thickened and prominent upper lip, which, by being reduced in size, is rendered far more shapely. The operation consists in cutting through the

whole length of the lip from above downwards on each side of the mesial line, so as to leave a tongue about one-third of an inch in width. This is then turned up; and, its end being well pared, and the under surface of the tip of the nose properly vivified, it is fixed by means of a fine hare lip pin and twisted suture, which should be left in for about four days. Union takes place in a few days; but, until this is firm, the new columna must be properly supported with narrow strips of plaster fixed to the cheek on each side. No twisting of this small flap is required, as the mucous surface speedily becomes cutaneous, and *vice versa*. The division in the upper lip must be treated in the same way as an ordinary hare-lip, and unites without difficulty, lessening greatly the deformity in this part.

ALA.—When one ala only is deficient, the rest of the nose being sound, a flap of skin of the proper shape to restore the deformity, having been raised from the cheek, may be applied to the previously pared edges of the part requiring it, and fixed there by a few points of fine suture. If the loss of the substance of the ala be very considerable, or if it extend to a part of the body of the nose, then it is more efficiently restored by bringing a long narrow flap from the forehead in a way that will immediately be described. In the majority of cases the destruction of the ala and of the body of the nose is so considerable, that other plans, to be presently described, are required for the repair of the deformity.

NOSE.—For the restoration of the entire nose, two procedures have been employed: viz, 1, the Tagliacotian Operation; 2, the Indian Operation.

1. The *Tagliacotian Operation* consists in taking the integument and cellular tissue required for the repair of the lost organ from the inside of the arm. Here a flap of sufficient extent is to be marked out and dissected up with its subjacent cellular tissue, leaving it merely attached to the limb by a root at its distal end. No attempt at fixing this flap to the nose should be made for at least a fortnight, during which time it should be kept upon a piece of wet lint, and allowed to thicken, granulate, and become vascular, so as to fit itself for adhesion to the new surface to which it is to be applied. The remains of the deformed nose having then been properly pared and the flap shaped, they must, after all bleeding has ceased, be properly adjusted and fixed to one another by points of suture. The arm must then be closely attached to the head, so as to be as nearly as possible immovable. At the end of about ten days, when adhesions have taken place, the connecting medium may be cut across, and the part left to be supported by the vitality which it may gain from the new surface to which it is now attached. This process is comparatively seldom had recourse to, for obvious reasons. The uncertainty of maintaining the vitality in the flap, the extreme tediousness of the prolonged constrained position in which it is necessary to keep the patient, and the great difficulty of guarding against movements of the arm, especially during sleep, and which, however slight and involuntary, would be sufficient to disturb union between the opposed surfaces, and occasion the failure of the operation, have caused this plan of procedure to fall into disuse; and it is now, I believe, universally abandoned by surgeons in this country, having been replaced by the more certain procedure, which will now be described, of borrowing the skin for the new nose from the forehead.

2. The *Indian Operation*, a knowledge of which was brought to this country by Carpué in 1814, is extremely successful in its results, though requiring a good deal of nicety for its proper execution. The operative procedures required by this method are somewhat complex, and may con-

veniently be divided into three distinct periods; 1, the Dissection of the Flap from the Forehead, and its Attachment to its new situation; 2, the Separation of the Root of the Flap where it is turned down from the forehead, and the Formation of a proper Bridge to the Nose; 3, the Formation of the *Columna Nasi*.

1. *Formation and Attachment of the Flap.*—In the shaping of the flap, care must be taken that it is of sufficient size; as during the after-part of the treatment it often has a tendency to shrivel, and more inconvenience usually results from its not having originally been made large enough, than the reverse. The size adapted to the particular face may best be judged of by moulding a thin piece of gutta-percha to the nose, then flattening it out by dipping it in hot water, and using this as the guide

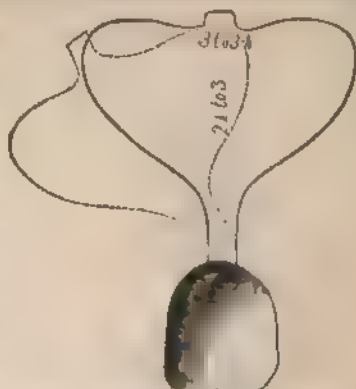

Fig. 343.—Diagram of Flap in Rhinoplasty Operation

for marking the outline of the flap upon the forehead. This should be traced with tincture of iodine, which will not be washed off so readily as ink by the flow of blood, which is often rather free. This flap should be of the shape in Fig. 343, taking care that it is rather square at the angles, and not too much rounded off. The size will necessarily vary according to the character of the countenance, and the extent of loss that has to be repaired. When the whole of the nose requires restoration, it is usually necessary to make it about two and a half to three inches in length, by about the same in width at the broadest part. It may either be taken from the middle of the forehead, or obliquely from one side: if the latter, the right side is the most convenient. It must now be dissected off the forehead; in doing this, care must be taken not to remove the pericranium, but at the same time to cut the flap as thick as possible, especially at its root between the eye-brows. It must also be but little handled, and, above all, not pinched, either with fingers or forceps. The dissection should be commenced at the root, so that the outline may not be obscured by blood; and this part should be left long, in order to admit afterwards of a very gradual and easy twist. In order to facilitate this, it is also desirable to make the incision on the right side a little lower than that on the left. After the flap has been raised throughout the whole of its extent, a piece of wet lint should be applied to the forehead, with a view of arresting the bleeding, before the next step is taken. This consists in paring the surface and edges of the stump of the nose, and removing the integuments from it in such a way as to leave a triangular raw surface. In doing this care must be taken—whilst a good base of attachment is left—not to remove the parts too widely, lest the cheeks, by separating, have a tendency to gape too much, and the nose to become flattened out. The integuments also should be dissected away in such a manner as to form a deep groove shelving inwards, so as to receive and hold the flap more securely and with less overlapping of the edges. The operation must now be discontinued for a few minutes until all bleeding has ceased, and the cut surfaces have become glazed; this point is of great importance in securing direct adhesion, and must be carefully attended to. The bleeding having been arrested by exposure to the air, and by the torsion rather than the ligature of any spouting branch, the flap from the forehead

should be brought down by a twist from left to right, and attached by a few points of fine suture on each side to the edge of the incision, around the nasal aperture. A pledget of soft lint, moderately greased, should now be gently insinuated under the flap, the lower part of the incision in the forehead drawn together by a point of suture, but not so as to constrict the root in any way, and the rest of the exposed surface covered with water-dressing. The parts will then present the appearance of Fig. 345, taken from

Fig. 344.—Depressed Nose.

Fig. 345.—New Nose, day after Operation.

patient of mine the day after the operation. Fig. 344 represents the deformity for which the operation was performed. The patient should be put to bed with a piece of soft lint laid over the whole of the face, so as to maintain its temperature; and, if it be winter, he must be placed in a room that is kept well warm day and night. The diet for the first few days should be simple, but abundant, consisting chiefly of nutritious slops.

The dressings must not be disturbed for three days: by this time, if all go well, the flap will be found somewhat tumid, warm, and sensitive, but pale in colour. The plug in the nose will now require changing, lest it be rendered offensive by the discharges; its withdrawal and the substitution of another must be done with the greatest gentleness, the surgeon bearing in mind that any undue pressure or traction may destroy adhesions, and prove fatal to the vitality of the flap. If the sutures produce no irritation, they may be left in till the fifth or sixth day, by which time the adhesions will be tolerably perfect, and they may with safety be cut and withdrawn. As the adhesions strengthen and the vitality of the flap improves, it must be elevated by putting underneath it a larger plug of lint; for which, after a time, may be substituted a small gutta-percha tube moulded to the figure of the inside of the nose. (Edema of a somewhat solid character is apt to come on in the flap, giving it a white appearance; but this is of little moment, and will gradually subside as the circulation through it becomes more actively established. The flap gradually becomes thicker and firmer, throwing out granulations from its under surface, which eventually becomes clothed with mucous membrane. The wound in the forehead must be dressed like an ordinary ulcer, and be well touched with nitrate of silver from time to time, to insure its contraction. It usually cicatrises with great readiness, and leaves remarkably little deformity.

2. *Separation of the Root of the Flap.*—This may be done about a month after the flap has been fashioned, when its vascularity, through its lateral adhesions, will be perfected. The division of the root is best done by passing a narrow-bladed bistoury under the twist, and cutting upwards towards the eyebrows, removing a wedge-shaped portion of the soft parts, so as to make a smooth and proper bridge.

3. *Formation of the Columna Nasi.*—The addition of the columna is now all that is wanted to make the nose complete. This must be made from the upper lip, perhaps at the same time when the bridge is fashioned, and may be cut and fixed in the way that has been already described in speaking of the restoration of this feature, the interior of the apex of the new nose having been well pared to receive it. The columna requires to be well supported by means of a narrow strip of plaster passing from one cheek to the other, and usually requires a good deal of fashioning before it is perfect; indeed, this is the part of the operation that I have found always most troublesome, and requiring most attention.

The new nose must continue to be supported from beneath, for some months after its formation, by plugs of lint or small gutta-percha tubes, as it will evince a great tendency to contract and to alter in its general outline and shape; becoming, if the surgeon be not careful, either depressed or dumpty. The sensibility of the new nose is entirely destroyed for a time after the division of the bridge; but it slowly returns from all sides, appearing first in the neighbourhood of the adhesions between it and the cheeks, then near the columna, next in the bridge, and thus the organ at last has its sensation restored; for this, however, several months will usually be required, and the part in which it returns last of all is its central portion. The annexed cuts (346, 347) give a very faithful representation of a

Fig 346.—Patient before Rhinoplasty Operation

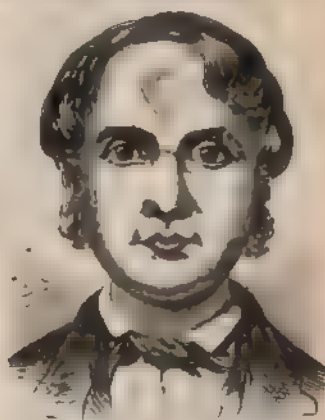

Fig. 347.—Same Patient some months after Operation

patient on whom I operated, before and after the restoration of the lost organ.

The success of the case will depend very greatly upon the minute attention which the surgeon bestows on the details of the operation, and on the care which he takes in the after-treatment. During the operation, the chief points to be attended to are, that the flap be made of sufficient size, that all oozing have ceased before the cut edges are brought into contact, and that no tension nor constriction be exercised. A principal source of failure in

the operation, or in the result so far as concerns the after-appearance of the patient, is gangrene of the flap, in whole or in part, arising from the root being too narrow or too tightly twisted, or from the flap being too roughly handled in its dissection. So also, if it be cut too small and not properly supported afterwards, the result will not be very satisfactory. Other accidents occasionally happen; thus erysipelas may occur, destroying at once the vitality of the flap, or coming on at a later period, and causing the new nose to slough under the attack of inflammation, which it has not sufficient vitality to resist, as happened in one of Liston's earlier cases; or the new nose may be destroyed by a return of the lupus which proved destructive to the old one. Hemorrhage may also occur from underneath the flap. In the last case operated on by Liston before his death, and which was completed by Mr. Morton at University College Hospital, hemorrhage to the extent of more than a pint took place on the ninth day, without any evident cause, from under the flap, and could only be arrested by plugging. Further, the operation is not without its dangers. Dieffenbach lost two patients out of six on whom he operated in Paris; their constitutions probably having been in an unfavourable state.

FISTULOUS OPENINGS THROUGH THE NASAL BONES leading into the interior of the nostrils are occasionally met with. Such apertures as these are, perhaps, best closed by paring the edges, and then bringing forward a flap of neighbouring skin by the gliding operation. In some cases of this kind, procedures may be required, in which the surgeon may display much ingenuity and benefit his patient greatly. The cuts represent a case many years since

Fig. 348.—Opening into Anterior Nares.

Fig. 349.—The same, closed by Operation.

under my care, before and the day after operation, in which a large aperture into the side of the nose, resulting from necrosis of the left nasal bone consequent on scarlatina (Fig. 348), was successfully closed by a flap of skin taken from the forehead by the twisting process (Fig. 349). The patient who was a child at the time of the operation, has now grown into a comely young woman, presenting scarcely a trace of the operation.

OPERATION FOR DEPRESSED NOSE.—Sometimes the nose is depressed and flattened in consequence of the loss of the cartilages, vomer, and septum, though the external parts remain entire. Dieffenbach has proposed a plan for raising it by slitting it longitudinally into three pieces; dissecting the

lateral slips from the osseous attachments; paring the edges to such an extent that they overlap, and stitching them together; then bringing the whole organ forwards by pushing long hare-lip pins across its base, so as to elevate and narrow its attachments, which are brought more into the mesial line. Fergusson has improved this procedure by not slitting the nose down, but dissecting it away from the bones from within the nostril, and then pushing long steel-pointed silver needles across from cheek to cheek, and twisting their ends over perforated pieces of sole-leather, through which they had previously been passed, thus bringing the whole organ bodily forwards. The columna is next fashioned in the way which has already been described; and the nose is completed.

PLASTIC SURGERY OF THE LIP.

HARE-LIP.—By hare-lip is meant a congenital perpendicular fissure or fissures through the upper lip, the result of an arrest of development. The condition thus produced in man is, according to Geoffroy St. Hilaire, not analogous to what is met with in the hare, but to that which occurs in animals of a lower grade of organisation—in fishes. The arrest of development takes place opposite the line of junction between the intermaxillary and superior maxillary bones, and is usually associated with a certain amount of disunion or malformation at the line of junction between these bones. When the arrest of development takes place on one side only, the hare-lip is said to be *Single*. In it the mesial side of the gap is usually rounded; the outer edge is flattened; and the frænum at the angle is long and subcutaneous. It most frequently, so far as I have observed, occurs upon the left side. Not unfrequently there is a fissure on each side of the mesial line; and then the hare-lip is said to be *Double*. When double, the fissure is deeper on one side than on the other, and usually extends into the nostril, and is associated with cleft palate; though sometimes it stops short of this. In these cases the nose is usually flattened and expanded, and between the fissures there is always a central or medium lobule, consisting of the intermaxillary bones in a rudimentary condition; to this a triangular labial nodule is commonly attached. In many cases this is pushed forwards, and tilted on its base, so that the alveolar border projects forwards. Sometimes the projection is so considerable that it is attached to the tip of the nose.

Moham fissure is so rare that there are scarcely any authentic cases of it in the records of surgery. Delahaye, however, mentions one instance of mesial fissure of the upper lip with two lateral fissures, and Nicati has described one in the lower lip, the only case of the kind that I have met with on record.

The cleft in hare-lip corresponds to the line of junction between the embryonic intermaxillary bones and the superior maxilla. The fissure, when single, may be confined to the lip; but in the majority of cases it extends to the alveolus of the upper jaw, giving rise to a deep notch between the outer incisor and the canine tooth. When double, the four incisors, usually imperfectly and irregularly developed, are included in the central intermaxillary tubercle. Meckel and Nicati have described a rare form of hare-lip, in which the fissure corresponds to the line of junction between the central and lateral incisors. In many cases the fissure extends back into the palate; this more frequently happens when

Fig. 350.—Jaw in Double Hare-lip.

the hare-lip is double, and in these cases every variety of palatal deformity is met with (Fig. 350).

Age for Operation.—The cure of hare-lip can only be effected by a properly conducted operation. In the performance of this, the first point that has to be determined is the age at which it should be done. On this there has been, and is still, a good deal of difference of opinion. Surgeons generally are, however, I think, agreed that it is better not to perform the operation during dentition; at all events not during the cutting of the incisor teeth, when there is much local excitement and general irritability of the nervous system; but they are not agreed as to whether it should be done before or after dentition. In support of the opinion that it is more prudent to wait until after this period, it is alleged that very young infants are especially liable to convulsions; that the performance of operations on them is troublesome; and that it interferes with suckling. These statements, however, are not carried out by what we meet with in practice. I think there is no evidence to show that there is any danger in operating during early infancy; indeed, I believe that very young children, those but a few weeks or months old, bear operations remarkably well. I have repeatedly operated at these tender ages, not only for hare-lip, but for hernia, the removal of tumours and navi, the division of tendons, &c., and have never seen any bad results follow. Besides this, the performance of the operation is easier at a very early age than when the child has reached its first or second year; when, intelligence being more developed, it knows what it has to suffer, and screams and struggles more than a very young infant does, whenever it sees the surgeon, or when he makes an attempt to examine the wound or dressing. After the operation also, the child will, when young, take to the breast without difficulty and with the greatest avidity. The act of suction is advantageous, as in it the sides of the incision are more closely compressed and brought together. At very early ages, union of the wound takes place with great readiness and solidity; and, as no time has been given for the rest of the features to become distorted, there will not be that permanent flattening and deformity of the face which is apt to continue after the hare-lip is cured, if the operation be deferred to a more advanced age. For these various reasons I agree with Dubois, Fergusson, and Butcher, that the operation had best be performed early; if possible, at about the sixth week after birth, or from that to the third month, which may, I think, be considered the time of election for this procedure. At this time the vitality of the child is good, and the tissues are not so lacerable as at an earlier age. Should circumstances require it, however, the operation might be done at a much earlier period than this. Thus, at the urgent solicitations of the parents, I have performed it within the first 24 hours after birth, and several times during the first week. But in these early days of life the operation is not without danger; the vitality of the child is often feeble, it suffers greatly from the loss of even a very small quantity of blood, and the tissues are so lacerable that there is great danger of the pins or stitches cutting out. I would therefore not advise its performance then.

It is scarcely necessary to observe that, as union by the first intention is aimed at, the operation should not be undertaken unless the health be good, and certainly not if the child, at whatever age, have but recently recovered from measles, scarlet fever, or other infantile disease.

OPERATION FOR HARE-LIP.—In the treatment of hare-lip, there are three main objects to be kept in view: 1. The procuring of union by the direct adhesion of the out edges of the fissure; 2. The prevention, as far as possible, of deformity during the process of union, and, 3. The avoidance

of all traction on the line of incision that may interfere with these results.

These principles of treatment are carried out by paring the edges of the fissure freely, bringing them together by means of the twisted or interrupted suture, and taking off all tension by means of strips of plaster and the cheek-compressor. But the details of the treatment vary so much, according as the fissure is single or double, or complicated by more or less projection of the intermaxillary portions, that the steps of each operation require to be separately described.

Single Hare-lip.—The operation for single hare-lip is performed in the following way. The child having been well pinned in a jack-towel that swathes it tightly, the surgeon, sitting down, places his feet on a stool so as to raise them; and, covering his knees with a piece of tarpanlin, holds the child's head firmly between them. He first freely divides the frænum and all membranous connections between the angle of the cleft and the gum of the upper jaw, and then, putting the lip on the stretch by seizing the extreme edge of the cleft with a pair of artery-forceps or a tenaculum, pares the edges of the cleft by transfixion with a narrow-bladed bistoury, or fine scalpel, from above downwards, first on one side, then on the other; taking care that the incisions unite neatly and cleanly above the upper angle of the fissure, which must be well cut out; and that they extend sufficiently far outwards to cut away the rounded portion of the prolabium which forms the side of the base of the fissure. Care should be taken that enough is cut away; there is more danger usually of taking too little than too much.

In single hare-lip, where the lips are very lax, the incisions may be straight; but if the gap be wide and the tissue deficient, or in double hare-lip, they should be somewhat concave inwards; in this way there is less likelihood of an unseemly notch being left (Fig. 353).

Fine hare-lip pins, made of soft iron wire, with steel points, should then be deeply introduced through the lip from one side of the fissure to the other. The pins should be entered at about a quarter of an inch from the pared edge on one side, and brought out at a corresponding point on the other; care being taken that, though they are passed deeply, the mucous membrane is not transfixed—if it be, it will be doubled into the wound, and thus interfere with union. Two pins are usually required: if the child be some years old, and the fissure very long, three may be used. The lower pin should be introduced first underneath or through the cut labial artery, in such a way that its pressure may stop the bleeding from this vessel, which is often rather free: in passing this pin, great care should be taken to bring the opposite sides of the fissure well into contact, so as to be on a level below, that no irregularity may be left in the prolabium. The twisted suture is then applied

Fig. 351 —Application of Twisted Suture.

Fig. 352 —Application of Pins and Sutures in Hare-Lip.

in the usual way, (Fig. 351) first round the lower pin, and then round the upper one (separate threads, however, being used for each); and lastly, the two are united by a few cross turns, so as to press down and support the whole length of the fissure (Fig. 352). In applying the twisted suture, the surgeon

must be careful, whilst drawing the edges closely into apposition, not to apply the threads too tightly, lest sloughing result; and in crossing the from one pin to the other, great caution must be used not to draw the pins together horizontally, lest puckering of the line of union take place. The pins are then cut short, the whole is coated with a layer of collodion, and a piece of plaster is put under the ends of the pins to prevent excoriation of the skin. In addition to the pins and twisted suture, I invariably introduce one point of interrupted suture through the mucous membrane of the lower part of the fissure, just inside the mouth; and I look upon this of great consequence in order to prevent the notching, which is otherwise very apt to occur, in consequence of that portion of the incision between the lower pin and the edge of the lip being kept open by the child in suckling or protruding its tongue against it. At the end of from 72 to 96 hours, according to the age of the child, the pin should be withdrawn, or it may be removed by pushing it through the lip by a gentle rotatory movement, in a way that the cut end does not tear or lacerate the aperture in the lip. The threads, matted together with exudation and a little blood, form a good crust which may be left on for two or three days longer, and then allowed to separate of itself; the less any crusts that form over the line of incision, and interfere with, the better will usually be the result. The lip may, if thought desirable, be supported by a strip of adhesive plaster, which should, indeed, be continued for about a fortnight after the operation, so as to prevent stretching of the cicatrix and notching of its lower part. The point of interrupted suture may be left in for about four days. It sometimes, though rarely, happens in single hare-lip that the intermaxillary portion is so large and projecting, that there is difficulty in bringing the lateral segments together of it. Should this be the case, the better plan is to notch it at its alveolar border in the side that is not fissured, and then to break it back so as to remove all projection. If the fissure be wide, and the child restless, so that there is danger of the parts being dragged upon during its screaming or crying, it is a very good plan to apply the spring cheek-compressor, invented by Mr. Hainsby, here represented (Fig. 353). Indeed, whenever

obtainable, this excellent contrivance should be employed. Its use adds greatly to the success of the operation.

Double Hare-lip.—The operation of double hare-lip is performed on the same principle as that for the single form of the disease, viz., of procuring union by adhesion between the opposite surfaces. The difference in the operations consists chiefly in dealing with the intermediate portion of the lip and alveolus. The management of the intermaxillary process must vary according to its size and degree of projection. If it be small and rudimentary, or fixed to the tip of the nose, as in Fig. 355, it should be cut off with bone-nippers, as it would prevent the lateral segments from coming into proper apposition. More commonly, when this is done, there is

Fig. 353.—Hare-lip. Spring Cheek-compressor

and even dangerous bleeding from a dental artery deep in the bone, which requires to be touched with a red-hot needle or wire before the hemorrhage from it will cease. If the central intermaxillary portion be large and projecting

ould be bent or broken back by strong forceps covered with vulcanised rubber. If it be large and not projecting, the soft parts should be pared on each side, and transfixed by the hare-lip pins, and thus be joined between and united to the pared lateral surfaces; indeed, it is always advisable not to remove this, unless it be awkwardly situated, as in 354. When it is left, though the union may not appear quite so perfect

Fig. 354.—Hare-lip. Projecting intermaxillary portion.

Fig. 355.—Hare-lip. Intermaxillary portion fixed to nose.

and uniform as it would if the lateral halves had been directly united, yet eventually the case will turn out better; the central portion becoming developed, and forming the natural mesial projection of the lip, which is lost when the lateral halves are directly united. Butcher has invented some very simple and ingenious forceps for the partial section and bending back of the intermaxillary process. In some of these cases great nicety is required in planning the incisions, and in the introduction of the sutures. The central portion is most advantageously pared in a somewhat concave manner, so that the freshly cut edges of the lateral halves are received into and more accurately fitted upon it. Should, as often happens in single as well as in double hare-lip, one of the lateral segments be tied down to the gum and alveolus by a doubling of mucous membrane, this must be freely divided, and the portion of lip, with perhaps the corresponding ala of the nose, freely dissected up from the osseous structures, so as to admit of its being moved forwards without too much traction being put upon it.

Treatment by Simple Suture.—During several years I have been in the habit of treating hare-lip of all kinds, double as well as single, with the simple interrupted suture alone, without using any pins. I have in this way treated most successfully many cases in children, whose ages have varied from a few days to four years, with most satisfactory results, and with less marking of the lip than I have ever seen attend union by means of the twisted suture, to which I now generally prefer the simple suture as being equally safe, more simple, and followed by less scarring of the lip, provided the case be not too complicated, nor associated with very wide fissure in the palate, or with great projection of the intermaxillary bones. In these circumstances, the pins should be preferred.

When the fissure is single, the edges, having been pared in the usual way, should be brought together by two points of suture; the first passed deeply near the free edge, and in such a way as to compress the cut coronary artery; the other nearer the nasal angle. These sutures should be of thick well-waxed dentist's twist that will not cut out too readily, or, what is better, of silver wire. A point of fine interrupted suture should then be inserted through the mucous membrane inside the lip. The lip may then be supported by two narrow strips of plaster, one placed between the sutures, the

other between the upper suture and the nose. On the third day the upper suture should be taken out, but the lower one may be left in for a day or two longer, when it and the one through the mucous membrane may be removed together, unless the latter has already cut its way out. If silver wire sutures are used, they may be left in for six or seven days without producing irritation. The lip must then be supported for a few days with a strip of plaster.

In the case of double hare-lip the same plan is to be adopted, first on one side, then on the other; but here, as the gaps are wider, and the tension, more particularly when the intermaxillary prominence is very projecting, is apt to be considerable, it is necessary to support the cheeks, and thus to prevent undue traction on the stitches, by means of the cheek-compressor. In this way all risk of the stitches cutting out before union is completed is avoided; and excellent and solid union will speedily be obtained, even in cases of double hare-lip, with some intermaxillary projection and fissured palate.

The operation occasionally fails. The probability of the occurrence of such an untoward event is, however, greatly diminished by the use of the cheek-compressor. It may, however, happen either in consequence of the child's health being in an unsatisfactory state, so as to prevent union by the first intention; or in consequence of the pins having been withdrawn too early, before secure cohesion has been effected. Under such circumstances as these, an attempt might be made to unite the granulating edges by the re-introduction of the pins or sutures, and by firmly fixing the lip by means of the cheek-compressor. Such attempts, however, rarely succeed; should they not do so, it will usually be found most prudent to wait at least a month before taking any further steps, and then to pare the edges afresh and repeat the original operation.

CONGENITAL TRANSVERSE FISSURES OF THE CHEEKS, extending from the angle of the mouth to the anterior border of the masseter or up towards the malar bone, are occasionally met with, and have been specially described by Klein and Nicati. Such malformations require to be treated on exactly the same principles, and with the same attention to details, as hare-lip; union between the pared edges being effected by means of hare-lip pins and the twisted suture.

CHEILOPLASTY.—Simple plastic operations are commonly practised on the lower lip for the removal of cancrroid disease, by cutting out a V-shaped piece of the lip, including the whole diseased structure, and then bringing together the opposite sides of the incision by hare-lip pins. These operations have already been described and figured at page 860. We shall consider here those cases in which it becomes necessary to repair more or less extensive loss of substance in the labial structures. The restoration of a portion of the lip that has been destroyed by accident or disease, is not so readily effected as that of the nose; yet a good deal may be done to restore the deformity. The plan originally introduced by Chopart consists, when it is the lower lip that is deformed, in carrying an incision from behind the lower jaw down to the hyoid bone, so that a square flap may result, which is detached from above downwards. This flap is then brought up, and fixed to the pared edges of the remaining portion of the lip by points of suture; the head being kept properly inclined, in order to prevent undue tension. After sufficient union has taken place to preserve the vitality of the flap, its lower attachment may be divided. The flap should, if possible, not be twisted, though it is not always practicable to avoid this. This operation is not usually very satisfactory in its results, as the new flap is apt to become

oedematous and inverted at the edge, or the flow of saliva may interfere with proper union. In those cases in which the greater portion of the lower lip has been excised for cancerous disease affecting its upper margin, the most successful procedure for the restoration of the deformity consists in a modification of the plan recommended by Serres; and from this I have derived excellent results, as in the case which is here represented (Fig. 356). The

object of the operation is to raise the lower lip to a level with the incisor teeth. An incision, about three quarters of an inch in length, is made directly outwards from the angle of the mouth, on each side, into the cheek; from the extremity of this, a cut is carried obliquely downwards on to the upper margin of the lower lip, so as to excise the included triangular piece;

Fig. 356 — Lines of Incision in Cheiloplasty Fig. 357 — Incisions and Sutures in Cheiloplasty

the lower lip is then dissected away from the jaw, from the inside of the mouth, and a V-shaped piece is taken out of its centre. By means of a hare lip pin on each side, and a point of suture, the incisions in the angle of the mouth are brought accurately together; and in the same way the vertical one, in the centre, is united (Fig. 357). In this way the whole of the lower lip is raised, and brought more forwards. If care have been taken, in removing the cancer from the edge of the lip, to leave the mucous membrane rather long (which may always be done, as the skin is affected to a greater extent than it), a good prolabrum may be formed, and the restoration effected with but little deformity. Care must be taken to prevent union from occurring between the inside of the lower lip and the gum, by the interposition of a strip of oiled lint.

Dr. Buchanan, of Glasgow, as far back as 1841 published an account of a method for restoring the lower lip when affected by extensive cancerous

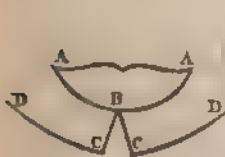

Fig. 358

Fig. 359

Fig. 360.

Buchanan's Operation for the Restoration of the Lower Lip.

disease, which leaves most satisfactory results. The accompanying figures illustrate the kind of case in which Dr. Buchanan's operation is applicable,

the lines of incision required, and the appearance presented by the chin and lip after the disease has been removed, and the flaps brought into proper apposition.

The steps of the operation are simple, and the result is excellent.

The diseased part of the lower lip is first removed by an elliptical incision (Fig. 358, *A B A*). An incision, *B C*, is then carried downwards and outwards on each side on to the chin; and another incision, *C D*, upwards and outwards parallel to, and corresponding in length to, *A B*. The flaps formed by these incisions are represented in Fig. 359. They are detached from their subjacent connections; and the whole is raised upwards, so that the original elliptical incision comes into a horizontal line, and is made to constitute the margin of the new lip; the secondary incisions under the jaw coming together in a vertical direction, in which they are retained by twisted and interrupted sutures (Fig. 360).

PLASTIC SURGERY OF THE PALATE.

Various degrees of congenital deformity may occur in the palate and uvula; thus the uvula alone may be bifid, or the cleft may extend through the greater part of the whole of the soft palate; or the hard palate may be divided as well (Fig. 361); and, lastly, the separation may extend forwards to the integuments of the face, producing single or double hare-lip. The soft palate and uvula are not unfrequently cleft without the hard palate being divided; and, in some very rare cases, the lip and the hard palate are fissured without the soft one being cleft.

Fig 361. Fissure of Hard and Soft Palate

These malformations necessarily give rise to great inconvenience, by interfering with deglutition, and rendering speech nasal and imperfect. During the swallowing of fluids, there is a tendency to regurgitation

through the nose, though this is occasionally prevented by the approximation of the edges of the fissure in the soft palate.

Age for Operation.—In the treatment of these malformations, the first question to be determined is the age at which the operation should be performed. As the success of the operation depends in a great measure upon the patient remaining perfectly tranquil and steady during the necessary procedures, which are of a tedious and protracted character; upon his assisting the surgeon by opening his mouth, and not struggling on the introduction of the instruments; and, after the operation, upon his making as little movement as possible in speech or deglutition for some days; it is usually considered expedient not to interfere with this malformation until the patient has attained the age to understand the necessity of remaining quiet, and to be able to control his movements; yet some observations by Ferguson and Sedillot have shown that the necessary operation may be done successfully on young children. It need scarcely be remarked, that the general health ought to be in the best possible state, before any procedure requiring immediate union of parts be attempted.

STAPHYLOPLASTY.—The operation for the cure of a cleft in the soft palate may be said to have been introduced by Roux; for, although several attempts at the cure of this deformity had been made by surgeons before his time, yet he was the first to establish Staphyloplasty as a distinct operation. Many

modifications of Roux's plan have been practised by Grafe, Warren, Dieffenbach, Liston, and others, in order to render it more easy of execution and certain in its results, and especially by making incisions through it so as to take off the traction on the sutures, but to Fergusson is due the great merit of introducing a new principle of treatment in the operation—viz., the application of myotomy to it, thus paralysing the movements of the muscles of the palate. Fergusson found that the great cause of failure in these cases was the mobility of the parts, and the traction exercised by the muscles, principally the levator palati and the palato-pharyngeus, on the line of union; in order to obviate this, he conceived the happy idea of dividing these muscles. Before Fergusson laid down the principles of this operation it is true that various cuts had been made in the palate by different surgeons, with the view of taking off the tension after the sutures were tied. Thus Dieffenbach, Pancoast, and Liston, all recommend that the traction on the stitches should be lessened by longitudinal or transverse incisions across the *velum pendulum palati*. Mettauer practised several small incisions for this purpose; and Mason Warren divided the anterior pillar of the fauces and its attachments to the posterior pillar, coming nearer than any previous operator to Fergusson's method. These operations, however, were done almost at haphazard, and in an empirical way, without the recognition of any distinct principle being involved in them.

In the operation as performed by Fergusson, there are four distinct stages. 1. *The muscles of the palate are divided*, by passing a curved lancet-ended knife through the fissure behind the velum, midway between its attachment to the bones and the posterior margin, and about half-way between the velum and the end of the Eustachian tube. By cutting deeply with the point of the knife in this situation, the levator palati is divided. The uvula is then seized and drawn forwards, so as to put the posterior pillar of the fauces on the stretch, which is to be snipped across, so as to divide the palato-pharyngeus. The anterior pillar, the palato-glossus, may then be notched in a similar way. 2. *The next step in the operation consists in paring the edges of the fissure from above downwards*, by means of a sharp-pointed bistoury. This is best done by seizing the lower end of the uvula, putting it on the stretch, and cutting first on one side and then on the other, leaving the angle of union to be afterwards removed. The patient should then be allowed to remain quiet, and to gargle the mouth with cold water or to suck ice, so as to stop the bleeding. 3. *When the bleeding is arrested, the surgeon proceeds to the next step, that of introducing the sutures*; this may be done by means of a *nerve-needle*, armed with a moderate sized thread, being passed from below upwards on the left side of the fissure, about a quarter of an inch from the margin; the thread should now be seized with forceps, and one end of it pulled forwards through the fissure. This may again be threaded in the needle and passed through the opposite side of the fissure from behind forwards through the right side; as the point of the needle appears, the thread should again be seized and the needle at the same time withdrawn; the suture is then tied by means of the surgeon's knot; and in this way, according to the extent of the fissure, from two to four sutures may be passed and tied lightly, and the knots cut close. An important improvement in this method of passing the sutures is now very generally adopted. It consists in passing a single suture through the left side of the cleft from before backwards in the usual way. A needle, having an eye at its point, and threaded with a loop instead of a single thread, is now passed through the right side of the cleft, the loop drawn through, and the needle removed. The single suture is then slipped through the loop.

This is then withdrawn, carrying with it through single ligature. In this way the sutures, being before backwards, can be inserted more evenly puckering when knotted. In tying the knots, that no undue traction be exercised upon the sutures is not to draw, but simply to hold, the of the muscles has caused these to be relaxed, so and merely require to be held in apposition must next be put to bed, and every care taken the palate. He should be restricted to fluid days, and should be directed to swallow this and indeed should not be allowed anything solid taken place. All coughing, spitting, or swallowing interdicted. 4. *The stitches should be left in* need not be disturbed so long as they produce require removal by the eighth or tenth day, with advantage for some time longer, until the union is perfect; they should then be cut out, the upper one first, the middle next, and there be any aperture left in the palate, where this may be closed by touching it with a point.

The voice in these cases does not usually at after the operation, although in some cases it month or six weeks, the patient may advantage of instruction, with the view of regulating the the actions of the soft palate.

In dividing the levator palati, Pollock adopts that of Fergusson. Instead of cutting from through the curtain of the soft palate so as to then pushing a narrow-bladed knife through side of the hamular process, he readily dividing raising the handle and depressing the point. levator palati, which is analogous to the plan Sédillot (Figs. 362—364), appears to be more

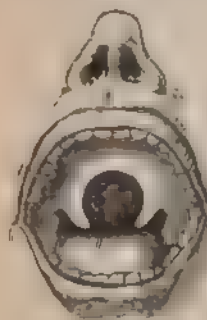

Fig. 362.

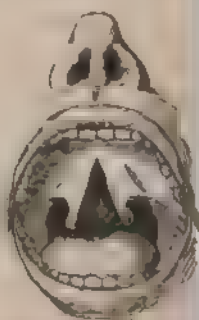

Fig. 363.

Sédillot's Operation for Stenopharynx

than the division of the muscles of the velum from left closes without difficulty by granulation, and tension from the parts.

CRANOPLASTY.—*Fissures of the Hard Palate* are usually closed by means of "obturators" made of gold, vulcanised India-rubber, or ivory. To Dr. Warren, of Boston, is undoubtedly due the merit of having been the first to close these fissures by a surgical operation. This he did by dissecting the soft tissues from the palatal arch between the margin of the cleft and the edge of the gum, and then uniting them in the middle line by means of stitches in the same way as in fissured soft palate. This operation has been brought before the Profession in this country by Avery and Pollock, who have invented some ingenious instruments for its proper performance.

The operation is performed in the following way. An incision having been made along the edge of the cleft, at the junction of the nasal and palatal mucous membranes, the soft covering of the hard palate is carefully dissected or scraped down off the bones by means of curved knives, great care being taken that the mucous membrane and its subjacent fibro-cellular tissue, which varies greatly in thickness in different cases, be not perforated. Langenbeek has particularly recommended that the periosteum be detached with the fibro-mucous tissue. When these structures have been well loosened on each side, the covering of the palate will be found to hang down as a curtain from the vault of the mouth,—the two parts coming into apposition along the mesial line, or possibly overlapping.

The edges, being then smoothly pared, are brought into apposition by means of a few points of suture, introduced in the ordinary way and without any dragging. On this point great care is necessary. The knots having been tied, the patient is confined to bed for several days, and allowed an abundant, but fluid or pulpy diet. Union will usually be found to be perfect at the end of a week. At a later period, the fissure in the soft palate, which always accompanies that in the hard, should be closed: but it is of the greatest consequence that this should not be attempted at the same time that the operation is done on the hard palate.

PERFORATION OF THE HARD PALATE.—Perforations of the hard palate, consequent on necrosis of the bones, the result of syphilis or injury, are not amenable to surgical treatment. In such cases, a well fitting obturator will most effectually remedy the inconvenience.

CHAPTER LIX.

OPERATIONS ON THE AIR-PASSAGES AND CHEST.

LARYNGOTOMY AND TRACHEOTOMY.

The windpipe may either require to be opened to allow of the formation of a temporary breathing aperture, in consequence of the obstruction of the larynx by causes that are speedily removable; or it may be necessary to establish a permanent opening in the air-passages in those forms of chronic laryngeal disease, in which the obstruction depends upon organic alterations of structure which are not remediable.

Among the conditions requiring *temporary aperture*, may be mentioned all acute inflammatory affections of the larynx that give rise to obstructive oedema of the glottis; also traumatic conditions, such as the impaction of masses of food in the gullet, inducing asphyxia, and not capable of being immediately removed; scalds of the rima glottidis; the presence of foreign bodies in the

air-passages; and œdema of the glottis from wounds of the thyro-hyoid membrane.

The establishment of a *permanent aperture* in the air passages is especially required in chronic diseases of the larynx, attended by thickening of the mucous membrane, by abscess, or by necrosis of the cartilages—in fact, by any such conditions as do not admit of removal; so also, in polypi of the larynx, a permanent opening below the obstructed point may be required.

Opening the Windpipe in Croup and Diphtheria.—The question as to whether the windpipe should be opened in cases of croup has been much discussed. Were croup merely a disease of the larynx, and did death in it result from simple laryngeal obstruction, it would doubtless be proper to perform this operation. But in croup there are two distinct sources of danger; 1, that arising from asphyxia dependent on laryngeal inflammation, obstruction by plastic deposits, and spasm; and 2, that which is due to the extension of inflammatory action below the larynx into the bronchi and lungs. By tracheotomy we can doubtless remove so much of the danger as arises from the laryngeal obstruction, but we cannot remove that which is dependent on the often concomitant broncho-pneumonia. In this respect the propriety of performing tracheotomy in the croup of children differs remarkably from the expediency of having recourse to the same operation in the acute laryngitis of adults, in which the lungs are rarely implicated to a serious extent. In fact, the question as to the performance of tracheotomy in the croup of children must be answered by the amount of laryngeal asphyxia and the extent of pulmonary implication. If the child be in danger of death from uncomplicated laryngeal inflammation, obstruction, and spasm, timely tracheotomy will undoubtedly rescue it from this immediate danger, and will be a proper operation; but, if extensive broncho pulmonary inflammation already exist, it will be worse than useless, and should on no account be practised. A serious objection to the performance of tracheotomy in the croup of young children is, that it is by no means an easy operation or one devoid of immediate danger. If chloroform be not given, the struggles and writhings of the child will materially embarrass the surgeon in his attempts at opening the windpipe. But even if chloroform be administered, which should always be done when practicable, and this source of difficulty removed, there is, unless care be taken, no little danger of hemorrhage; and I have heard of several cases in which this has occurred to a fatal extent. Although, therefore, as a general rule, I fully agree with Porter in reprobating this in ordinary cases of croup, yet cases are doubtless occasionally met with, in which the disease is so clearly limited to the larynx—the respiration being free throughout the lungs and bronchi—that the surgeon may feel himself justified in endeavouring to save the little patient, struggling against overpowering asphyxia, by opening the windpipe. In several such cases, to which I have been called by other practitioners, and which were apparently most favourable to the operation, I have considered myself justified in doing this, though rarely with ultimate success. I believe that the general experience of British surgeons is unfavourable to it. On the other hand the French surgeons, and more particularly Trousseau, are strenuous advocates for the performance of tracheotomy in croup, and the operation is accordingly far more extensively practised in France than in this country. But even in Paris it is not a very successful procedure; thus it appears that, at the Hospital for Sick Children in that city, the operation was performed in 215 cases in five years, and that of these only 47 were cured. Unless we assume

that the disease, as occurring in Paris, is different from the form of croup we meet with here, it may fairly be doubted whether an operation which is in itself dangerous could be necessary in many of these instances, and whether a large proportion of the children might not have recovered under ordinary medical treatment and without having recourse to operation.

In *Diphtheria*, as in croup, there are several sources of danger. There is not only peril from the obstruction of the pharynx and larynx, by inflammation and the accumulation of exudation-matter, to such an extent as to induce asphyxia, but there is also liability to pulmonary inflammation and congestion, blood poisoning, and exhaustion of the system. In diphtheria, as in croup, tracheotomy may be performed when the patient is in imminent danger of death from laryngeal obstruction; and by it the fatal event may be warded off so far as it arises from this cause, and time be thus afforded for proper treatment. Even though the relief afforded by tracheotomy be only temporary in the majority of cases, and the patients generally eventually die of the constitutional symptoms, yet it is obviously proper in cases still uncomplicated, and where the danger of death from laryngeal asphyxia is imminent, that the surgeon should rescue the patient from his instant peril, and give him his only chance of prolonging or of preserving life, by opening the windpipe,—the trachea in children, the larynx in adults, being most suitable for operation. It has been very justly observed by Dr. Jenner that, by opening the windpipe in these cases, we save the patient from so terrible a death as that by asphyxia; and even if life be ultimately extinguished by the disease, temporary ease will have been afforded the patient, and death will occur in a less distressing manner; and that, if only one life in a hundred could in this way be saved, we should be justified in having recourse to the operation.

The prospect of saving life after opening the windpipe in cases of diphtheritic asphyxia will greatly depend upon the age of the patient. Under two or even three years of age, recovery is extremely rare; as age advances, the chance of life proportionately increases, and in adults the prospect of recovery is considerable. In many cases the patient will get great temporary benefit from the operation, and will appear to be doing well for several days, perhaps for eight, ten, or fourteen; and then to the great disappointment of the surgeon he will die, not from the effects of the operation, but from blood-poisoning or from the extension of the disease to the bronchi and lungs.

After operations of tracheotomy in croup and diphtheria, it is a question how long the tube should be left in. As a general rule, I think from three to four days are sufficient, care being taken to cleanse it thoroughly during this period. After withdrawal, respiration will in a great measure be carried on through the aperture, which will but gradually close. Should this prove insufficient, the tube may always be inserted again. Occasionally false membranes are expelled, or may be withdrawn from the opening in the windpipe; and through it the interior of the larynx may be spunged out with solution of nitrate of silver, if thought desirable.

NECESSITY FOR PROMPTITUDE.—When it has been determined to open the windpipe for acute disease, more especially supervening on chronic laryngitis, the less delay there is in having recourse to operation, the better; as the patient may at any moment be seized with laryngeal spasm, and be carried off. The operation ought always, however, to be completed, even though the patient have apparently expired before the windpipe has been opened; for resuscitation may, even in these extreme cases, be effected by artificial respiration. When life hangs on so slender a thread as it does in urgent cases of laryngeal obstruction, the first touch of the knife may cause a

spasmodic seizure that may give rise to apparent death. It has twice happened to me to operate under such circumstances, and in both cases to be fortunate enough to save the patient's life. In one case to which I was called some years ago by my friend Mr. E. Baker, the patient, an elderly woman, was apparently dying from the supervention of acute upon chronic laryngeal disease. I lost no time in making an incision into the crico-thyroid membrane, but at the first touch of the knife she sank back apparently dead. I immediately completed the operation, and introduced a large silver tube, through which the lungs were inflated; in the course of a few minutes, the action of the heart recommenced, and the patient eventually recovered. She has never, however, been able to breathe without the silver tube, which she wears in her windpipe up to the present time. In another case to which I was hastily summoned by my friend Mr. Tweed, I found the patient, a young woman, in the last stage of asphyxia from acute disease of the larynx. I immediately proceeded to operate, with the assistance of my then house-surgeon, now the Professor of Surgery at Glasgow, Mr. Lister. As the patient's neck was short and thick, and the veins excessively turgid, there was profuse hemorrhage on the first incisions being made; while we were waiting a minute or two until this would cease before opening the windpipe, the patient fell back and apparently expired. I lost no time in plunging the scalpel into the crico-thyroid membrane, and cutting down through the cricoid cartilage, so as to make a free aperture into the air-passages. On endeavouring to set up artificial respiration, I found the chest clogged with inspissated mucus, which prevented the entrance of air into the lungs; the life of a fellow-creature being at stake, and dependent on the immediate and full establishment of artificial respiration, I felt that there was only one thing to be done—to empty the chest of the matters loading it, and that this must be done instantaneously. I accordingly applied my lips to the wound, and sucked out three or more mouthfuls of blood and mucus, when I had the satisfaction to see that air could be made to enter the lungs. By keeping up artificial respiration for some time, the heart began feebly to act, the face to become less livid, and the circulation to be re-established, the patient eventually did well, and is now alive and in good health.

OPERATIONS.—In opening the windpipe, the surgeon has the choice of two situations in which he may make the aperture; either in the crico-thyroid membrane by *Laryngotomy*, or in some part of the trachea by *Tracheotomy*. Besides these two established operations, some surgeons have performed a third—*Laryngo-tracheotomy*, by opening the crico-thyroid membrane, and dividing the cricoid cartilage with the upper rings of the trachea.

Whichever operation is performed, so soon as the windpipe is opened, the patient is seized with an attack of spasm and convulsive cough, often attended by much struggling and distress, during which the whistling occasioned by the passage of the air through the new passage is very loud and marked. The patient, however, soon recovers himself, and then breathes naturally and easily, the signs of asphyxia disappearing.

LARYNGOTOMY is an easy operation. The crico-thyroid membrane is almost superficial, and may readily be reached by making a vertical incision in the mesial line, between the sterno-thyroid muscles, about an inch in length, and then a cross cut through the membrane with an ordinary scalpel. The air-passages having thus been opened, a silver tube, curved on the flat, may be readily introduced and retained by tapes round the neck. The only troublesome result that can occur in this operation is the wound of a small arterial branch, the inferior laryngeal, which crosses the membrane.

I have never seen any trouble arise from this ; but, should it occur, the hemorrhage would readily be arrested by the application of pressure or suture.

TRACHEOTOMY consists in making an opening into some part of the trachea, exposing the tube and cutting across one or more of its rings.

In performing tracheotomy, the patient's shoulders should be supported with pillows, and his head be thrown as much back as practicable. An incision about an inch and a half in length should then be made with a scalpel, directly in the mesial line, from the cricoid cartilage downwards, after dividing the integuments, any veins that present themselves should be avoided as carefully as possible, being held aside with a blunt hook. By using the point of the scalpel to a limited extent, and dilating the deeper portions of the incision with its handle or with a director, the trachea may be reached with safety.

Fig. 365.—Operation of Tracheotomy.

It should then be transfixed and drawn forwards by a sharp hook, and opened by pushing the point of the knife, with its back turned towards the sternum, between two of the rings, and cutting upwards, through about three of them (Fig. 365). The tube must then be introduced, and retained by tapes round the neck.

The question as to the safety of the administration of chloroform in these operations often occurs. I believe that it may always be given safely except in cases of extreme syncopal asphyxia, where, as sensibility no longer exists, it is unnecessary. Laryngeal inflammation and obstruction is always associated with so much spasm, more particularly in children, that it will often be found that the patient respire more easily and fully whilst under the influence of chloroform than before it commenced its inhalation ; and, as the anaesthesia materially facilitates the operation by doing away with his writhings and strugglings, I now invariably have recourse to it where I perform tracheotomy on children. In laryngotomy in the adult, it does not appear to me to be necessary.

Difficulties.—This operation is often attended by extreme difficulty, and not unfrequently by much danger.

The difficulties occurring in tracheotomy are chiefly referrible to four heads, 1, Difficulty in Exposing the Air-tube ; 2, Profuse Hemorrhage ; 3, Difficulty in Opening the Air-passages ; and 4, Trouble in Introducing the Trachea-tube.

1. The difficulty in *Exposing the Tube* increases greatly as the incisions approach the sternum, and is especially great in children and in stout short-necked persons.

There are three situations in which the trachea may be opened ; either above, underneath, or below the isthmus of the thyroid body, which usually crosses the air-tube opposite its third or fourth ring. Above the isthmus, the trachea is comparatively superficial, and is not covered by any venous plexus, nor does any other source of difficulty present itself to the surgeon.

Where the isthmus crosses the trachea, this tube is overlaid by a venous plexus as well as by the glandular structure. Below the thyroid gland, the air-tube is overlapped by the sterno-hyoid and sterno-thyroid muscles, and by the inferior thyroid veins, which are of large size, together with some tracheal branches from the inferior thyroid artery; and not unfrequently an irregular arterial branch ascends in this situation in front of the trachea to supply the thyroid body. The carotid arteries also are in close relation to the trachea on each side; and opposite the episternal notch it is crossed by the left carotid and by the innominata, which vessel has been seen by Macilwain to cross the tube at the very point where tracheotomy is usually performed. A glance at these important relations will suffice to indicate the difficulty that must, in many cases, occur in exposing and opening the trachea. This difficulty is greatly increased when the veins of the neck have become turgid in consequence of the pulmonic obstruction. It will also be seen that the trachea is less covered, and may consequently be much more readily reached above, than below the isthmus of the thyroid gland. Though some surgeons, as Velpeau for instance, have recommended the opening to be made in the lower part of the tube, no advantage whatever is gained by so doing, whilst the difficulties of the operation are only seriously increased; and in practice it is almost invariably opened at its upper part, usually between the second and third or third and fourth rings, though the incision may, if necessary, be carried downwards as low as, or even through the isthmus.

2. The *Hæmorrhage* may occur either from arteries, from veins, or from the thyroid gland. Arterial hæmorrhage is less frequent and troublesome than the bleeding from other sources. When it occurs, it chiefly happens from the wound of some anomalous branch, or from that of the small tracheal vessels. Desault has, however, mentioned a fatal case, in which death arose from a wound of the carotid. The arterial anastomosis of the isthmus of the thyroid body may, if this part be enlarged, occasion some difficulty in the performance of the operation; but the main source of danger unquestionably proceeds from the *venous bleeding*. Not only are the plexuses of veins of large size, more particularly where they cover the lower part of the trachea, but they become immensely gorged by the asphyxia that necessitates the operation. Hence, when they are wounded, the bleeding may be so abundant as scarcely to be controllable, and may very greatly retard the after-steps of the operation. Many surgeons of authority in these matters advise that the windpipe should not be opened until all, or nearly all, the bleeding has ceased; lest the blood, entering the bronchi and lungs through the aperture, asphyxiate the patient. But in this way much valuable time may be consumed, and the patient may be fatally exhausted by a tedious and prolonged operation, and by the loss of an unnecessarily large quantity of blood. The hæmorrhage in this operation is almost entirely venous, and is, in a great measure, dependent on the distension of the veins of the neck, which occurs in asphyxia as the result of the accumulation of blood in the right cavities of the heart, consequent upon the obstructed circulation through the lungs; and the bleeding will continue so long as that obstruction remains unremoved. But as the respiratory process is re-established, this obstruction to the pulmonic circulation diminishes, the cardiac cavities become unloaded, the venous turgescence of the neck subsides, and the hæmorrhage proportionately lessens. This I have repeatedly found in asphyxia artificially induced in animals; and I have often seen it in the human subject, in cases in which it has become necessary to open the windpipe at once, without waiting to arrest hæmorrhage. Hence, except in

those instances in which an arterial twig or large venous trunk has been wounded, and which must of course be secured, the occurrence of bleeding, though tolerably smart, need not deter the surgeon from opening the windpipe; as the relief afforded to respiration will induce a corresponding and rapid diminution in the venous turgescence of the neck, and in the consequent flow of blood from the wound.

3. Another difficulty in tracheotomy sometimes attends the process of *Opening the Trachea* after it is exposed. In consequence of the convulsive breathing of the patient, the sterno-mastoids are put upon the stretch, thus increasing considerably the depth of the wound in the neck; and, at each short and gasping respiration, the air-tube is rapidly pumped or jerked to and fro, approaching to and receding from the surface in such a way that the scalpel cannot be thrust into it with safety. In order to do this with the least risk, a sharp-pointed hook should be passed between two of the rings, and the tube, being thus fixed, opened by cutting upwards (Fig. 365).

Fig 365.—Trachen-hook—Director.

the hook, being grooved along its convexity, as Dr. Edwards recommends (Fig. 366), is to be introduced under the cricoid cartilage, and the air-tube pulled up and opened by sliding the scalpel along the groove of this hook-director. I have found it advantageous in some cases to open the trachea with a cutting hook, such as is here represented (Fig. 367). By means of

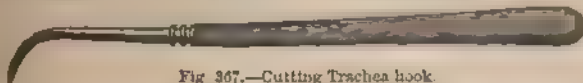

Fig 367.—Cutting Trachea hook.

an instrument of this kind, the trachea is first fixed and then divided without danger to the patient. The danger from hemorrhage, and the difficulty in opening the trachea, are much greater in children than in adults. Before the age of puberty, this tube is deeply seated, covered with a quantity of loose granular fat, containing many veins, and is of small size, so that a slight deviation of the incision to one side or the other may readily lead the surgeon astray, and into dangerous proximity with the carotid artery.

4. After the trachea has been opened, the next point is to *Introduce a proper Tube*. In doing this, special care must be taken not to push the tube into a sort of pouch which always exists at the lower angle of the wound, between the trachea and the deep fascia of the neck. This error is not only embarrassing in the highest degree to the surgeon, but dangerous to the patient by the delay it occasions, by the compression exercised on the trachea below the opening into it, and by the suction of blood into the aperture in the air-tube. It is best avoided by expanding the tracheal opening with the dilator (Fig. 370), and passing the tube between the blades of that instrument. In the first instance, a tube of a conical shape should be employed, as it is not only introduced more readily than a cylindrical one, but fills up completely the aperture in the trachea, so as to prevent the draining of blood into the lungs. In passing the tube into the trachea some difficulty may be experienced, owing to the elasticity of the sides of the incision in the windpipe, in consequence of which one of them is apt to get doubled in under the end of the instrument. This may be avoided by the use

of Dr. Fuller's bivalve tube introduced by slipping a cannula into it (Fig. 369);

Fig. 368.—Bivalve Tube, closed. Fig. 369.—Bivalve Tube with Cannula introduced.

may be held aside with the forceps or a finger under the other. If the rings of the tube are not removed, the silver tube may most conveniently be cut by means of the trachea-forceps between or under their blades.

Some surgeons prefer, instead of the

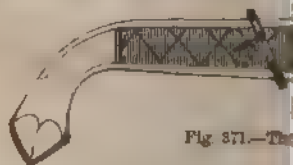

Fig. 371.—The trachea-tube.

cutting forceps (Fig. 371), or with a trachea-tube, which is there left in, though ingenious and in some respects so safe or easy of management, especially the trachea-hook.

Tracheotomy in Children is never an easy operation. The difficulty of the operation arises from the small size of the trachea, and the quantity of blood over it. The danger of the operation arises from the venous plexus in connection with the trachea. In performing this operation, an anæsthetic must always be administered. This may be done even if the most urgent asphyxia be present: the spasm, in great measure, is relieved by the anæsthetic. If not given, the struggles of the child will add much to the danger of the operation. The knife should be carefully placed on the medial line; and, when opened, the knife should be used as a lever, rather pushed and held aside with a finger. The trachea must be raised up by transfixion with the trachea-tube, the knife being neither thrust so deep

turned laterally. As soon as the trachea is opened, the tube should be introduced; and this step of the operation is greatly facilitated by holding the trachea well up and drawing it forward with the hook. When the tube is fairly in, the hook must be withdrawn.

COMPARISON OF TRACHEOTOMY AND LARYNGOTOMY.—On comparing tracheotomy as ordinarily performed, with laryngotomy, I think there can be little doubt that the surgeon should give the preference, in all cases where it is practicable, to the latter operation, on account of its greater simplicity, safety, and rapidity. In all cases in which the obstruction to respiration is produced by inflammatory effusion into the submucous cellular tissue, whether dependent upon idiopathic or erysipelatous laryngitis, œdema glottidis, or chronic disease of the larynx, or upon the irritation and inflammation excited by swallowing boiling water or the stronger acids, the swelling, for reasons that have already been mentioned, never extends below the true vocal cords; hence an opening into the crico-thyroid membrane will always be below the seat of obstruction. An objection, it is true, has been urged to laryngotomy in these cases, that it does not allow of the patient wearing a tube without much irritation being induced. This, however, I have not found to be the case in my practice. I have had patients who have worn silver tubes in this situation a considerable number of years, in one case as many as twelve, and in whom no special irritation has been occasioned by them. When the windpipe requires to be opened for the extraction of a foreign body, tracheotomy should be performed in preference to laryngotomy, as the latter operation does not admit of sufficient space for its expulsion or extraction. In children the larynx is so little developed, that tracheotomy becomes necessary.

In my opinion, laryngotomy is the operation that should, in cases such as above mentioned, be preferred in the adult; and this opinion is based on the following reasons.

1. As in laryngotomy the air-tube is always opened below the seat of obstruction, there can be no necessity to make an aperture farther from the seat of disease. In laryngitis, whether that affection assume the acute or the chronic character, the obstruction to breathing is in a great measure mechanical, and depends upon the infiltration of the submucous cellular tissue of the larynx, and partly of the large plane of this tissue, which lies behind the box of the larynx, and which, by expanding, as it were, into the pharynx, obstructs deglutition, and afterwards, by the extension of this swelling and infiltration to the lips of the glottis and the interior of the larynx, causes an impediment to the entrance of air into the bronchi. But, as has been pointed out by Mr. Prescott Hewett, this submucous cellular tissue terminates at the true vocal cords, where the mucous membrane becomes directly applied to the subjacent fibrous structures; the swelling and consequent mechanical impediment is hence confined to the limits of the thyroid cartilage, and any opening made below this will clear the lowest limit of the disease, which is always accurately and almost mathematically bounded below by the vocal cords. Hence an aperture in the crico-thyroid membrane is quite as effectual as one in the trachea.

2. Laryngotomy is a far safer operation than tracheotomy. On this point I need scarcely dwell; a glance at the anatomy of the parts concerned will be sufficient to establish it. The crico-thyroid membrane is nearly subcutaneous, and no parts of importance can be wounded in opening it, if we except the small inferior laryngeal artery, which crosses it, and which might be cut across, but from which I have never seen any trouble arise. The trachea, on the contrary, is not only deeply seated, but covered by a large

plexus of blood-vessels, which, when rendered turgid by the asphyxiated condition that exists when an operation is required, pours out a large quantity of dark blood, and thus seriously embarrasses and delays the surgeon at a time when the life of the patient depends on the speedy admission of air to his lungs.

3. Laryngotomy can be much more quickly performed than tracheotomy. This I look upon as an inestimable advantage in many of the cases requiring operation; a few seconds, more or less, being sufficient to turn the balance either in favour of life or of death. The rapidity with which laryngeal obstruction—partly mechanical and partly from spasm—sets in, is sometimes so great, more particularly when an acute inflammation supervenes on chronic disease of the larynx, that life may be extinguished before the surgeon has time to open the windpipe, if he endeavour to do so by tracheotomy. In extreme cases, as where the lungs have become slowly engorged, the action of the heart is already enfeebled, and a sudden spasm occurring at the glottis will at once place the patient beyond recovery. But, even though life appear for the moment extinct, it is the imperative duty of the surgeon to open the air-passages as speedily as possible, and to endeavour, by means of artificial respiration, to recall the flickering spark; and it is impossible to experience a greater satisfaction in the exercise of our profession, or to witness a greater triumph of art, than in thus snatching a patient out of the very jaws of death.

Laryngotomy should, therefore, be practised on the adult in impending asphyxia from the following causes:—1. Acute laryngitis; 2. Erysipelatous laryngitis—œdema glottidis; 3. Chronic ulceration and disease of the larynx; 4. Scald of the pharynx, &c., from swallowing corrosive liquids; 5. Spasm from pressure on the recurrent laryngeal nerve; 6. Diphtheritic exudation.

Tracheotomy should, as a general rule, be preferred in children, and should be performed on them for obstruction to respiration from—1. Croup; exudation; 2. Diphtheritic effusion; 3. Swallowing boiling water; 4. Foreign bodies in the air-passages; 5. Impaction of food, &c., in the pharynx.

TRACHEA-TUBES should be of such a calibre throughout as to admit of respiration being carried on through them, without any effort on the part of the patient. Many of those that are to be met with in the instrument makers' shops, though very wide at the mouth, are far too narrow and contracted at the lower aperture to allow a free and unimpeded passage for the air of respiration, being made very conical in order to admit of easy introduction, and to occlude completely the opening in the windpipe, so as to prevent the entry of any blood by the side of the tube. The disadvantages attending this mode of construction may in a great degree be remedied, by having a longitudinal opening like the large eye of a catheter cut in the mid of the tube, immediately above the inferior aperture.

One great difficulty which the surgeon has to meet in cases of tracheotomy or laryngotomy, is to keep the tube from being clogged and obstructed by mucus. It is usually stated that the tube may be kept clear by the occasional introduction of a feather, of a piece of sponge fixed to a stick, or a bit of lint wrapped round a probe. In this way it is true that the frothy or spumous mucus that collects in the tube may be readily enough cleared away; but this simple means will in very many cases be found to be quite ineffectual in removing another kind of mucus that in certain conditions rapidly accumulates to a considerable extent within the tube. On examining a trachea tube that has been worn for but a few hours, it will be found that its interior becomes gradually lined by a coating of dry, gummy, and very tenacious mucus, which is so firmly adherent to the metal as to render it

necessary, before the tube can be properly cleaned, to detach this lining by means of a penknife or pointed probe: or, what is better, by pouring boiling water through the tube. This tenacious mucus, collecting in largest quantity at the inferior aperture, and at the curve of the trachea-tube, may block up its calibre to a very great and dangerous extent, whilst the mouth of the tube appears to be perfectly pervious and free, and though feathers and pieces of stick, armed with sponge or lint, have been introduced from time to time; but these, passing over this dry mucus, are quite unable to detach it from the side of the tube, and merely bring away the sputa and more frothy mucus.

Mr Obré has devised a very simple means to remedy this inconvenience. It consists in the trachea-tube being made of uniform calibre throughout, and having an interior tube accurately fitted to it, and projecting about one-eighth of an inch beyond the lower extremity of the outer tube. It is in the projection of the internal tube beyond the lower end of the external one that the great utility of this contrivance consists. If the two tubes be of the same length, or still more, if the innermost tube be the shorter, a plug of mucus may be left at the end of the outer cannula, on the withdrawal of the inner tube. But if this be the longer of the two, the end of the outer tube will be effectually cleared every time it is withdrawn, which may be done as often as any mucus collects, without in the slightest degree disturbing the patient. The two tubes are fixed by means of a button, attached to the edge of the outer one (Figs. 372, 373). The bivalve trachea-tube (Figs. 368, 369)

Fig. 372—Trachea tube, Side view

Fig. 373.—Trachea tube, Front view

Fig. 374—Laryngeal Tube.

is constructed on the same principle, the inner tube being longer than the outer; and possesses the additional advantage of being readily removed for the purposes of cleaning, and as easily replaced. When used for laryngotomy, the tube may conveniently be curved on the flat (Fig. 374): the longest diameter being lateral instead of antero-posterior, thus being adapted to the form of the aperture in the crico-thyroid membrane.

TAPPING THE CHEST.

Paracentesis Thoracis may best be done with an ordinary trochar of moderate size; and the most convenient spot for the puncture is usually the side of the chest in the fifth intercostal space, at the line of insertion of the serratus magnus. The skin having been punctured with a scalpel, the trochar should be pushed over the upper margin of the sixth rib into the middle of the space, so as to avoid the intercostal artery, and must then be thrust sharply and boldly into the pleural sac, so as to make sure of perforating the thickened pleura or any false membranes that may line its interior, and which, if the instrument be pushed slowly on, might be carried before it and thus prevent the escape of the fluid. Air may in this operation

gain entrance into the pleura, and, decomposing the fluid, become a source of constitutional irritation. In order to obviate this inconvenience, the instrument figured in the accompanying sketch (Fig. 375) will be found

Fig. 375 — Trochar for Tapping the Chest.

useful; the trochar having been introduced, and the stop-cock shut as the piston-stylet is withdrawn, a bladder is attached to the end of the cannula, and when this has been filled the stop-cock is again closed, the bladder emptied and re-applied (Fig. 376). Or, if the surgeon prefer it, he may attach

Fig. 376.—Paracentesis Thoracica.

a long vulcanised India-rubber tube to the cannula, leaving the free end in a basin of water, into and under which the pleuritic fluid may be drawn off without the possibility of air being sucked into the chest. By one or other of these methods, as much of the fluid as is desired may be safely removed. The quantity that may be drawn off is often very considerable. I have removed from 40 to 50 ounces from the chest of a child four years of age, and from the adult as much as 90 ounces. After the withdrawal of the cannula the puncture is closed by a pad of lint, strapping, and bandage, and will, if the fluid have been serous, usually readily unite. After tapping the lung will either expand and fill up the cavity previously occupied by the fluid; or, if adhesions prevent this, the thoracic parietes will gradually collapse.

If the accumulation be an *empyema*, the cannula or an elastic tube may be left in the chest, and the pus drawn off, or removed as it re-accumulates; or a gum catheter or drainage-tube may be left in, and the pus allowed to drain off as fast as secreted. Should air have got admission into the pleural sac, it will be necessary to make the opening free, so as to secure a ready exit for the fluid, lest putrefactive changes ensue in it. In *hydrothorax*, however, it is of great consequence to prevent the entrance of air; and here every precaution to this end should be taken.

In *Hydrops pericardii*, the pericardium may be tapped by making an incision through the skin and cellular tissue in the fifth intercostal space, and then puncturing the membrane, with a fine trochar at that point where palpitation and auscultation have indicated the greatest amount of fluid. The trochar should be passed obliquely.

Drainage-Tubes.—Dr. Goodfellow and Mr. De Morgan have advantageously adopted the use of Chassaignac's drainage-tubes in the treatment of empyema, with the view of preventing the accumulation of pus, its fetid decomposition, and consequent irritative fever, and of allowing the gradual expansion of the previously compressed lung, or collapse of the chest-wall.

The mode of introducing the drainage-tubes into the pleural sac, adopted by De Morgan, is the following. A puncture with a trochar having been made in the usual situation between the fifth and sixth ribs, a long iron probe, slightly bent, is passed through this opening, and pushed downwards and backwards. It is then made to press against the thoracic wall at its lower and posterior part; and, being felt through the intercostal space, it is cut down upon, and its end exposed. A silk thread carrying the drainage-tube is now passed through the eye of the probe; and as this is drawn out at the lower opening, the thread and tube necessarily follow. The ends of the tube projecting from the opposite openings are then tied together, leaving the body of the tube in the pleural sac. The pus drops out as it forms; and thus the chest is kept empty by drainage through the tube and the lower counter-opening.

CHAPTER LX.

DISEASES OF THE BREAST.

DISEASES of the *Breast*, when they occur in the female, are of much interest to the surgeon; not only on account of their great variety, but from the difficulties attending their diagnosis, and from the importance of determining the question of operative interference in connection with them.

Diseases of the breast seldom occur before puberty, being most frequently met with either during lactation, when the functions of the gland are in a high degree of development; or towards the termination of menstrual life, when the actions of the organ are necessarily influenced by the changes that are taking place in the uterine system. Before puberty, the breast occasionally but rarely becomes the seat of inflammation and abscess; in all probability accidentally, these changes taking place in it in the same way that they might in any other part of the body. More serious disease has, however, been met with in the mammary gland, even at this very early age; thus, Lyford has recorded a case of cancer of the breast in a girl of eight. As the period of puberty approaches, the breasts often swell, become hard, knotty, and somewhat painful, indicative of some commencing change in the generative system. In other cases again, a precocious hypertrophy may take place, frequently attended with severe neuralgia in the part. When puberty occurs, the breasts naturally enlarge, and often become tender; and occasionally one undergoes a certain degree of hypertrophy, increasing greatly in bulk beyond the other. These various changes, though exciting

alarm in females, cannot be regarded as of great importance, and seldom require more than the simplest surgical treatment.

ANOMALIES OF DEVELOPMENT

The mammary gland is subject to certain anomalies. Thus, in some instances it has been found to be absent. Cooper and Froriep both relate instances in which it was undeveloped, and in which the ovaries were also undeveloped. An anomaly consists in the development of a number of breasts. Birkoitt has collected fourteen reported cases, in which there were two breasts; more frequently there is but one breast, sometimes two; and occasionally, though very rarely, more than two, constituting quintuple mammae. *Supernumerary* breasts are found to occur; two to each breast have been found communicating with the gland, and passing milk. Most of these breasts are situated somewhere in the neighbourhood of the axilla, on the anterior part of the thorax; and where they have been found placed in two parallel rows, one above the other. They have been met with in very strange situations, as seen on the outer part of the thigh, in the arm, &c. In children have even been known to have been present at birth.

NEURALGIA.

NEURALGIA OF THE BREAST occasionally occurs, and may constitute a positive disease, either in girls or in women of mature life, when it not unfrequently complicates other diseases of this organ. It is especially apt to occur in females of the hysterical temperament, though it is also met with in ruddy-looking women, who are perhaps subject to it in the back, and in other situations. Most commonly it is irregular; and uterine congestion, inflammation, &c. discovered on examination; indeed, of late, at least in this country, has been drawn to these affections, and it is not difficult to detect one or other of these conditions in the breast.

Symptoms.—In neuralgia of the breast the breast is of normal size and consistence; but in some instances it is more or less indurated and hypertrophied. There is a constant and aching, deeply in its substance, with cutting and lancinating or radiating sensations that extend to the arm. These painful sensations are constant, and are not menstrual period, and not unfrequently alternate with it.

Diagnosis.—The diagnosis of this affection is not difficult, many disease may usually be effected by attending to the radiating character of the pain, to the temporary nature of it occurs, to its shifting seat, and to the absence of any disease in the breast.

Treatment.—The treatment consists especially in the regulation of the uterine organs; unless this be done, the disease will prove to be excessively rebellious and troublesome. The speculum, however, when necessary, and in cases of any uterine irritation that may be found, this is the best remedy, with greater readiness than by any other plan of treatment.

antihysterical constitutional remedies may be employed ; the preparations of iron administered, when necessary ; and the local pain relieved by the application of belladonna and opiate plasters, or by inunctions with atropine ointment.

HYPERTROPHY.

SIMPLE HYPERTROPHY OF THE BREAST is not unfrequently associated with very severe neuralgia of the organ. An increase of size, such as naturally takes place during pregnancy, between the fourth and the ninth months, will occasionally commence at puberty, and go on until the organ attains an enormous bulk, as in Fig. 377, which represents the breast of a girl of fifteen, who was under my care for this condition. In some cases the breast has been found after death to weigh as much as twenty pounds ; and after removal, a breast of this kind, taken from a young woman under thirty, has weighed no less than twelve pounds, being entirely composed of its normal tissues, greatly hypertrophied. In these cases of hypertrophy both breasts are usually affected, though one is commonly more so than the other. When first this morbid condition commences, the breast preserves its usual shape, though it is increased in bulk ; but as it enlarges it gradually projects forwards, drawing down the skin of the shoulders, of the sides of the chest, and even of the back, and hanging downwards until, as in a case mentioned by Bérard, it has been known to reach to the knees.

Treatment.—The treatment of this Fig. 377.—Simple Hypertrophy of Breast in a Girl fifteen years old.

affection is very unsatisfactory. The general health must be attended to, and an endeavour may be made to excite lactation, and thus to unload the vessels of the breast by the employment of galactagogue remedies. I do not think that amputation of the organ should be performed in these cases unless the growth attains so great a size as to render life a burden.

LOBULAR HYPERTROPHY OF THE BREAST has been described by Sir A. Cooper as occurring chiefly in unmarried women between thirty and forty years of age. It appears on manipulation to be composed of several solid but moveable masses, which after a time begin to diminish in size, until the breast at last atrophies, and is in a great measure absorbed. It seems to me to be rather a species of the chronic mammary tumour than a pure hypertrophy.

ABNORMAL CONDITIONS OF THE LACTEAL SECRETION.

The lacteal secretion is occasionally the cause of abnormal conditions in the breast. Thus the milk may appear at *unusual times*, a twelvemonth, for instance, after weaning ; it has occasionally been known to be secreted in children, and in some remarkable instances in men. In other instances

again, after parturition, there is a total *Absence of Milk*, either owing to want of development in the gland, or to debility on the part of the mother. The opposite condition will occasionally occur, and an *Excessive Flow of Milk* may continue in hysterical females after the child has been weaned. In such cases as these, the *galactorrhœa* may be checked by the application of the extract of belladonna to the breast, aided by the employment of tonics, the administration of acids, &c.

LACTEAL TUMOUR.—It may happen during lactation that one of the lactiferous ducts becomes obstructed, either by its being obliterated by inflammation or occluded by the deposit in it of a small concretion—a lacteal calculus. In either case the walls of the duct may be expanded, so that at last it constitutes a moderate-sized cyst, fluctuating on pressure, and evidently containing fluid. In some cases, the lacteal tumour has been known to attain an enormous size. Walpy has related a case in which he drew off ten pounds of milk by tapping a collection of this kind. These tumours may exist for a considerable time. Dupuytren records an instance in which one had existed for ten months, and Cooper one of a year's duration. In these chronic cases the milk usually undergoes changes, becoming creamy, thick, and oily; and in some instances it would appear to leave a solid residue by the absorption of its watery parts. In other instances the milk appears as if diffused through the substance of the gland and its ducts, constituting a spongy semi-fluctuating tumour. Velpeau has pointed out that these lacteal deposits undergo a series of changes, somewhat similar to those that take place in blood that has been extravasated; becoming absorbed in whole or part in some instances, in others remaining fluid, and in others becoming encysted.

Treatment.—In these cases, the readiest mode of getting rid of the tumour is, as Sir A. Cooper advises, to make an oblique puncture from the nipple towards it, by means of a trochar and cannula, so that a fistulous track may be left, along which the milk is discharged, and thus got rid of; the child being at the same time weaned, so that the secretion may cease.

In some cases after weaning, the milk may be diffused into the substance of the gland or collected into masses of curd, forming hard nodules, which give a good deal of trouble, and may eventually go on to some of the forms of inflammation that will immediately be described; these swellings are usually best removed by frictions with somewhat stimulating embrocations such as camphorated oil, &c., by which their absorption is promoted.

INFLAMMATION OF THE BREAST.

Inflammation of the Breast may take place at any period of life, but is usually associated with that change in the function of the gland which occurs during lactation. It is commonly met with during the first month or two after the birth of the child, and seldom occurs during weaning, but may, as Nunn has shown, be the consequence of unduly prolonged suckling, and thus appear at a late period—the tenth or eleventh month. It is more frequently met with in weakly phlegmatic women. The inflammation may affect any one of the constituents of which the breast is composed, and may be limited to this; thus it may take place in the nipple, in the subcutaneous cellular tissue lying between the skin and the gland; in the gland itself; or in that extensive plane of cellular membrane upon which the gland rests, and which intervenes between it and the pectoral muscle. But although the inflammation commonly affects these different parts, in many cases the whole of the breast appears to be affected, and no distinct implication of any special tissue can be made out.

INFLAMMATION OF THE NIPPLE AND AREOLA usually occurs at an early period of lactation in delicate women, and especially with the first child. It commences with the follicles of the part, being accompanied by superficial suppuration, abrasion, fissure, and cracks, with oozing of a small quantity of serous, sero-puriform fluid, great pain during suckling—so great, indeed, as to prevent the proper continuance of this act; and it is usually attended by a good deal of constitutional irritation. In some instances, the fissured state of the nipple would appear to precede the setting in of inflammation; in other cases, the inflammation is the primary condition. When the areola and nipple are inflamed, these parts become conical, red, and swollen, with much pain, owing to the density of the subcutaneous tissue in this situation.

Treatment.—When this disease, commonly called *cracked nipple*, has set in, most relief is afforded by the application of the nitrate of silver to the bottom of the fissures, and over the inflamed surface. This application, though painful at the time, gives the patient afterwards more complete ease than any other with which I am acquainted. In some instances the application of the citrine ointment, and in other and slighter cases that of collodion, is useful. When inflammation exists, with superficial abrasion, but without any distinct crack, the employment of astringent applications, such as the tinctures of myrrh and of catechu, borax and honey, or spirit and water, may be useful. In these cases also a leaden nipple-shield may be employed with advantage, and the state of the infant's secretions should be carefully attended to: the occurrence of aphthous ulcers in the mouth being followed with especial frequency by the disease in question.

Abscess of the Areola not unfrequently occurs in suckling women, with the ordinary signs of local inflammation, terminating in circumscribed suppuration. The *Treatment* consists in the application of warm poultices made with lead lotion, and lancing the part early. In doing this, care should be taken that the cut be made from the centre of the nipple towards the circumference of the areola, so as not to divide the lacteal ducts.

INFLAMMATION OF THE BREAST, which, as it generally terminates in suppuration, is usually called *Milk Abscess*, may occur in three situations: 1, in the Subcutaneous Cellular Tissue, *Supramammary Abscess*; 2, in the bed of Cellular Tissue in which the Mammary Gland is lodged, *Submammary Abscess*; and 3, in the Gland itself, *Mammary Abscess*.

1. *Inflammation, followed by Abscess of the Subcutaneous Cellular Tissue of the Breast*, though commonly occurring during lactation, is more frequently met with than any other form of inflammation in this region at other periods of life, more particularly about the age of puberty. Its symptoms are those of simple phlegmonous inflammation, differing in no way from abscess of this kind in other situations, except that it is always distinctly circumscribed.

2. *Inflammation in the Cellular Plane between the Mamma and the Pectoral Muscle* diffuses itself over the whole of the cellular layer, and almost invariably runs into abscess with considerable rapidity, giving rise to great pain in this situation of a deep, heavy, and throbbing character, much increased by moving the arm and shoulder, and attended by swelling, oedema, and a slight red blush upon the skin. The breast becomes prominent, is conical and projecting, the whole organ being pushed forwards by the pressure from behind; it is not readily moveable on the pectoral muscles, and the subcutaneous veins become engorged, and at last abscess forms. It is not always easy in these cases to determine whether suppuration has taken place or not, the depth at which matter forms rendering it impossible in the early stages to detect fluctuation until it approaches the surface; its presence

may, however, be suspected on the occurrence of deep-seated throbbing pain, œdema, and some superficial redness. The abscess at last points at some part of the margin of the gland, usually at its lower and outer side, where the matter seems to gravitate, after a time, however, it will commonly appear at other points of the circumference of the gland, beyond which it always extends, though it seldom, if ever, perforates the structure. I have, in more than one instance, seen a series of four or five apertures, forming a large circle round the margin of the gland. It very commonly happens that the apertures through which the pus discharges itself in these situations, degenerate into fistulous canals, by no means easily closed.

3. *Inflammation of the Mammary Gland* itself is not of such frequent occurrence as either of the other forms of abscess. When the whole of the organ is affected, it gives rise to great swelling of the breast, with severe aching and lancinating pain, and much constitutional disturbance, usually of an irritative type. Not unfrequently one lobule only of the gland becomes inflamed; and then the local signs are proportionately limited, and occasionally cease. As Velpeau has pointed out, one lobule after another may become inflamed, so that a succession of abscesses forms in different parts of the gland. As the inflammation advances to suppuration, the skin is reddened, assumes a dusky hue, becomes glazed, has a peculiar greasy appearance, and pits on pressure. When matter has formed, the tension of the superficial parts, with œdema and perhaps deep-seated fluctuation, determine its presence.

Treatment.—In the treatment of inflammation and abscess of the breast occurring during lactation, it must be borne in mind that we have not a sthenic inflammatory condition to deal with, but that the disease almost invariably happens in pale delicate women, commonly of a strumous habit, and weakened by recent parturition; indeed, the affection appears to be rather an inflammation of an irritative and congestive, than of a sthenic character. It is therefore obvious that antiphlogistic means of an active nature are not admissible; and the best plan of treatment appears to consist in keeping up the strength of the patient by proper constitutional support, at the same time that the local inflammation is checked by topical antiphlogistic measures. The first thing to be done is to prevent the occurrence of suppuration; if this can be accomplished, which is, however, rarely the case, much will be gained. In order to effect this, the breast should be supported in a sling, so as to lessen congestion in it; and the arm at the same time should be fixed to the side, in order to prevent traction of the pectorals and movement of the submammary cellular tissue. If the patient's strength be good, leeches may be applied; in the majority of cases, however, they will not be required, but warm evaporating lead lotions or the assiduous application of camomile or poppy fomentations may be substituted in their stead; at the same time, the milk should be drawn off by means of a breast-pump or sucker, the child being put to the unaffected breast or weaned, and an occasional saline purgative administered. When suppuration is impending, the application of fomentations may be continued, the patient being allowed a more liberal supply of nourishment, with a moderate quantity of malt liquor; and, so soon as matter can be felt, it should be cut down upon and let out by an aperture in the most dependent position. It is of great importance that the matter should be let out early, and by an opening into the lowest part of the abscess: if it be not, it burrows deeply, diffusing itself through the cellular tissue under, behind, and around the gland, and, opening at several points, leaves long fistulous tracks perforating the breast in various directions. When suppuration is

ing on, the patient's strength must be supported with tonics, the mineral acids, bark, and quinine. Porter must be liberally allowed, and plenty of nourishment given. The sinuses that are left may usually be induced to close by attention to the state of the general health: should they not do so, however, the employment of pressure and the use of stimulating injections may, at a time, accomplish this. In the event of their proving rebellious, it has been proposed to slit them up; but this is an unnecessarily severe practice, and may, I believe, in all cases be dispensed with.

CHRONIC ABSCESS OF THE BREAST may assume two forms: the *Diffused*, and the *Circumscribed or Encysted*.

Chronic Diffused Abscess of the breast may occur at all ages, in the single or in the married. It usually appears in the submammary cellular tissue, often without any external exciting cause, but as a consequence of impaired health, in atrophic or cachectic females, and is possibly connected with uterine derangement. It may acquire a very large size, and, pushing the mammary gland before it, gives the breast a conical-pointed shape. Fluctuation soon becomes apparent, and the ordinary local signs of chronic cold or congestive abscess disclose themselves.

The *Treatment* of chronic diffused abscess of the breast consists in making a free outlet for the pus in a dependent situation, and then introducing a drainage tube; at the same time that the general health is improved with iron or cod-liver oil on ordinary medical principles.

Chronic Encysted Abscess of the breast is a disease of great importance, inasmuch as it closely simulates various tumours in this situation; so much so, indeed, that it is only with extreme difficulty that the diagnosis is effected in some cases, and the breast has in numerous instances been amputated on the supposition of its being the seat of tumour, when it was merely affected with this variety of abscess. It usually commences as the result of pregnancy, whether complete parturition or miscarriage takes place, sometimes as a consequence of lacteal inflammation, but usually without any injury or other direct local cause. An indurated indolent swelling forms, and this may gradually soften in the centre; but fluctuation may for a long time be very indistinct, and even absent, being obscured by the thick wall of plastic matter that is thrown out around the collection of pus. It is owing to the deposition of this dense mass of limiting fibrine, that the encysted abscess is commonly developed as a hard and apparently solid lump. It is in general not very distinctly circumscribed, and of but moderate magnitude; after a time it remains stationary, or but slowly increases with but little pain during a space of many months; it is not unfrequently attended with retraction of the nipple.

Diagnosis.—The diagnosis of this form of abscess is of great importance, inasmuch as it has not unfrequently been excised for *tumour* of the breast. I am acquainted with many instances in which this mistake has been committed. Such an error may, however, commonly be avoided by attention to the following points: 1, that it is almost invariably preceded by impregnation, parturition, or miscarriage; 2, that there is more or less oedema of the subcutaneous cellular tissue covering it; 3, that, although it is of slow formation and without pain, it is not distinctly circumscribed, but gradually fuses in an irregular manner into the neighbouring tissues; 4, that it is not freely moveable, but rather incorporated with adjacent parts; and 5, that elasticity, or even deep fluctuation, may be commonly felt at one part of it. Should there be much doubt in the case, the introduction of a grooved needle, by giving issue to the pus, will always determine its true nature; indeed, this simple means of diagnosis should never be neglected in all cases in which

there is reason to suspect the possibility of the apparent tumour of the breast being in reality an abscess.

Treatment.—In encysted abscess, as well as in the diffused form, the drainage-tube is most useful; but should the mass of plastic matter be very large and dense, a seton may advantageously be passed across it in a perpendicular direction, so that the tumour may be softened down and caused to disappear by the inflammation thus excited in it.

In all cases of chronic abscess of the breast, but more particularly in the submammary, the arm should be kept in a sling or bandaged to the side.

TUMOURS OF THE BREAST.

The study of the various tumours of the breast, more especially in a diagnostic point of view, is of the first importance to the practical surgeon; for, though it might be supposed that it would be easy, if not to recognise the minuter shades of pathological difference between morbid growths so superficially situated as those of the mammary gland, at all events to diagnose the malignant from the non-malignant affections of this organ, yet in practice nothing is more difficult in many cases: and it not only requires great experience, but also an intimate acquaintance with the special course and symptoms of each particular disease, to come to a correct conclusion as to its nature. Even with all the light which experience and a careful examination of the characters of the tumour may throw upon the nature of the disease, it will be impossible for the surgeon to avoid occasional errors in diagnosis.

NON-MALIGNANT TUMOURS.

Mammary tumours may be either simple or malignant. The recognition of the different varieties of simple tumour that affect the breast-gland, is principally due to Sir A. Cooper; and this department of surgical pathology has of late years been much extended by the researches of Velpeau and Birkett. The non-malignant tumours of the breast comprise the *Chronic Mammary Tumour*, the different varieties of *Cystic Growth*, the *Painful Tubercle*, *Hydatid Cysts*, and various forms of *Fibrous*, *Cartilaginous*, and *Ossaceous Growths*.

CHRONIC MAMMARY OR ADENOID TUMOUR is perhaps the most common variety of these benign structures. It usually occurs as the result of blows, squeezes, or lacteal irritation, and is almost invariably met with in young women under thirty years of age—seldom, if ever, commencing at a later period than forty; usually in persons otherwise healthy; and most frequently in those of a sanguineo-nervous temperament. This tumour is generally of small size when first perceived, and may remain stationary for many years, or it may slowly increase, and at last attain a considerable bulk. In other cases it may very rapidly grow to a great size. In a case on which I operated some years ago, the tumour had continued for eighteen years of about the size of a walnut, but in the course of six months it increased to an enormous magnitude, and on removal weighed nearly five pounds.

This tumour usually commences as a small, moveable, finely nodulated growth, attached by a pedicle to one side of the mammary gland; it is hard and incompressible, often appears isolated, and is not generally painful, it increases slowly, without discolouring the skin or becoming attached to it, and is frequently many years in attaining a moderate size. It is often floating, as it were, in the substance of the gland, into which it can be pushed back. This tumour is frequently mistaken for a cancerous growth, and the diagnosis is often as difficult as it is important; though in many cases the

otherwise good health of the patient, the mobility of the mass, the absence of all implication of the skin or glands, the want of hardness, and its circumscribed character, will usually indicate its true nature.

On examination after removal, it appears irregularly lobulated, is encapsulated, and its cut surface will be found to present a bluish or greyish-white colour, which, after exposure to the air, assumes a rosy tint; and, on pressure, drops of a thick creamy fluid will often be seen to exude. Under the microscope it has been found by Burkett to consist of imperfectly developed hypertrophy of the glandular tissue; the terminal cells of which are filled with epithelial scales.

Treatment.—This consists in attention to the general health, and in the employment of local absorbent remedies. In this way, tumours of this description have occasionally disappeared; in some instances, they have been known to become spontaneously absorbed after marriage or during pregnancy. If obstinate, their dispersion may be facilitated by the occasional application of two or three leeches, followed byunction of iodide of lead ointment; and by the internal administration of Plummer's pill, and the compound decoction of aloes. In addition to these means, the employment of compression will be found especially serviceable; this may be applied either by means of Arnott's slack air-cushion, or by Tauchou's plan, which consists of a pad to which a spiral spring is attached, and which, being compressed by a proper arrangement of bandages across the chest, will keep up steady and continued pressure upon the tumour. I have employed this kind of apparatus, which is far less expensive and cumbersome than the air-compressor, in several cases of mammary tumour, with great benefit. The advantage attending it is, that it can be used in conjunction with absorbent ointments, which cannot be used with the air-bag, as the grease entering into their composition destroys the macintosh cloth of which it is made. In this way absorption may not unfrequently be secured; and I am disposed to think that not a few of the so-called cases of cancer of the breast that have been reported as having been cured by pressure, were in reality instances of the chronic mammary tumour in which absorption had been brought about in this way. Should the growth attain too great a magnitude to admit of absorption by the means that have just been recommended, its excision must be practised. In doing this it is not necessary to remove the whole of the breast, but it will be quite sufficient to extirpate the tumour itself, and at most the small lobe of mammary gland connected with it. This may be done, if the growth implicate the edge of the mammary gland, by two incisions that radiate from the nipple as from a centre, thus inclosing a triangular portion of the breast. If it be very moveable, and in the substance of the gland itself, it may often be enucleated through a simple incision. In removing this tumour there are two little practical points that should, if possible, be attended to. 1. The gland should not be incised through its whole thickness, so as to open up the cellular bed which is interposed between it and the pectoral muscle. If this be interfered with, infiltration of blood or of pus into it may occur, and deep abscess may form under the breast or at the lower edge of the gland, leading to very troublesome consequences. 2. The wound must not be closed tightly by sutures and plasters. If this be done, the discharges are retained, and burrowing of unhealthy matter often results. I have found it better to leave the wound open, and to dress it from the bottom.

When the tumour has been allowed to attain a very large size before removal, it will generally be necessary to extirpate the nipple and the whole of the mammary gland, which will be found, perhaps, in an atrophied but

otherwise healthy state. The largest tumour cystic development, which I have had occasion to remove, weighed five pounds.

In some rare cases, adenocoele, without any other disease, after operation, even though the whole of the breast is extirpated with the tumour. In one case, where the adenocoele weighed about four pounds, with a contracted and atrophied mammary gland, from a lady who had a recurrence took place in 1861, and again in 1862, were developed at some little distance from the site of the first operation proved on careful examination to be purely a new formation.

PAINFUL MAMMARY TUMOUR.—It occasionally happens that a mammary tumour becomes the seat of a neuralgic pain, attended with very considerable distress, constituting the form of disease that goes by the name of *neuralgic mammary tumour*. This condition most frequently occurs in women of an irritable and delicate constitution, and is attended with disorder of the uterine functions, the pain recurring at the menstrual periods, and appearing to be essentially owing to the twigs of the intercosto-humeral nerves in the axilla.

The *Treatment* of this affection must have regard to the neuralgic condition. This is commonly treated by the administration of alteratives and tonics, more especially of iron and zinc, with cod-liver oil if necessary. The iodide of lead ointment, conjoined with the use of the affected breast. In many cases the pain subsides from time to time, especially in the winter months, the neuralgia more effectually than any other remedy. In others, again, pressure will be found serviceable, and the excision of the tumour may in this, as in the case of the neuralgia, be necessary.

CYSTIC TUMOUR OF THE BREAST is one of the most common malignant affections of this organ. It may be divided into 1. As a *Single Unilocular Cyst*; 2. As several small cysts, together, a *Compound Cyst*; and 3. As the *Hydatid Cyst*, in which the cystic development appears to be analogous to that of the chronic mammary tumour. In the case of non-malignant cystic tumour, we occasionally meet with the breast.

1. *The Single or Unilocular Cyst* of the breast is sometimes called by Sir B. Brodie as the *Sero-cystic Tumour*, and by others as the *Hydatid tumour*, usually occurs in the form of a swelling of the size of a filbert, containing a clear serous fluid, and is moveable under the skin. When more than one cyst of this kind is present in the breast, the disease is called *Compound Cyst*. In the greater development than the others, the cyst is more difficult to detect. These cysts, when single and small, contain a clear fluid, but as they increase in size, or become compound, they assume a greenish-brown or blackish tinge from the presence of blood. They continue for a great length of time of small size, and then gradually increase until they contain several ounces of fluid, become very tense, with the skin drawn tight, and the areolæ shining. Sir B. Brodie is of opinion that

distention of the lactiferous tubes, and refers to a preparation in which this position can be demonstrated.

The *Diagnosis* of the affection may usually be readily effected by feeling a globular elastic cyst or cysts under the skin; the mammary gland being movable, and not adherent to any of the adjacent structures. In those cases, however, in which the tumour lies deeply, the diagnosis may not so easily be made, more especially from some of the cystic forms of cancer to which I shall afterwards have occasion to advert. In fact, nothing is more easy than to diagnose the true nature of a superficially seated cystic tumour, — nothing more difficult in some cases than to diagnose one deeply seated at the under surface of the mammary gland. Whenever the surgeon has any doubt about the existence of fluid in a tumour of the breast, he should introduce an exploring trochar; when, if the disease be cystic, the fluid will be discharged. If the tumour prove to be solid, no ill consequences will result from the simple puncture. Several instances have occurred to me in which, from the want of this simple precaution, very excellent surgeons had condemned, as cancerous, tumours of the breast which proved to be cystic.

Unilocular cysts of the breast occasionally attain an immense size, at the same time that their walls remain thin and supple. In some of these instances, the fluid continues to the last of a truly serous character; in other cases, however, it becomes more or less glairy or mucilaginous, and hence Velpeau has described this variety as the *Sero-mucous Cyst*. In other cases the walls of the cysts have been known to undergo calcareous degeneration. When these cysts attain a very large size, their walls being thin, and the skin covering them tense, they may become translucent, and thus constitute true hydrocele of the breast, resembling in many respects similar serous tumours that form in the neck.

2. *Compound Cysts*.—In the majority of instances, as has already been observed, no material alteration takes place in the cyst, except, perhaps, its gradual increase in size; but in other instances, peculiar changes occur in it, in consequence of which it becomes filled up by a dense solid growth springing from the interior, at last undergoing ulceration, and giving rise to a series of destructive changes. The pathological phenomena that accompany these changes have been ably investigated by Sir B. Brodie. He finds that, in the first instance, one or more membranous cysts, containing serum, are formed in the breast; the fluid gradually becomes darker in colour, and opaque; after a time a fibrinous excrescence, of a lobulated or foliated form, springs up into the interior of the cyst, gradually displacing and occasioning absorption of the contained fluid, and at last filling up the whole of its interior; and then, coming into contact with the capsule by which it is compressed, or with which it may be firmly incorporated, the whole tumour is converted into a solid mass, in which the remains of the cysts still continue to be perceptible. Sir B. Brodie thinks that there is reason for believing that a growth of a fibrinous substance takes place from the outer side of the cyst as well, thus adding to the general size of the breast. If one of the larger cysts be laid open, or if the pressure of the intracystic growth cause inflammation and ulceration of its capsule, this may at last be perforated, and a fungous mass will sprout through it, presenting many of the ordinary symptoms of a malignant growth; being irregular, dark-coloured, bleeding readily, and increasing rapidly in size, and indeed, in some cases, actually undergoing encephaloid transformation. When such changes as these have taken place, the tumour assumes a formidable character, and will rapidly prove fatal by the induction of exhaustion and hectic. Tumours

of this description, composed of cysts having intracystic growths sprouting from their interior, may attain an immense magnitude and weight. They have been met with of six, eight, or even twelve pounds weight; but the largest is one described by Velpeau, which weighed forty pounds.

3. *Cystic Sarcoma.*—The various forms of cystic tumour that have just been described, when associated with the development of fibrous intracystic matter, constitute forms of the so-called *cystic sarcoma*. Another variety of this disease, however, is not unfrequently met with, in which the sarcomatous or solid element of the tumour preponderates over the cystic part of the growth. In these cases the tumour will be found to be composed of dense, white, lobulated, or foliated structure, closely resembling that of the chronic mammary tumour, and consisting either of imperfect hypertrophy of the breast-gland, or of the deposit of a fibrous material. This mass is studded throughout with a number of small cysts, varying in size from a pin's head to a hazel-nut, and usually containing clear fluid. If some of these cysts increase out of proportion to the rest, the tumour will assume more of the true cystic character.

This form of cystic sarcoma usually occurs in women from thirty to thirty-five years of age, as the result of injury or as the remote consequence of some inflammatory action during lactation. On examining a breast affected in this way, it will be found that the tumour, which may either be confined to one lobe or may implicate the whole of the gland, is hard, heavy, and solid to the feel; on careful examination, however, its surface may be found to be finely nodulated; and, occasionally, a larger cyst than usual may be found projecting, which is recognised by its elastic feel and globular shape. The disease is slow in its growth, and does not implicate the adjacent cutaneous or cellular structures; hence, the tumour is movable on the pectoral muscles, and the skin is unattached to it. The axillary glands, also, are not enlarged, at least not to any material extent. The nipple is usually be found to be normal in its shape, and not depressed.

The eventual development of malignant action in these cystic tumours, and the deposit of encephaloid matter in the interior of the large cysts, must not be overlooked. A tumour of this kind may be benign for many years, and remain generally so throughout the greater portion of its structure; yet, after removal, encephaloid may be found to have formed in some of the cysts. In the case from which the following drawings (Figs. 378, 379) were taken, the tumour had existed for more than twenty years before removal, having commenced at the age of twenty-eight; but, after extirpation, cancerous encephaloid matter was found at the bottom of some of the cysts, which, as the constitution was uncontaminated, was doubtless of recent formation; and the surface of the fungus was epitheliomatous.

Treatment.—The treatment of these various forms of cystic and sarcomatous growths varies, according to the number and size of the cysts, and the quantity of solid matter deposited inside and around them. When the cyst is small and single, the fluid contents may be let out by puncturing with a small trochar; but a cure cannot usually be effected in this way, as the fluid readily reaccumulates. In cases of this kind, Sir R. Brodie found considerable advantage from the application of stimulating embrocations, more particularly of one composed of equal parts of camphorated spirit and weak spirit, with one-eighth part of liquor plumbi. In other cases, blistering and the application of the tincture of iodine may be serviceable. Under these plans of treatment, I have several times seen the tumour disappear. Occasionally it will suppurate spontaneously, and is thus got rid

if; or it may be opened, a tent of lint introduced, and thus suppurative granulation established in it.

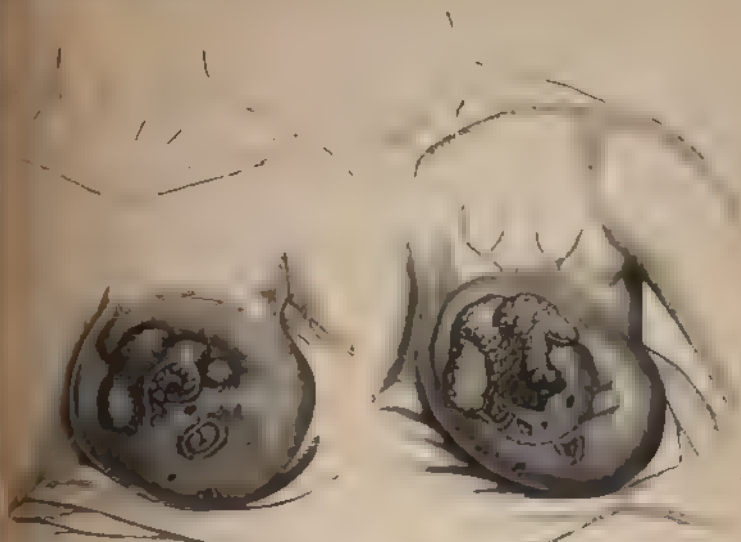

Fig. 378.—Ulcerated Cystic Tumour of Breast, of 20 years' duration.

Fig. 379.—The same Cystic Tumour, six months later, with Cancerous Deposit.

Operative Treatment.—If the tumour be unilocular and single, containing serous fluid, possibly with fibrinous matter in its interior, it may often be dissected out of the cellular bed in which it lies, and be separated from its attachment to the mammary gland, this structure and the nipple being otherwise left intact. In this way I have successfully removed large unilocular cysts of the size of a shaddock. If the cysts be compound and numerous, the case is more serious, and then their extirpation only is not advisable.

When the disease is truly a *Cystic Sarcoma* it is better either to leave the tumour and treat it by palliatives, or to remove the whole breast; partial removal of the breast, extirpation of the tumour with its lobe of the mammary gland only, is not usually a very successful operation. Recurrence of cystic development will almost certainly occur; and often very severe inflammation of the glands and of the adjacent textures is set up. This I have seen on several occasions, and therefore think it better that the breast should either be left, or removed *in toto*. Such an operation, however, should not be undertaken in the early stages; as the tumour may continue for many years without seriously troubling or endangering the patient, and may perhaps eventually undergo atrophy or absorption. If, however, it show a disposition to increase, to become troublesome by its bulk, or painful, it should then certainly be extirpated; and this operation may always be performed with a good prospect of success, inasmuch as the disease is not malignant, and does not tend to contaminate the constitution. It is a remarkable fact, however, which has been adverted to by Lawrence and Brodie, that, even though the whole of the breast be extirpated, a similar affection occasionally recurs in the cicatrix, requiring subsequent operation; and then, perhaps, being permanently eradicated. This must either be owing to some portion of the cystic structure having been left in

the first operation, or to the development of new cysts in the site of the former; but to which cause it is referable, is still uncertain. The repeated recurrence of these cystic tumours is very remarkable. Cowper has related a case in which the growths had to be removed eight times in many recurrences. After the removal of the cystic sarcoma, a recurrent tumour of cancerous character is sometimes developed in the same site; even in cases in which there is good reason to believe that there has been no carcinomatous element in the primary disease. Yet in other instances it is doubtless owing to the cancerous degeneration of the cystic growth, and may originally have been benign, but in which a malignant action has established itself before removal.

Sanguineous Cysts are occasionally met with in the mamma. They represent the ordinary characters of cystic development, but are sometimes accompanied by bleeding from the nipples, and, when tapped, are found to contain dark thin sanguinous fluid.

VARIOUS RARE TUMOURS.—Besides these tumours, the breast is occasionally the seat of other morbid growths; for instance, fibromata, myxomata, and cartilaginous masses have been met with. All these affections, however, are of extremely rare occurrence; and, when they form, it is almost impossible to determine their true nature until after removal. Their recognition is usually practised on account of the obscurity attending the diagnosis, and the fact of their commonly being mistaken for cancerous growths.

The most important of these, perhaps, is a *Recurrent Fibrous Tumour*, which shows a remarkable tendency to return after removal. This may do many—as often as eight or ten—times.

Sir A. Cooper describes a *Scrophulous Tumour* of the breast; the precise nature of which is not very apparent from the account given by that surgeon. It is not improbable, however, that it is of tuberculous character; and Velpeau states that he has found tubercle occurring in the breast in two forms: in the first, primarily deposited in the skin and subcutaneous cellular tissue; and in the other, as a fibro-tuberculous affection of the gland itself.

Hydatids of the breast are of rare occurrence, and have been principally described by Sir A. Cooper; cases have also been related by Grawitz and others. These hydatid tumours are so excessively rare and obscure, that their true nature would not, in all probability, be suspected until after removal. They present the ordinary characters of deeply seated cysts, with fluctuation and some induration round the globular swelling, and an absence of pain. In such a case, an incision into the tumour will cause the escape of the acanthocysts, and the ultimate suppuration of the cavity in which they lodged, which will gradually cicatrise.

In some rare cases, tumours containing *Fœtal Remains* have been met with in the breast; these, however, are rather matters of pathological curiosity than of practical importance.

MALIGNANT TUMOURS OF THE BREAST.

All the various forms of cancer have been met with in the breast; scirrhus, however, occurs with far greater frequency than any of the other varieties. Occasionally the encaphaloid form of the disease is met with, but it is very rarely occurs. There is, however, a preparation in the University College Museum illustrating the disease, and I have once removed a very large encaphaloid tumour from this region. Cancer of the breast, whatever form it assumes, is invariably primary; it may affect one lobe only, or be infiltrated into the whole gland; and it may commence in the nipple or in the ducts of the

the breast. Most frequently one side only is affected; but in some cases both mammary glands are implicated.

SCIRRHUS.—Scirrhus is the form of cancer which is commonly met with in the breast. It may occur in several ways: either affecting the nipple; implicating the skin, primarily deposited in the form of an intramammary tumour; or infiltrating the whole substance of the organ. It most commonly commences as a circumscribed tumour of small size, at first perhaps smooth and round, hard and indolent in its character, with little or no pain; it is readily movable, may be situated in one lobe, and is attached perhaps to the rest of the gland by a distinct pedicle. As it increases in size, it becomes hard, knobbed, and irregular, perhaps presenting a finely granular feel, and becoming fixed to the gland and adjacent parts. When the disease begins as scirrhous infiltration of the breast, the mass is from the first, hard, rugged, irregular, nodulated, and heavy; often somewhat square in shape, and early accompanied by adhesions to adjacent parts. In other cases, the development of the scirrhous mass is accompanied by a corresponding atrophy of the mammary gland, which becomes shrivelled and disappears entirely. In some instances, rather large cysts may form in connection with the scirrhous mass. In a woman, whose breast I once removed for what was supposed to be cystic sarcoma, but which proved after the operation to be a scirrhous tumour, the mass contained several cysts as large as cherries, filled with dark or greenish fluid, and projecting from its surface; and in a lady under my care for scirrhus of the breast, a tumour as large as a pigeon's egg, containing sanguinolent fluid, formed on the surface of the tumour.

As the swelling increases in size, it has a tendency to be more fixed to the adjacent parts, becoming adherent to the pectoral muscles, and incorporated with the cellular tissue at the border of the axilla. The tumour also begins to form a distinct external projection, and becomes more irregular in shape; it is the seat of severe pain, more particularly at night; and is usually covered by a plexus of blue and dilated veins. The ordinary symptoms of cancerous cachexy now appear, and the disease then makes still more rapid progress.

The tumour may in some cases remain for a great length of time without implicating the skin; but most commonly, after it has existed for a few months, this tissue becomes more or less involved in the morbid action. Instead of being loose and movable over the surface of the cancer, it will be found, on being pinched up between the fingers, to dimple at one part, where it may be felt to be attached by a kind of cord-like process to the tumour beneath it. After a time, that portion of the skin which first became fixed in this way acquires a reddish or purplish colour, and is covered with thin, scaly, epidermic desquamations, and becomes permeated by a number of small ramifying vessels. A crack or fissure eventually forms in this; a small exudation of a mucous fluid takes place, which dries into a scab; under this, ulcerative action sets in, which speedily assumes the ordinary characters of a scirrhous ulcer, having hard, elevated, and everted edges, a greyish-green or foul surface, and discharging a quantity of very fetid pus. In some cases ulceration may take place at several points, and thus the whole surface of the breast become converted into one immense chasm, which may even extend up into the axilla.

The skin, when affected, often assumes a red, glazed, hard, and brawny character, being shining, and as if greasy upon the surface, having its pores enlarged, and enveloping the side of the chest in a kind of stiff solid casing, attended usually by much pain, considerable oedema of the arm, and an

aggravated form of constitutional cachexy : ulcer of this hardened mass, and then speedily destroys it. The cancerous development seems to develop its energy chiefly upon the cutaneous structures. It is small, atrophic, and implicates the nipple. The cancer spreads into the surrounding integument, which is assuming a hard, leathery character, or feeling, but without discoloration, but presenting a hypertrophy being enlarged, and the interspaces between them the infiltrated skin assumes a brownish or purplish rough desquamating crusts, so as to resemble the diseased state of the integuments will extend very far or further development of the tumour situated in this way seen the integuments of the whole first clavicles to below the mamma, and from one axilla to the other, hard, and leathery, of a brownish-red colour, for some time, but without ulceration. This condition is remarkable that in it the axillary glands are not yet rendered cachectic, at nearly so early a stage as the cancer primarily originates in the mammary gland, and in the skin.

Another way in which the skin becomes implicated in the formation of a scirrhus tubercle or nodule is in the internal or axillary border of the mamma. From this the cancer extends inwards, implicating the gland in a secondary and limited extent.

The *Pain* is in many cases but trifling in the early stage, so much so, indeed, that it is the tumour, often first excites alarm ; as it increases, however, the pain becomes more particularly at night, is greatly aggravated by the pressure of the mass, and chiefly extends up to the shoulder and arm. It usually becomes most severe about the time when the cancer usually becomes most severe about the time when but as the cutaneous infiltration goes on, it gradually leads to the destruction of the cutaneous nerves.

Retraction of the Nipple commonly commences when the skin is implicated ; it appears to be owing to the nipple becoming involved in the mass of the tumour, and to the shortening of the lacteal ducts ; in consequence of the nipple being completely buried. This sign has, I think, more value than it deserves in connection with cancer, as it is not of malignant disease, and is occasionally met with in other tumours.

The *Axillary Glands* usually become enlarged, and attain a greater size than that of the original tumour. A kind of indurated cord may be felt external to the absorbents, from the edge of the pectoral muscle to the supraclavicular or subclavicular glands may be felt. In fact, the whole of the glandular structures in the axilla undergo cancerous infiltration. When this is the case, the pressure exercised upon the axillary vein may occasion the swelling of the arm. The glandular infiltration usually increases rapidly, and is implicated. In some cases, scirrhus of the axilla is the primary disease ; and in other instances it happens that

ected, the chief virulence of the disease appears to expend itself upon them. The tumour of the breast ceases to enlarge, or may even atrophy, whilst the secondary glandular deposits in the axilla become greatly developed.

As the scirrhus extends, it may gradually affect the subjacent muscles, cellular tissue, the ribs, and at last the pleura, giving rise eventually to hydrothorax or secondary visceral deposits. In many instances, however, the disease proves fatal by the induction of exhaustion. The constitutional cachexy is in many cases not very distinctly marked, until after the skin has become involved; but then it rapidly increases, more especially when ulceration takes place. Indeed, the cancerous degeneration of the skin may be looked upon as an epoch of peculiar importance in scirrhus of the breast, as it is at this period that the pain increases, that the lymphatic system becomes infected, and that the constitution becomes distinctly poisoned.

Duration.—The duration of life after the occurrence of scirrhus of the breast varies greatly; so much so, that the disease may be considered as assuming an acute and a chronic form. The acute variety principally occurs in ruddy and plethoric women, and commonly proves fatal in a few months. In those who are of a more feeble and delicate constitution, the disease, as a general rule, takes a slower course. Sir A. Cooper states that the disease, on an average, is from two to three years in growing, and from six months to two years in destroying life after being fully formed. In this estimate, which is probably correct, Walshc agrees; so that the average duration of life in cancer of the breast would probably be about three years. As a general rule, the progress of scirrhus is slower in old people, in whom it occasionally gives rise to a kind of atrophy of the breast, with shrinking and induration of the tumour. There are many instances on record, however, in which cancer of the breast has existed for a far longer period than has just been mentioned; for ten, twelve, or even, as in a case related by Sir B. Brodie, for twenty-five years.

Pathological Structure.—After removal, scirrhus of the mamma presents considerable variety in appearance. In the majority of instances it occurs as a peculiarly hard, knobbed, and irregular mass, creaking under the knife when cut, and presenting on section a greyish or bluish grey, semi-transparent surface, traversed in various directions by bands of a more opaque character, and exuding on pressure a thin reddish juice. In many instances, masses of an opaque appearance and yellowish tint may be seen in the midst of the tumour. These, which look like tuberculous deposits, consist in reality of fatty degeneration of the scirrhous structure. In other cases again, on pressing the tumour, small drops of a thick creamy fluid will appear to exude at various points. This appears to be the inspissated and altered secretion of the gland retained in the ducts. Cysts are occasionally, though rarely, met with in scirrhus of the breast; these are usually small, and contain clear fluid, being deeply imbedded in the substance of the tumour; in other cases they may be large and globular, and filled with a bloody or dark-green liquid. The microscopical characters of scirrhus of the breast are such as are represented in Fig. 165.

ENCEPHALOID.—Encephaloid of the mammary region and gland is by no means of such common occurrence as scirrhus, yet all the varieties of this form of cancer have been met with in the breast; and fungus hæmatodes has been seen to spring from the bottom of cystoid growths previously developed in this region. Encephaloid of the breast may sometimes acquire a considerable size; thus, Cruveilhier relates a case in which the tumour

weighed nearly twelve pounds. The structure of from that of the same affection in other situations soft varieties may be met with, and in some advanced growths occur.

Encephaloid usually begins deeply in the substance sometimes, but more rarely, at a little distance globular tumour, which rapidly increases in bulk it are not at first adherent, but are usually pushed become permeated by a largely ramified network have seen the integuments, early in the disease, as to mask the subjacent tumour. The mass at several soft and rounded tumours, which communicating sensation, perhaps causing the surgeon to cystic formation or an abscess; with which it is founded in those cases (rare, it is true) in which cedematous. The breast now rapidly assumes a form; the skin covering it at its most projecting reddened, and at last gives way, leaving a large fungous mass of greyish or reddish-brown colour good deal of discharge of a foul, bloody, and often disintegrated masses are occasionally detached by and cases may even occur in which the whole of the away, and, cicatrization taking place, a tolerable These instances, however, are so rare as scarcely the necessarily fatal character of the affection. In structures in the vicinity of the tumour, following occurs in this as in true scirrhus of the breast. It always extremely rapid, particularly in young and

Colloid of the breast is of rare occurrence, and associated with scirrhus or encephaloid. It is and, slowly growing, may attain a very large size of the breast of a lady a colloid tumour which, she had attained a weight of six pounds. Its colour after careful examination by Dr. Harley. In smooth, somewhat lobed, but not adherent to the On section after removal, it was found to be of varying shades, and composed of a dense, smooth loculi and sacs filled with glairy, transparent colloid

CAUSES OF CANCER OF THE BREAST.—These obscure character.

Sex is certainly the circumstance that has the the occurrence of mammary cancer, the disease almost entirely confined to women; yet instances met with in the male breast occasionally occur. In the female may possibly be owing to the great and functional activity of the breast in women. In this organ at puberty and during pregnancy, the it undergoes, the inflammatory affections to which it is exposed, the frequent irritation to which it is exposed uterine derangement, and the diminution in its place at the change of life, are sufficient to explain organ to disease generally; and may not improve reason why it is so peculiarly the seat of cancer.

Age.—The age at which cancer of the breast

between the thirtieth and fiftieth years. According to Birkett, it is most commonly met with between the ages of forty-five and fifty—a period of life that is popularly looked upon as specially obnoxious to this malady. At these ages, cancer of the breast usually affects the form of scirrhus. When it occurs, as it very rarely does, in early life, it more frequently assumes the encephaloid character. I have, however, removed a scirrhus breast from an unmarried woman of twenty-three years of age. In elderly women also, scirrhus is the prevalent form; though I have seen several instances of encephaloid at an advanced period of life, one case in a woman upwards of seventy years of age. Indeed, cancer in either form may affect this organ up to the latest periods to which life is prolonged. Married women are said to be more liable than single ones to cancer of the breast; it may, however, fairly be doubted whether they are proportionately so; and it is a common belief, founded, I believe, in some degree on truth, that the disease is most common in those women who have not borne children.

Injuries inflicted upon the breast, such as blows, squeezes, &c., are commonly referred to, and are greatly dreaded by women, as the causes of cancer. That they might be so in constitutions otherwise predisposed to the affection, does not appear improbable; and that they are so in reality in many cases, I have not the least doubt. The number of instances that have fallen under my observation, in which a blow or squeeze of the breast has speedily been followed by the appearance of a cancerous tumour in it, leaves no doubt whatever on my mind of the truth of the popular belief that associates the injury with the disease, in the relation of cause and effect. *Lactal inflammations* are likewise frequently supposed to tend to the production of cancer of the breast. Of this doctrine I think that we do not possess at present sufficient proof; though it appears highly probable that disturbances of the functions of the organ during lactation may predispose to the occurrence of this disease.

DIAGNOSIS.—The diagnosis of cancer of the breast from other diseases affecting this organ is of the first importance, and is attended by corresponding difficulties. The great point is to determine whether the tumour of the breast is of a cancerous character or not; that the surgeon should go beyond this, matters little in practice—and, indeed, except in some of the forms of cystic disease of this organ, few practitioners would feel disposed to endeavour to carry their diagnosis beyond this point. The great and essential difficulty in determining the nature of a tumour of the breast consists in the fact of the same signs being more or less common to many growths in this region; a hard, circumscribed, indolent mass, chronic in its progress, with a certain amount of pain, being the usual characteristics presented by all solid mammary tumours; and though in nine cases out of ten a tumour presenting these characters, which has existed for a year or more in an elderly woman, and has resisted ordinary absorbent and alterative treatment, is scirrhus, yet instances of the reverse occasionally occur. Nothing can better exemplify the difficulty of diagnosis in tumours of the breast, than the circumstance, which is not unfrequently witnessed, that after the removal of the diseased mass, its section, and careful examination, surgeons of equal experience will differ as to whether it is malignant or not, and to what class of affections it should be referred; and, indeed, in many of these cases it is impossible to ascertain its precise nature without having recourse to microscopical observation.

It is extremely difficult to lay down any definite rules of diagnosis by which the question as to the malignancy of a tumour of the breast can be solved. In the majority of cases of *cystic growth* in this region, there is little difficulty; the existence of cysts of sufficient size to be readily felt or seen

through the skin being generally characteristic of the non-malignant cystic growths. It must be borne in mind, however, that cases, such as one which allusion has already been made, may occur, in which cysts are combined with cancerous development.

The diagnosis between *cystic sarcoma* and some forms of *cystic cancer* of the breast is not always easy; indeed, it may be impracticable, and only determinable after removal by microscopical examination. I have had in the hospital a patient fifty-nine years of age, in whose breast a hard tumour as large as half an orange, had existed for five years; it was perfectly and freely movable, unconnected in any way with the skin; there was no retraction of the nipple, and no lancinating pain. On its upper side, several large cysts could be felt, and seen through the skin. On examination after removal, it was found to be encysted scirrhus, with large cysts of the size of cherries, containing bloody and yellow fluid. The only very suspicious circumstances here were the age of the patient, and the existence of one small indurated gland in the axilla.

In these cases of doubt, the safer plan is always to make an exploratory puncture, and, if necessary, to examine under the microscope the contents withdrawn by the groove in the needle or by the trochar; indeed, if there be the slightest doubt as to the nature of the tumour, this exploratory puncture should never be omitted before its removal is determined upon. I have more than once seen tumours which had been positively pronounced to be scirrhus, and for which amputation of the breast had been recommended, prove to be cystic, and disappear entirely when their contents were withdrawn.

Between cancer and the ordinary *solid tumours* of the breast the diagnosis is often extremely difficult; but we may arrange the chief signs of the two forms of disease in distinct groups, when, by comparing them together, the differences may be more clearly seen.

NON-MALIGNANT TUMOURS.	SCIRRHUS TUMOURS.
<i>Feel.</i> Moderately hard, nodulated, irregular in shape; occasionally more or less lobed; not very distinctly circumscribed; sometimes elastic in parts.	<i>Feel.</i> Of stony hardness, knobby and distinctly circumscribed, or somewhat square, and occupying the whole of the substance of the gland.
<i>Mobility.</i> Considerable, though occasionally there is a deep pedunculated attachment.	<i>Mobility.</i> At first considerable, but soon becomes fixed to the deeper structures by a broad attachment.
<i>Skin.</i> Of the natural colour throughout, though thinned and expanded, with the tumour lying close beneath it. Only implicated in the advanced stage of cystic sarcoma.	<i>Skin.</i> Early implicated--at first dimpled, then red or purple, and in other cases brown and leather-like, so that it does not admit of being pinched up into folds; or nodulated, purplish red masses form in it.
<i>Nipple.</i> Usually not retracted.	<i>Nipple.</i> Usually retracted.
<i>Veins of the Skin.</i> Not much dilated.	<i>Veins of the Skin.</i> Very greatly dilated.
<i>Pain.</i> Often moderate, if severe, continuous or of a neuralgic character, much increased by handling.	<i>Pain.</i> Severe and lancinating, especially at night after handling, and when the skin is implicated, but not continuous.
<i>Axillary Glands.</i> Of usual size, or but slightly enlarged and movable. Lymphatics not affected; supraclavicular glands not affected.	<i>Axillary Glands.</i> Enlarged, indurated, and fixed. Indurated mass of lymphatics under and parallel to edge of the axilla, stretching into the axilla; supraclavicular glands enlarged.
<i>Constitutional Infection.</i> None.	<i>Constitutional Cachexy.</i> As disease advances.

Rapidity of growth, although always a very suspicious circumstance, cannot by itself and without other signs be taken as unequivocal evidence of malignancy of action. I have seen a chronic mammary tumour increase from the size of a hen's egg to that of the adult head in less than six months, and after removal not present the slightest evidence of malignant disease, on the most careful examination.

Recurrence after removal, though a very suspicious circumstance, is by no means a proof of malignancy. Rapidly growing adenocoele will recur. This I have seen happen three times in a lady, otherwise in perfect health, and without a trace of malignant disease in the system or in the tumour. So also the recurring fibroid tumour has been removed eight or ten times from the breast, before its complete extirpation has been effected.

TREATMENT.—In cases of cancer of the breast, the first question that presents itself to the surgeon is, whether any plan of treatment short of the removal of the tumour holds out a prospect of cure, or even of relief; and if not, whether the extirpation of the cancerous breast can be undertaken with a prospect of ridding the patient of an otherwise fatal disease, or at least of prolonging her existence. To these questions the remarks made at pp. 490 *et seq.*, on the general treatment of cancer, may be considered applicable. The management of cancer of the breast, however, involves so many special considerations of importance, that it becomes necessary to consider its bearings somewhat in detail.

No constitutional means appear to be of the slightest service in arresting, and still less in removing, cancerous tumours of the breast. The advantages stated to have been derived from the use of arsenic, conium, iron, and various preparations of mercury, have not been borne out by experience; and, indeed, it may be stated generally that these and all other known remedies are perfectly valueless in the curative treatment of this disease.

Compression by various means, whether by plasters, as employed by Young; by agarie, as used by Recamier; by the sprung pads of Tanchou; or by the slack air-cushion of Dr. Arnott, has been much praised, not only as a palliative, but as a curative means of treatment in this disease; and cases are recorded, which, however, even the warmest advocates of this plan of treatment are forced to admit to be altogether exceptional, in which the employment of this means has been stated to have effected a complete removal of the tumour. But, although I am not prepared to deny that hard and chronic tumours of the breast may have become absorbed during the employment of this treatment (and indeed I have had occasion to observe this in my own practice, in cases of chronic mammary growth), I think that evidence is altogether wanting to show that an undoubted case of cancer of the breast has ever been cured by this means. And, notwithstanding the high authority with which some of these alleged cases of cancer have been brought before the profession, no positive proof has been adduced to show that the tumour that was observed was really and truly of a cancerous character, and that it may not have been either a chronic mammary tumour, or an encysted abscess of the breast. Every practical surgeon well knows that it is utterly impossible, in the present state of science, to diagnose in many cases with complete certainty the true nature of a tumour of the breast, and must frequently have witnessed cases in which, after extirpation, the morbid growth has been found to be of a different character from what had originally been supposed. I am acquainted with at least eight or ten cases in which some of the most experienced surgeons, both in this country and in Paris, have amputated the breast for supposed scirrhus; when, after removal, it was found simply to have been the seat of a chronic abscess with very dense walls. And with

regard to a hard, chronic, and indolent tumor, will hazard a positive diagnosis as to its nature, until they have actually seen a section of that men of equal experience will differ as to its nature. For these reasons, in the utmost hesitation the cases of suppuration cured by the advocates of compression recorded by these gentlemen as instances of this plan of treatment may have been other than those of a cancerous character.

But, though there is no evidence before me of compression as a curative agent in cancer when practised with Dr. Arnott's slack air, it is of considerable value as a palliative in this disease; when it may undoubtedly at a time, diminish the size of the swelling, attacks of lancinating pain which are so connected with the pressure, much relief to the use of belladonna plasters, or of atropine with the internal exhibition of conium. In some cases, however, when the skin is involved, increasing the pain, and acting as a source of some cases of this kind, in which the slack air I have seen relief afforded by moderate pressure supported by an elastic bandage, belladonna dusted on the innermost layer of amadou, moulded to the part, may sometimes be used, and kept on by turns of an elastic roller. In very tender, the application of bread poultice and lead lotion is of use. When the disease is advanced, internal administration of conium, so as to produce local application of chlorinated lotions to the application of the watery extract of conium much use. In cases of this kind, the tumor, greatly vaunted, and portions of the disease removed by these means.

Caustics, applied in accordance with the plan, may occasionally be advantageously employed on the breast, when excision is not practicable, and the patient positively refuses to submit to the operation, so that the effects of loss of blood, and cancer is already ulcerated.

OPERATION.—The constitutional and local effects of the breast being thus, at the most, of a palliative operation always presents itself at last. The first operation are, in the first place, by the external application prevent constitutional infection, and thus save from her necessarily fatal affection; or, failing of the constitutional infection, and thus attain far these objects are attained by amputation. The subject of important inquiry to the surgeon, is discountenanced by many excellent pathologists, on the intrinsic danger it may possess, for, although syphilis or some similar accidental complication

hazardous about it ; nor from its being now, as formerly, open to the objection of subjecting the patient to unnecessary pain, all suffering during its performance being prevented by anaesthetics, and little inconvenience being experienced at subsequent dressings, which are usually of a nearly painless character ; but the great objection lies in the fact of the disease, in many cases, returning and running its course as rapidly after the operation as if none had been performed, and in others perhaps even more rapidly.

The principal points in connection with the operation appear to resolve themselves into two questions :—1. In any case of cancer of the breast, may constitutional infection be prevented by amputation of that organ ; and, if so, under what circumstances will this most probably happen ? 2. Although the disease may eventually return in the part or elsewhere, may not excision arrest the rapidity of the fatal termination ? (*Vide p. 496.*)

1. In answer to the first question, it is not easy to give a very definite reply. Nothing shows more clearly the utter worthlessness of many so-called surgical statistics, than the discrepancy that exists between those which have been published as exhibiting the liability to relapse of cancer after operation. Thus, Hill states that, out of 88 cancers on which he had operated, at least two years before the return was made, there were only 10 relapses, and 2 deaths ; whilst Alexander Monro states that, out of 60 cancers which he had seen removed, in only 4 patients was there no relapse at the end of the second year. Boyer saved 1 only in 25, and Macfarlane gives a still more unfavourable account of his practice ; for he says that, out of 32 cases of cancer operated upon by himself, there was not one instance of radical cure ; and of 80 other cases with which he was acquainted, the result was in every instance unfavourable. Warren, on the other hand, saved 1 in 3 ; and Cooper 1 in 4. Amidst such conflicting statements as these, it is clearly impossible to eliminate more than the general fact, which is well known to every surgeon ; that, in a large number of the cases of cancer operated upon, there is a tolerably speedy return of the disease. In these cases there are, however, many points to be taken into account, of which gross statistics can take no cognisance ; much being necessarily dependent upon the skill with which the operation is performed, as well as upon the care employed by the surgeon to cut widely of the disease, and to extirpate completely not only the whole of the morbid mass, but those tissues in its neighbourhood which might be supposed to be implicated.

In many of these cases, also, it is by no means improbable that the practice, at one time pretty generally followed, may have been adopted, of merely extirpating the tumour without removing the whole of the breast. I am therefore disposed to look upon any deductions based upon the statistics of such men as Hill, Macfarlane, and Benedict, as of very little value when applied to the surgery of the present day.

It would, however, appear from those inquiries, that in a certain proportion of cases, whatever the precise ratio be (and this is still undetermined), the disease may be effectually removed by extirpation of the breast.

2. As to the second question, whether as a general rule life may not be prolonged by the performance of the operation,—it would appear, if the statistics collected by Leroy D'Etiolles are accurate, that hitherto it has not been so. Dr. Walshé comes to the conclusion that the operation cannot, as a general rule, be regarded as a means of prolonging life, but that in the majority of cases, death is hastened by such interference. Sir A. Cooper and Sir B. Brodie both agree that, in most cases, the disease returns in two or three years after the operation, and then kills the patient.

But though the general result of a statistical inquiry into this subject,

based upon the imperfect materials and probably present before the profession, leads to the conclusion that cancer of the breast, when indiscriminately performed, failed to cure the disease, but has actually in many cases hastened its fatal termination, yet it must be admitted that it does occur in which life is certainly prolonged beyond its average duration in this disease. The case in which no return took place for twenty years that he has removed encephaloid tumours of the breast has remained free from the disease for eight or ten years, and other surgeons relate similar instances in which life has been prolonged after the performance of the operation. The opinion of the most eminent practical surgeons is decidedly in favour of recourse to it under certain circumstances.

The only reliable statistics that we possess on the subject are those collected by Paget and Sibley. Paget states that of 121 cases submitted to operation; of these the average duration of life was 64 months. Of 64 operated on, the corresponding average duration of life was 11 months. In the first two years of the disease the duration of life was much less in those operated on than in those not operated on; the former less than 11 per cent., in the latter more than 11 per cent. The longest duration of life in cases not operated on, a little more than 12 years. The average duration of life in unoperated cases was 18 months. In those subjected to amputation of the breast it was 11 months.

There is, however, another point of view from which the question may be considered; for, even if they do not positively improve the patient's condition, and place her in a more comfortable position during the remainder of her existence, they do remove so much pain from the local affection, or, if the patient is much affected by the fetor of the discharges, they afford a position of far greater comfort by having the irritation removed; and though she die eventually, she is much less suffering to herself and others from the secondary deposits in the lungs or liver, than to be afflicted with the local affection.

In considering the propriety of operating in cancer of the breast, the utmost importance to distinguish those cases in which it possibly be the means of preserving or prolonging life, and those in which there is no prospect of its being of any service, but which inevitably hasten the patient's death. Whatever the result be in determining the question, whether in cancer of the breast generally the operation will effect a cure or prolong life, is of less value in their application to individual cases. For his opinion respecting the propriety of amputating the breast of a patient before him, it is not sufficient for him to know the general result of the operation may be, but he must know whether the particular instance under consideration is a favourable case, exceptional perhaps, in which there is a fair prospect of the disease entirely from the system, or at all events of its long existence. In order to do this, it is necessary to establish some rules that may guide us in selecting those cases in which it may be advantageously done, and in setting aside

that it will almost to a certainty hasten the patient's death. And, indeed, the absence of all such considerations in general statistical investigations into the results of operation for cancer, that deprives them of much of their value as guides in actual practice.

Though nothing can be more unsurgical or improper than the indiscriminate extirpation of all cancerous tumours of the breast from every patient who may present herself in whatever stage of the disease; and though such a practice would doubtless be followed by fully as disastrous results as those that occurred to Macfarlane, Benedict, and others; yet there can be little doubt that a surgeon who would employ a certain principle of selection, could obtain a very different and a far more successful result in his practice. Sir B. Brodie has very clearly and succinctly pointed out the most important circumstances by which the question as to the propriety of operating in these cases should be determined. Before doing so, he very justly dwells on the fact that in many cases the operation may fail, and the disease speedily recur, through the negligence of the surgeon in leaving behind portions of the gland, slices of the tumour, or contaminated tissues, and that thus the operation may receive discredit for what is in reality the fault of the surgeon who has performed it.

With reference to operations, cancerous diseases of the breast may be divided into three classes:—1. Those in which it is the duty of the surgeon to discountenance excision; 2. Those in which operation is of doubtful expediency; and 3. Those in which it is the duty of the surgeon to recommend it.

1. *Cases unfit for Operation.*—In this class we may include the following conditions: *a.* Those cases in which there is strongly marked constitutional cachexy; *b.* When both breasts are involved; *c.* When there are secondary deposits in internal organs; *d.* When the glands under, and especially above, the clavicle are much enlarged; *e.* If the tumour be adherent to the ribs and intercostal muscles; *f.* When the skin is hard, brawny, and infiltrated, of a reddish-brown colour, having a hard, leathery feel, or a greasy, glazed appearance; *g.* If the tumour be rapidly growing in a patient with a strong hereditary taint; *h.* If it be extensively ulcerated and fungating.

2. *Doubtful Cases.*—*a.* If the patient be aged, weak, or anæmic, and the tumour large, it is seldom expedient to operate, as the shock may destroy life. *b.* When the skin is merely dimpled in by a kind of pedicle passing from the tumour to its under surface, an operation may be performed, unless other circumstances should contraindicate it; but in such cases it is necessary widely to excise the integument surrounding the attached point. The cancer-cells, as I have more than once had occasion to observe, will be found to have diffused themselves extensively through the neighbouring skin, which, to the naked eye and to the touch, has a perfectly healthy appearance, the tumour being surrounded by a kind of halo or atmosphere of cancer infiltration. *c.* When there is but moderate enlargement of the axillary glands, which are so situated as to admit of removal, the operation may be performed. *d.* When the cancer is ulcerated, it is seldom proper to operate; but if all other conditions be favourable, this even need not in some special cases be a bar. As Sir B. Brodie has pointed out, the patient's existence may sometimes be prolonged, and her comfort materially increased, by removing the diseased and ulcerated mass.

3. *Cases favourable for Operation.*—The exclusion of all the cases that fall under the preceding categories will necessarily limit very materially those in which an operation may be undertaken; it can, however, be performed

with every prospect of its being advantageous to the patient, if the tumour be of moderate size, slow or nearly stationary in its growth, unconnected with or at least merely attached by a pedicle to the skin, pretty distinctly circumscribed, movable on the subjacent parts, and not complicated with enlarged glands in the axilla or elsewhere. The patient has an especial good prospect of recovery, according to Brodie, if the disease be seated in the nipple.

When once a tumour of the breast has been ascertained to be of cancerous character, the sooner it is removed the better, unless one of the special reasons adverse to operation that have just been adverted to should exist. I cannot conceive that any good can come of delay in these cases. The disease (for reasons stated at pp. 488-489) appears in the early stages often to be entirely local; there is no evidence of constitutional infection, but if the operation be delayed the skin speedily becomes implicated, the axillary glands enlarge, and cancerous cachexy sets in. As a general rule, it may be stated that in all cases of cancer of the breast the whole of that organ ought to be freely removed, especial care being taken that no slices of mammary structure be left behind; and after removal the under surface and edges of the gland ought to be carefully examined, with the view of seeing that the extirpation has been complete. When the cancer is infiltrated, the whole of the breast and the surrounding cellulo-adipose structures must be very freely removed, as there is often a halo of cancer-deposit around the morbid mass, in tissues apparently healthy. It may happen that the tumour, especially if scirrhus, is apparently isolated, and situated at the outer border of the gland, scarcely, if at all, connected with that structure. Here the question will arise, as to whether the whole of the organ ought to be removed or not. In determining this we must, I think, be guided by the position of the scirrhus mass and the size of the breast. If it be situated towards the sternal or under aspect, however isolated it may appear, it will be found that the mammary gland will probably have become infiltrated more or less, lying as it does between the morbid mass and the lymphatic vessels. When, however, the tumour is seated at the upper or outer border of the gland, when it appears to be detached from the breast, lying rather in the axilla or below the clavicle than in connection with the gland; when the breast itself is very large and fat, but healthy to the feel, without hardness or retraction of the nipple; when there is no sign whatever of deep infiltration of the breast—it may then be a question whether it will not be more prudent to extirpate the tumour alone, with the adipose bed in which it lies, and a deep slice of the adjoining mammary gland, than to perform the more serious operation of removing the whole of the breast. In determining this point we must, I think, be guided by the situation of the tumour, the feel of the breast, and the size of that organ. If the tumour be distinctly axillary, if the breast feel perfectly soft and healthy, with the nipple projecting, and if it be of very large size, the surgeon best consults the patient's safety by simply removing the tumour with a deep slice of the contiguous portion of the gland; but if there be any hardness or suspicious nodulated feel about the mammary gland, if the line of demarcation between it and the tumour be not defined, and particularly if the patient be thin and the breast small, so that the operation is not a very severe one, the extirpation of the whole of the breast ought certainly to be practised. However widely the parts are removed, the line of incision usually comes together readily and evenly, owing to the laxity of the integuments in the mammary region.

I have observed in those cases in which it becomes necessary to extirpate tumours of the mammary region, without removal of the gland, that

myxoid has more frequently followed the operation than when the gland, being affected, has required removal.

Return of Cancer after Operation may take place in three situations; in the cicatrix of the part operated upon; in the neighbouring lymphatic glands; or in some internal organ. When cancer recurs in the neighbourhood of the previously affected part, it is probably owing to the cancer-cells having infused themselves so widely into the skin, the subcutaneous cellular tissue, and muscles, or neighbouring lymphatic glands, that after the removal of the tumour these cells become the germs of new growths. Under these circumstances, it may recur in the cicatrix and then implicate the glands; or in the glands, without the cicatrix having been previously affected. In local relapse of this kind, it often happens that the disease, so reproduced, runs a course more rapidly than if no operation had been performed; the increased action set up in the part during the healing process appearing to give augmented force to the reproductive energy of the cancerous growth. In some cases it even returns in the cicatrix before cicatrization is completed, the ulcerated surface then assuming the ordinary character of the cancerous ulcer. In other cases the cicatrix, some weeks or months after it is fully formed, assumes a dusky red or purplish tinge, becoming hard, stony, and nodulated at points; these nodules being round or oval, often very numerous, and varying in size from a pin's head to a pigeon's egg, studding the whole length and breadth of the cicatrix, and at last running into true cancerous ulceration. Under such circumstances the only hope of prolonging the patient's life lies in the speedy excision of the whole of the diseased structures, or their extirpation by caustics, provided there be no deep affection of the glands, nor evidence of internal secondary deposit. But if the axillary glands be much enlarged, either alone or together, with recurrent disease in the cicatrix, or if there be any sign of internal cancer, further operations will be improper.

AMPUTATION OF THE BREAST.—The operation for the removal of a breast, whether affected with cancer or with other disease, may be performed in the following way. The patient should lie upon a table, with the arm hanging over the side, tied down or held by an assistant. If the tumour be large, and the loss of blood a matter of much consequence, another assistant should compress the subclavian artery on the first rib. The hemorrhage will, however, depend more on the nature than on the size of the tumour. In all cancerous tumours, but especially in the encephaloid, it is considerable, and from many enlarged vessels. In simple tumours, even of very large size, it is often trivial. I have removed a simple tumour of the breast of many pounds weight, and only had to tie one spouting vessel. Indeed, nothing indicates more conclusively the enormous vegetative activity of cancerous tumours, and the great drain they must exercise upon the system generally, than the large size and great number of their supplying arteries, compared with those sent to a simple tumour many times larger than the malignant one. If the veins about the part be much dilated, measures should be taken to arrest the flow of blood from them, as it may sometimes be dangerously profuse; indeed, South relates the case of a patient who died from this cause during the operation.

Some surgeons make a perpendicular, others a transverse incision. I prefer an oblique incision following the course of the fibres of the great pectoral muscle; as it enables the surgeon, if necessary, to extend the cut into the axilla for the removal of enlarged glands, and, after cicatrization, allows of the movements of the arm without undue traction. An oblique elliptical incision, of sufficient length, may thus be made, first below, and next above

the nipple, so as to include a sufficient quantity of skin, where the skin is somewhat involved, made in addition to this, so as to include in a triangular manner. When the tumour is very large, a vertical incision may very conveniently include the suspicious parts of the skin. The dissection is then carried down, by a few strokes of the scalpel, to the cellular bed in which it is situated. If the tumour is of large size, and especially if it be of simple character, the dissection may be done very expeditiously by drawing down the cellular tissue with the scalpel, when the pectoral muscle, and can readily be detached from the diseased breast, it and the tumour, as well as the surrounding tissue, must be carefully examined, in order to see if morbid tissue have been left behind; if so, it must be removed. Should it be found that there are lymphatic glands in the axilla, they may be extirpated either by extending the incision into this region, or by making a separate incision, and dissecting them out. In doing this, the edges of the wound must be very carefully used, and the glands rather taken out with the knife and the fingers, so as to avoid the risk of leaving any behind. The extirpation of the axillary glands is the most troublesome part of operations on the breast, and is much higher into the axilla and under the edge of the tumour than would at first appear. When exposed, they are to be removed with a hook or an artery-forceps, well drawn down, and then cut out with the knife, aided by a few cuts with the fingers. The less the point is used deep in the axilla, the more practicable with the knife; but, having been exposed in the way already mentioned, it is not difficult to remove them, and then tightly tied as high as possible with a ligature, the portion below the noose being then cut off. The two great dangers which attend extirpation of the axillary glands are, deeply situated and out of sight—hemorrhage from the dilated veins; and, the ligature being applied to a vessel which remains of it will slough away when the ligature is removed.

It occasionally happens that tumours are of a primary disease, unconnected with any malignancy, either in the upper extremity or in the breast, of a strumous or of a cancerous character; when strumous, they are readily enough removed, and they become so widely and deeply adherent, that their removal is undertaken without much danger. In such cases, the dissection is to expose the axillary and subscapular vessels, and the tumour is to be removed.

After any bleeding vessels have been ligatured, the breast has been taken out may be brought together by suture, and supported by a bandage, so as to prevent the wound from opening. In many cases it will unite by the yielding nature of the parts in this situation, and form into very good apposition, even though a consid-

By some it has been supposed that relapse of cancer is less liable to take place if the wound unite by granulation, than if it come together by more speedy union ; of this, however, there is at present no proof with which I am acquainted, though it is by no means improbable that the suppurative action may eliminate cancer-cells from the neighbouring tissues.

The *mortality after amputation of the breast* is not considerable, barely amounting to 10 per cent. The circumstances that chiefly influence it are the nature of the tumour, and the extent of the incision into the axilla. It is much greater after operations for cancerous than for simple tumours ; and the operation becomes dangerous in proportion as the dissection requires to be carried deeply into the axilla or under the pectoral. The danger here is threefold : 1, from hemorrhage ; 2, from the entry of air into a vein ; 3, and chiefly, from opening up the deep fascia of the axilla, and the risk of the occurrence of deep cellulitis. When death follows these operations, it is usually the result of erysipelas or of pyemia.

DISEASES OF THE BREAST AND AXILLARY GLANDS IN THE MALE.

The *male breast*, though very rarely the seat of disease, may occasionally become affected in a somewhat similar manner to the mammary gland in the female ; being, in some instances, *hypertrophied*, in others the seat of an *abnormal secretion of milk*, and, in other cases, affected by the formation of *cystic, sarcomatous, and scirrhus tumours*. These growths require removal by the same kind of operative procedure that is adopted when they affect the female breast, though of a less extensive character.

SCIRRHUS TUMOURS may form in men as well as in women, as primary

DISEASES OF THE ABDOMEN.

CHAPTER LXI.

HERNIA.

By *Hernia*, in its widest sense, is meant the displacement of any organ from the cavity in which it is naturally contained, by being protruded through an abnormal or accidental opening in its walls; when, however, it escapes through one of the natural outlets of the part, it is not considered hernial. Thus, the protrusion of the brain through an aperture in the cranium, or of the lung through one in the thoracic walls, or of a portion of intestine through the abdominal parietes, is termed a hernia of these organs; but the descent of the bowel through the anus does not come under this designation. Here, however, we have only to consider the hernial protrusions that occur from the abdomen—the common situation of this disease.

A hernia may occur at almost any part of the abdominal wall; though it is far more liable to do so in some situations than in others, being commonly met with at those points where the muscular and tendinous structures are weakened to allow the passage of the spermatic cord in the male, and of the round ligament in the female; or for the transmission of the large vessels to the lower extremity; hence the inguinal and crural canals are the common situations of this disease. It may, however, occur in various other situations, as at the umbilicus, the thyroid foramen, the sciatic notch, in the vagina, the perineum, through the muscular portions of the abdominal wall, the diaphragm, &c.

STRUCTURE OF A HERNIA.—In whatever situation it occurs, a hernia is composed of a *Sac* and its *Contents*.

The *Sac* is the prolongation of that portion of the peritoneum which overlies and corresponds to the aperture through which the hernia protrudes. It is in all cases composed of a *neck* and a *body*.

The *Neck* is usually narrowed, though in some old herniæ it becomes wide and expanded; it is commonly short, consisting indeed of a sudden constriction of the sac in this situation, as happens in many forms of femoral hernia; but in other cases it is elongated, narrowed, and thickened, and even vascular in structure. The neck of the hernial sac usually becomes greatly thickened and of an opaque colour, by the deposit of plastic matter in or upon it from the irritation to which it has been subjected by the pressure of the hernial tumour or the truss, by the incorporation of the subserous cellular tissue lying externally to it, or by the puckering together of its folds, which have been compressed by the aperture in which it lies.

The *Body* of the sac varies greatly in shape, being usually globular or pyriform, sometimes elongated and cylindrical; it may vary from the size of a cherry to a tumour as large as the head. When recent, it is usually thin and transparent, though in some cases it becomes greatly thickened, having arborescent vessels ramifying in it, and being almost laminated in structure; this is especially the case in old femoral herniæ. In other instances, however, it becomes thinned and atrophied as the tumour expands, so that

the contents become visible through it. This umbilical hernia, in which I have seen it as the skin. In some cases the hernial sac undergoes and is converted into a fibrous or even calcareous layer.

The sac, though usually forming a perfect tent, occasionally constitutes but a partial partition, particularly in such organs as the cæcum or sigmoid, which is partially uncovered by peritoneum. In other cases it is altogether absent; more rarely a double hernia is protruded into or placed behind the other. Double sacs occurring together; and Sir A. Cooper has met with in the same person.

The abdominal parietes outside the sac and the aperture through which the hernia protrudes, at a time, indurated and rounded at the edge, and situated in the moveable portions of the abdominal region, it becomes displaced in old hernia by the weight of the protrusion, usually towards the upper part. The cellular tissues always become greatly thickened so as to constitute one of the densest investments of the body. In old cases of hernia, closely to resemble other structures, such as the integument and fascia, stretched; often tense, but not unfrequently usually thinned, but, if a truss have been long used, and condensed by the pressure of the pad.

Contents.—The contents of the sac vary greatly. The pancreas having been found in hernial tumors of the Small Intestine, more particularly of the cæcum, constituting the form of hernia called *Enterocæle*. The diameter of the sac may vary from a small section of the intestine to a coil several times the diameter of the mesentery. After a portion of the intestine has protruded, the part tends to increase in quantity; until, as the greater portion has been known to lie in the sac, it is rarely found in a hernia, though the case is not infrequently met with. When intestine has been long protruded, it is covered by its coats, and narrowed, greyish on the surface, and loses its functions. The corresponding mesentery is atrophied, and vascular.

Omentum is often found in hernial sacs, but not unfrequently met with alone, constituting a separate form of hernia. After having been protruded for some time it becomes indurated and laminated, losing its ordinary cellulo-fibrous structure. Its veins usually assume a somnolent state. The mass of omentum acquires a triangular shape at the abdominal aperture, and the base being fixed to the parietes. In some cases it can be unfolded; in others, it is a conical mass. Occasionally apertures form in the omentum, through which intestine may protrude, thus becoming second sacs. In other instances, cysts are met with in the omentum, in which the intestine may even slip. When intestine is found in a hernia, the disease is termed *enterocele*. In these circumstances the omentum usually does not envelope the intestine. Besides these, the

Stomach, liver, spleen, and all parts of the intestines, bladder, uterus, and ovaries, have all been found in them.

Adhesions commonly form within the sac in old standing cases. These may take place between the contained viscera merely, as between two coils of intestine, or between these and the omentum, or they may form between the wall of the sac and its contents, either by broad bands, or else by bridging across from one side to the other, and in losing a portion of the viscera. In recent cases these adhesions are soft, and may readily be broken down; but when of longer duration, they are often very dense, and are especially firm about the neck of the sac.

Besides the viscera, the hernial sac always contains a certain quantity of fluid, secreted by and lubricating its interior. In most cases, this is in but small quantity; but in some instances, when the sac is inflamed, or the hernia strangulated, a very considerable bulk of liquid has been met with; I have seen as much as a pint escape from a large hernia in an old man. When abundant, it is generally of a brownish colour, though clear and transparent; it is met with in largest quantities in inguinal hernia.

Hydrocele of the Hernial Sac.—In some instances, the fluid becomes collected in a kind of cyst within the sac, formed by the omentum contracting adhesions to its upper part, and leaving space below for the fluid to collect, in which this accumulates between the omentum above and the wall of the sac below; this condition, represented in the following drawing (Fig. 382), has been called *Hydrocele of the Hernial Sac*, and constitutes a somewhat rare form of disease. The fluid is often in considerable quantity; in a case which I tapped some years ago, nearly three pints of dark brown liquid had thus accumulated, and were drawn off.

If we limit the term *hydrocele of the hernial sac* to those cases in which there is a slow and gradual accumulation of fluid at the bottom of an old hernial sac, which has been cut off from all communication with the peritoneum either by the radical cure of the hernia, or by the adhesion of intestine or omentum to the upper part and neck of the sac, it must be considered a disease of unfrequent occurrence; and but few cases are recorded by surgical writers. Curling, in his work on the *Pestis*, states that, during his connection with the London Hospital, he has seen only one case; and the only others with which I am acquainted, besides one that occurred in my own practice, are two related by Pott, two by Poilletan, one by Hoyer, and one by Lawrence. This disease must not be confounded with the accumulation of fluid, in whatever quantity, in strangulated hernia or in hernial sacs that communicate with the peritoneal cavity. Its distinguishing feature is the accumulation of fluid in a sac that has been cut off from all communication with the cavity of the peritoneum.

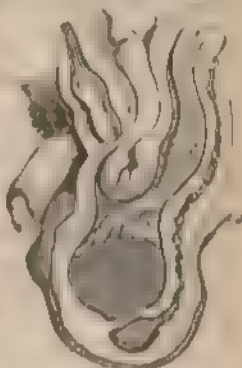

Fig. 382. Hydrocele of Hernial Sac.

Loose foreign bodies have occasionally been met with inside hernial sacs. They are usually rounded, smooth, and firm; vary in size from a pea to a chestnut; and are mostly single. On section they are found to consist of a fatty central nucleus with a laminated fibrous envelope, usually of considerable thickness. They are apparently composed of one of the glandular epiploicae, which has become detached, fallen loose into the peritoneal cavity, and become enveloped in plastic layers.

SIGNS.—The signs of hernia, though varying considerably according to the contents of the sac and the condition in which it is placed, present in all cases many points in common. There is an elongated or rounded tumour at one of the usual abdominal apertures, broader below than above, where it is often narrowed into a kind of neck; usually increasing in size when the patient stands, holds his breath, coughs, or makes much muscular exertion. It can be pushed back into the abdomen on pressure, or goes back readily if the patient lie down, but reappears when he stands up. On coughing, a strong and distinct impulse may be felt in it.

When the hernia is altogether *Intestinal*, it is usually smooth, gurgling when pressed upon, sometimes tympanitic and rumbling, and resonant on percussion. It may be returned into the cavity of the abdomen with a distinct slip and gurgle; it has a well-marked impulse on coughing, and is usually accompanied by various dyspeptic symptoms, and often with a good deal of dragging uneasiness.

Omental Hernia is usually soft and doughy, returning slowly on pressure into the abdomen, feeling irregular on the surface, and having an ill-defined outline. It occurs most frequently on the left side, and is rare in infants, in whom the omentum is short. In *Entero-cynplocle* there is a combination of the two conditions and their signs; but these are usually so uncertain, that few surgeons care to predict before opening the sac what the probable nature of the contents may be.

Cæcal Hernia necessarily occurs on the right side only. It is a large, knobby, and irregular tumour, irreducible, owing to the adhesions contracted by that portion of cæcum which is uncovered by peritoneum. The peculiarity of this hernia consists in the sac being absent, or only partial in the majority of cases, the peritoneum being stripped off as the gut descends. When this hernia is large, and partially invested by serous membrane, a sac usually exists at its upper aspect, into which a portion of small intestine may fall, and which may in some cases constitute a second hernia lying above or before the cæcal one, which will be found situated at the posterior wall when this hernial pouch is opened. Occasionally the vermiform appendix and the caput coli are found in the sac, but can rarely be returned. The rule of cæcal hernia having a partial peritoneal investment only, does not hold good in all cases; and instances have occasionally been met with in which this portion of intestine lay in a distinct sac.

Hernia of the Bladder or *Cystocèle* is of very rare occurrence; and, like that of the cæcum, is usually enclosed in a partial peritoneal investment, though it is not necessarily so. South states that there is a preparation at St. Thomas's Hospital, in which the fundus of the bladder, with its peritoneal covering, has passed into a distinct sac. In some instances the cystocèle is accompanied by an enterocèle. This hernia is always irreducible, is attended by a good deal of difficulty in urinating, with varying tension, according to the quantity of fluid contained; by squeezing it urine may be forced out through the urethra, and fluctuation has been felt in it. Urinary calculi have been formed in the tumour, and have been removed by incision through the scrotum, or have ulcerated out.

CAUSES.—The causes of hernia are usually sufficiently well marked. In some instances, the disease is *congenital*, arising from preteratural patency of the abdominal apertures; in other cases, it occurs at a later period of life, in consequence of some *forcible effort*, as lifting a heavy weight, jumping, coughing, straining at stool, or passing urine through a tight stricture. It is especially apt to occur from such causes as these in tall and delicate people, more particularly in those who have a natural disposition to weak-

ness, or bulging of the groin. The displacement of the abdominal viscera by a gravid uterus, will also occasionally give rise to the disease. Hernia is especially apt to occur from a combination of causes: thus, if an aged person, one with a feeble organisation, or whose abdominal apertures have been patent in consequence of rather sudden emaciation, make a violent effort, a hernial protrusion is very apt to occur.

Amongst the most frequent *Predisposing Causes* of hernia, are certainly sex, age, and occupation.

Sex.—Men are far more liable to this disease than women. Thus, according to Malgaigne, in France, one man in thirteen and one woman in fifty-two are the subjects of hernia. But, though men are more generally liable to hernia than women, they are less so to certain forms of the disease, especially to the femoral and umbilical. It is to the inguinal that they are particularly subject, although old women very commonly suffer from this form. According to Lawrence, out of 83,584 patients who applied to the City of London Truss Society, 67,798 were males, and 15,786 females. For the interesting statistical account of the relative frequency of the different kinds of rupture, deduced from the foregoing figures, I would refer to Lawrence's most excellent *Treatise on Hernia*, 5th ed. p. 11.

Age exercises a very material influence upon the frequency of hernia. Malgaigne, who has carefully investigated this subject, finds that in infancy the disease is sufficiently common, owing to the prevalence of congenital hernia at this period of life; and, that in the first year after birth hernia occurs in the proportion of 1 in every 21 children. It then goes on decreasing in frequency, there being 1 in 29 at the second year; 1 in 37 at the third year; until, at the thirteenth year, it has fallen to 1 in 77. Shortly after this, its frequency begins to rise again, and then goes on progressively increasing until the close of life; thus, at the 21st year, there is one case in 32; at the 26th year, 1 in 21; at the 35th, 1 in 17; at the 40th, 1 in 9; at 50, 1 in 6; from 60 to 70, 1 in 4; and from 70 to 75, 1 in 3. In women, hernia most frequently occurs from the 20th to the 50th years.

Occupation.—Those occupations in which the individual is exposed to violent muscular efforts, more particularly of an intermitting character, predispose strongly to the occurrence of hernia; and in these employments the tendency to the disease is often greatly increased by the injurious habit of wearing tight girths or belts round the waist, which, by constricting the abdomen, throw the whole pressure of the abdominal contents upon the inguinal regions.

CONDITIONS PRESENTED BY HERNIA.—The conditions in which a hernia may be found are very various, and entail corresponding differences in the result and treatment of the affection. When first formed, most hernie may be said to be *Incomplete*, being for a time retained within the orifice of the canal through which they eventually protrude. When they have passed altogether beyond the abdominal walls, they are said to be *Complete*; and this is the condition in which they are usually presented to the surgeon. A hernia may also be *Reducible*, *Irreducible*, or *Strangulated*.

REDUCIBLE HERNIA.

A hernia is commonly at first *Reducible*; that is to say, it may readily be pushed back into the cavity of the abdomen, protruding again when the patient stands up, holds his breath, or makes any exertion, and having a distinct and forcible impulse on coughing. Though the hernial contents, in these cases, are reduced into the abdomen, the sac is not; it almost immediately contracts adhesions to the cellular tissue, by which it is firmly fixed.

in its new situation ; though in some particular cases, as we shall hereafter see, it may be pushed back.

APPLICATION OF TRUSS.—In the Treatment of a reducible hernia, the object is, by the application of a proper truss, to retain the protrusion within the cavity of the abdomen. In order to do this, the patient must be provided with a proper kind of truss, adapted to the particular nature of the hernia. In umbilical and ventral ruptures, an elastic pad and belt may most conveniently be used. In selecting the truss, care should be taken that the spring be of proper strength, adapted to the size and power of the individual ; and that it be properly shaped, so that it does not touch any part of the abdominal wall, but merely bears upon the points of pressure and counter pressure. The pad should be convex, and firmly stuffed, and of sufficient size to press not only upon the external aperture, but upon the whole length of the canal. Before applying the truss, the hernia must be reduced, by placing the patient in the recumbent position, relaxing the muscles by bending the thigh upon the abdomen, and pressing the tumor back in the proper direction ; the truss should then be put on, and be worn during the whole of the day ; indeed, the patient should never be allowed to stand without wearing it. At night, it may either be left off altogether, or a lighter one applied. In some cases, the skin becomes irritated by the pressure of the pad ; under these circumstances, an elastic air-cushion may be used, or the parts subjected to pressure may be well washed with spirit lotion. The truss may be known to fit by testing it in the following way. The patient should be made to sit down on the edge of a chair, and then extending his legs, opening them widely, and bending the body forward, cough several times. If the hernia do not slip down behind the pad on the trial, we may be sure that the truss is an efficient one, and will keep the rupture up under all ordinary circumstances.

RADICAL CURE OF HERNIA.—Various means have been devised in order to effect the radical cure of a reducible hernia. The only plan that is at the same time perfectly safe and permanently successful, is the compression of a well made truss. In this way it not unfrequently happens that the hernia of infants become radically cured ; the same result, however, seldom occurs at a more advanced period of life. In order that compression may succeed in this way, it is necessary that it should not only be applied to the external aperture through which the rupture escapes, but to the whole of the canal. It must also be continued for a very considerable time, for at least a year or two, and care should be taken that during the treatment the rupture is not allowed to descend ; every time it comes down, any good time may have been derived is necessarily done away with, and the treatment has to begin, as it were, anew. After the cure is supposed to have been effected in this way, the application of the truss must be continued for a very considerable length of time, lest by any unfortunate movement the rupture descend again.

The operations that have been devised for the radical cure of hernia are all founded on one of two principles ; viz., the excitation of such an amount of peritonitis in the sac, or its neck, as to cure its obliteration ; or the plugging of the hernial aperture by invagination of the integumental tissue.

If the accomplishment of these conditions would always prevent the recurrence of the rupture, the radical cure might frequently be undertaken. But it is impossible to look upon the agglutination of the walls of the sac, or the closure of the abdominal aperture, as the sole conditions required. To accomplish the radical cure, it would be necessary in many cases to effect changes in the shape and connections of the abdominal contents, to alter the

size of the abdominal cavity, and indeed to modify in various ways many conditions independent of those immediately connected with the hernial protrusion. Many of the means of radical cure, by which obliteration of the interior of the sac or of its neck is sought to be effected by the application of sutures or ligatures, by the introduction of caustics, by excision, scarification, puncture, or injection with tincture of iodine, are attended with so much danger from peritonitis, and are so seldom followed by any good results, that their consideration need not detain us here, the more so as they are universally abandoned by surgeons of the present day.

The operations that are now practised for the radical cure of hernia are conducted on two principles, however much they may be varied in their details by the ingenuity of particular surgeons.

The first principle of treatment consists of invaginating simply a portion of the scrotum, and fixing it in the inguinal canal, where it becomes adherent, and so occludes the aperture of exit. Of this kind of operation Wutzer's is the best example. The second principle of treatment consists in excising a portion of the integumental structures, and then by means of sutures attaching these and the deeper parts together, and thus leading to the consolidation of the canal. Of this, Wood's operation is the best example. The following are the details of these procedures.

Wutzer's Operation.—The late C. W. Wutzer, of Bonn, adopted a plan of radically curing reducible inguinal herniæ, combining the two principles on which the older operations were founded, viz., the agglutination of the neck of the hernial sac by the excitation of inflammation in it, and the closure of the inguinal canal by the invagination of the scrotum; and he carried out these objects in a safer and more successful manner than by any of the methods previously employed. His plan of treatment consists in introducing a plug of the scrotum into the inguinal canal, and fixing it there by exciting adhesive inflammation in the neck of the sac. The details of the operation are as follow. The patient lying on his back, and the hernia being reduced, the surgeon pushes his index-finger up the inguinal canal as high as the internal ring, carrying before it a cone of the scrotal tissues; a box-wood hollow cylinder, about four inches long (Fig. 383, C), well oiled, is then pushed up as the finger is withdrawn, so as to occupy its place in the inguinal canal. Along the interior of this cylinder a flexible gilt-steel needle (A), fixed in a moveable handle, is then pushed, so as to traverse the invaginated scrotum, the hernial sac, and the anterior abdominal wall,

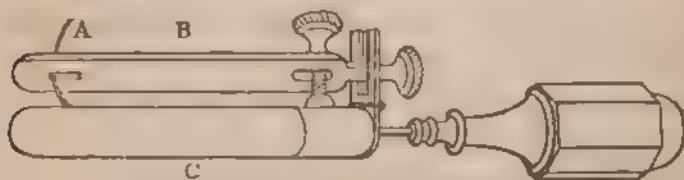

Fig. 383.—Wutzer's Apparatus for Radical Cure of Hernia

through which its point is caused to protrude. A concave box-wood case (B) is then passed over the projecting point of the needle, and fixed by the other end by a screw apparatus to the cylinder (C), so as to compress the inclosed tissues. The apparatus so fixed is left *in situ* for six or eight days; when, some discharge being established, it is withdrawn, and the invaginated scrotal plug supported by lint introduced up its interior, and by a spica bandage tightly applied. The patient is kept quiet for a fortnight longer,

when he is allowed to move about, wearing it months.

This method of treatment is easy of execution, more successful than any that have preceded it, and without the complications and excruciating pains that attend all plans for the radical cure, and without the danger of a dangerous amount of peritonitis between the lower part of the scrotal plug and inguinal canal and ring, and consequent failure of the canal and in the radical cure.

So far as the first objection is concerned, I can be attached to it. I have very often performed it, and have never seen the slightest evidence of a disorganization or other local mischief, except abrasion of the skin in some cases. With respect to the second objection, failures are not unfrequent; but on the other hand, I have now under observation several cases which have resulted, although several years, from the operation.

Wutzer's operation should, of course, not be performed in all cases of reducible inguinal hernia of large size, with a very patent ring, and without the omentum, no good result can be expected, and a radical cure. But on the other hand, if the hernia is small, and of recent occurrence, and if it be confined to the canal and have not as yet become irreducible, the best result may be expected; and there can be no danger to the patient the chance of a radical cure of his hernia by an operation that is not only simple and almost painless.

Wood's Operation.—In order to secure the closure of the canal, and especially the cohesion of the walls of the canal, Mr. John Wood has brought forward another method. This method consists in the approximation of the walls of the canal, by forming the boundary of the hernial canal, by a permanent ligature through a puncture in the skin, and to inguinal hernia, in order to promote the adhesion of the sac and cord from the skin, and to protect the sac and cord from the skin, transplanted by invagination of the skin by the ligatures till adhesion ensues to the skin and spermatic cord. The ligature is so applied as to pass over the places upon the structures forming the posterior wall of the canal, the triangular aponeurosis; and the lower portion of the external oblique muscle, and the lower portion of the external oblique muscle, the pillars of which are made to adhere by the ligatures, which is thus produced between the walls of the canal, the former is made to adhere to the latter, preventing the descent of a hernia into the canal, and the reproduction of the rupture is prevented. When the temporary effusion of lymph is reabsorbed, and the abdominal contents tending to protrude are prevented by the valve-like action of the posterior wall of the canal, itself upon the recently formed adhesions. The operation is a very adjunct in the cure, is rendered unnecessary

Operation.—The patient being laid on his back, with the shoulders well raised, and the pubes and scrotum shaved, the hernia must be reduced and held up by an assistant pressing upon the internal opening. The operator, standing at that side of the patient which is about to be operated on, makes, with a small tenotomy knife, an incision about three-fourths of an inch long through the skin of the scrotum over the lower part of the tumour; or, if this be large, about two and a half inches below the pubic spine. Then the knife, being inserted flatwise between the skin and the fascia, is made to separate them around the incision over an area of about a two-inch circle; a proceeding which the loose attachment of the skin easily allows. The knees of the patient should next be drawn up towards the abdomen, and held together so as to relax the structures connected with Poupart's ligament. The forefinger is next passed through the opening in the skin, and made to invaginate the detached fascia through the external ring into the canal, which is best done by using the right hand for the right side, and vice versa, keeping the palm directed forwards. The invagination of the fascia should be commenced from as low a point as the cutaneous incision will permit, so as to push the invaginating finger as much as possible between the sac of the hernia and the spermatic cord. When the finger is in the canal, its point should reach the internal opening of the hernia, and the cord should be distinctly perceptible to it and protected by it. The point of the finger will then be placed behind the lower border of the internal oblique, and must render this point prominent at the surface by being hooked forward. The surgeon will then be sensible of the edge of the conjoined tendon, raised in relief along the outer border of the invaginating finger. Next, the needle, stout, blunt-pointed, and curved, mounted on a strong handle, is to be passed along the outer border of the finger as far as just beyond the extreme joint, at which point it is made to pass through the conjoined tendon and the external oblique aponeurosis, till it is seen to raise the skin. The latter is then to be drawn upwards and inwards as far as possible before the needle is pushed through it. Then a strong, smooth, hempen ligature, well waxed and then soaped, is passed through the eye of the needle; and the latter is withdrawn, leaving one end of the ligature through the puncture. The invaginating finger is then placed on the outer side of the cord, behind Poupart's ligament, as far from the border of the external ring as possible, raising the ligament on its point. The needle carrying the other end of the ligature is then passed along the inner border of the finger, and pushed through the external pillar close to Poupart's ligament, opposite to the internal ring, the skin being drawn down till the point of the needle appears at the former puncture, through which it is then pushed. The loop of the ligature is then seized and retained in the puncture, the free end being withdrawn with the needle; care being taken to ascertain, before withdrawing the instrument, that the free end of the thread runs in the eye. Next, the forefinger, with the nail turned forwards, is to be placed inside the external ring just above the pubic spine, and pressed upon the posterior wall of the canal, so as to be sensible of the outer edge of the rectus muscle, and of the triangular aponeurosis and conjoined tendon covering it in this situation. At the same time, the scrotum must be drawn well over the groin of the patient, so as to bring the spermatic cord as far outwards over the external pillar of the ring as possible. The point of the invaginating finger will thus cover and protect the cord from injury. The needle is then passed through the triangular aponeurosis and conjoined tendon as far as to the border of the rectus, and pushed through the internal pillar of the external ring about half an inch above the pubic crest. The

skin being drawn downwards and inwards, the made to pass a third time through the original thread is then disengaged from the instrument. We then have two ends and a loop of the puncture in the groin, the former perforating the inguinal fascia, and internal pillar, and the latter the pillar of the ring. With one finger in the ring, traction on the ligature, be able to satisfy obtained on the posterior wall, and that the well drawn together. The ends of the ligature the outer side of the groin, and the loop crossed the median line. A glass or box-wood compress two and a half inches long by one inch wide along the axis of the canal upon the crossed passed over the compress threaded through the end in a loop-knot. The lower extremity of the pubic crest, up to which point the put tucked. A pad of lint is then placed on each it steady, and a linen pad and spica bandage be removed after twenty-four hours; the on sixth day; while the ligature threads may be weeks, according to the amount of action or of the inguinal canal.

IRREDUCIBLE HERNIA

Irreducible Hernia are usually of old date, rarely contain a considerable quantity of the intestine and mesentery. In many instances partly reducible, the greater portion remains the gut which slips up, and the omentum that

CAUSES OF IRREDUCIBILITY.—The irreducibility depends either on its shape, on the existence of nature. If the sac become the seat of an neck become elongated and narrowed, the hernia permanently protruding. So also, the expansion of the omentum, and the narrowing of its neck at the rupture. The existence of adhesions, of contents, or between protruded intestine and the sac, render a hernia irreducible; and most frequently changes in the shape of the sac or the omentum and bladder can never be returned, on account to which reference has already been made.

SYMPTOMS.—An irreducible hernia is inconvenient; it has a tendency to increase if left uncontained, as in some extreme cases it has been known to contain the abdominal viscera, forming an encysted mass of considerable size and weight, in which the penis and scrotum are included. If the irreducible hernia is of small size, it gives little trouble in the part, with dragging pains, and is void of colicky sensations and dyspeptic derangement. In these circumstances, as in a state of considerable enlargement, it becomes strangulated by violent efforts, and is attended with great pain.

TREATMENT.—For the above reasons, it is

rupture of this kind from external violence, but to endeavour to prevent its increase in size. This may best be done by letting the patient wear a truss with a large concave pad, which supports and protects it; provided the rupture be not of too great a size for the application of such an instrument. If its magnitude be very considerable, it must be supported by means of a suspensory bandage. Bransby Cooper has recommended that an attempt should be made to convert the irreducible into a reducible hernia, by keeping the patient in bed for several weeks, on low diet, with the continued application of ice to the tumour; and, if it contain much omentum, giving small doses of blue pill and tartar emetic, so as to promote the absorption of the fat. This plan, which appears to have answered well in some cases, certainly deserves a further trial.

INFLAMED IRREDUCIBLE HERNIA.—The occurrence of inflammation in an irreducible hernia is a serious complication, and one that simulates strangulation very closely. When this complication occurs, the part becomes swollen, hot, tender, and painful; there is not much tension in the tumour, which is seldom increased beyond its usual magnitude; there is a good deal of pyrexia, and symptoms of peritonitis spreading from the vicinity of the inflamed rupture set in. In some cases there is vomiting; but it is not constant, and never feculent, occurring generally early in the disease, and consisting principally of the contents of the stomach; being apparently an effort of nature to get rid of an indigestible meal. If there be constipation, as usually happens in all cases of peritonitis, it is not complete, flatus occasionally passing *per anum*, together with a small quantity of fluid faeces. It is of importance in these cases to observe that the inflammation commences in the body of the sac, and extends into those parts of the abdomen that are contiguous to its neck; the stomachal and intestinal derangements being secondary to this condition.

The *Treatment* of an inflamed irreducible hernia must be directed to the peritonitis which attends it. The application of leeches to the sac and its neck, the free administration of calomel and opium, and the employment of enemata, with strict antiphlogistic regimen and rest, will usually speedily subdue all inflammatory action.

INCARCERATED HERNIA.—An irreducible hernia occasionally becomes obstructed, then constituting the condition termed *incarcerated hernia*. This condition principally occurs in old people, from the accumulation of flatus, or of undigested matters, such as cherry-stones or mustard-seeds, in an angle of the gut. In these cases there is constipation, with eructation, and perhaps occasional vomiting. There may be some degree of pain, weight, or uneasiness about the tumour; but there is no tension in it or its neck, and the symptoms altogether are of a chronic and subacute character.

The *Treatment* of such a case as this should consist in the administration of a good purgative injection; the compound colocynth enema is the best, thrown up as high as possible by means of a long tube. Ice may then be applied to the tumour for about half an hour; and then the taxis, as will afterwards be described, may be used under chloroform. The ice may be omitted in those cases in which, on handling the tumour, gurgling can readily be felt; but the taxis should always be used, as by it the incarcerated gut may be partially emptied of its contents; or if any additional protrusion should have happened to have slipped down, this may be returned. After these means have been employed, an active purgative, either of calomel or croton oil and colocynth, should be administered; and, if any inflammation exists, this must be treated as already described.

STRANGULATED HERNIA.

A hernia is said to be *Strangulated* when a portion of gut or omentum that is protruded is so tightly constricted that it cannot be returned into the abdomen; having its functions arrested, and, if not relieved speedily, running into gangrene. This condition may occur at all periods of life, being met with in infants a few days old, and in centenarians. It commonly arises from a sudden violent effort, by which a fresh portion of intestine is forcibly protruded into a previously existing hernia, which it distends to such a degree as to produce strangulation. But, though old herniæ are more subject to this condition than recent ones, it may occur at the very first formation of a hernial swelling, the gut becoming strangled as it is protruded. There are therefore two distinct kinds of strangulation. One may be said to be of a passive kind, chiefly occurring in elderly people, the subjects of old and perhaps irreducible herniæ; which, in consequence of some accidental circumstance, become distended by the descent of a larger portion of intestine than usual, and this, undergoing constriction and compression at the neck of the sac, gradually becomes strangulated. The other kind of strangulation is most frequent in younger individuals; in it the symptoms are more active, the bowel becoming protruded in consequence of violent exertion, and undergoing rapid strangulation, the tension of the part not having been lessened by the previous long existence of an irreducible hernia.

MECHANISM OF STRANGULATION.—Strangulation has been attributed either to a spasmodic action of the walls of the aperture through which the hernia protrudes, or to changes taking place in the protruded parts, subsequent to and occasioned by their constriction by the tissues external to them. The strangulation cannot, I think, ever be regarded with justice as of spasmodic character; the aperture in the abdominal wall, through which the hernia escapes, being tendinous or fibrous, and certainly not in any way contractile, though the action of the abdominal muscles may undoubtedly increase the tension of its sides. The continued and permanent character of the strangulation, when once it has taken place, would also discountenance this opinion; those forms of hernia, indeed, as the ventral, which occur in purely muscular structures, are very rarely strangulated, and, when they are so, the constriction is generally occasioned by the formation of dense adventitious bands upon or within the sac, and not by any muscular agency.

Strangulation is characterised by congestion of the protruded part induced by the constriction to which they are subjected; the mechanism being as follows. A knuckle of intestine, or piece of omentum, is suddenly protruded during an effort of some kind. This immediately becomes compressed by the sides of the narrow aperture through which it has escaped; the return of its venous blood is consequently interfered with, and swelling and oedema rapidly ensue, together with stagnation of the blood in it. If the constriction be excessively tight, the walls of the ring being very hard and sharp, the part that is so strangulated may be deprived of its vitality in the course of a few hours. If the strangulation be less severe, the congestion will run into inflammation, the changes characteristic of this condition speedily supervening. In proportion as the congestion augments, and the inflammation comes on, the return of the protruded parts is necessarily rendered more difficult by the increase of their swelling.

SEAT OF STRICTURE.—The stricture is most commonly situated outside the neck of the sac, in the tendinous or ligamentous structures surrounding

it; not unfrequently in the altered and thickened subserous cellular tissue. In other cases, and indeed with great frequency, it is met with in the neck of the sac itself (Fig. 384), which is narrowed, elongated, and tubular; or constricted by bands that are incorporated with it. More rarely it exists in the body of the sac, which may have assumed an hour-glass shape. In some cases, it would appear as if this particular shape were owing to an old hernia having been pushed down by a recent one above it. The stricture is sometimes, though by no means frequently, met with inside the sac, consisting of bands of adhesions stretching across this, or of the indurated edge of an aperture of the omentum through which a portion of the gut has slipped.

Fig. 384.—Stricture in the Neck of the Sac.

LOCAL EFFECTS OF STRANGULATION.—The changes induced in the strangulated parts result from the pressure of the stricture, and the consequent interference with the circulation through them. If the strangulation be acute, that portion of intestine which lies immediately under the stricture will be seen to be nipped or marked by a deep sulcus, occasioned partly by the pressure to which it has been subjected, and partly by the swelling of the congested tissues beyond it. The changes that take place in the protruded intestine rapidly increase in proportion to the duration of the strangulation. The tightness of the stricture and the acuteness of the strangulation have, however, even more to do with these changes than its duration. I have seen the bowel so tightly nipped that, though the strangulation had only existed eight hours when the operation was performed, the vitality was lost in the part constricted (Fig. 390); and in other cases I have known the part to recover itself, although strangulation had lasted for five or six days before the operation was performed.

The first change that takes place in the protruded parts in a case of strangulated hernia is their *congestion*; this rapidly runs on to inflammation, and speedily terminates in gangrene. The protruded bowel becomes, at first, of a claret, maroon, or purplish-brown colour, sometimes ecchymosed on the surface, with thickening and stiffening of its coats, owing to effusion into their substance; some liquid is also usually poured out into its interior. In this stage, that of congestion, the omentum will also be found with its veins a good deal congested. When inflammation has set in, the bowel preserves the same colour as in the congested condition, but usually becomes coated here and there with flakes of lymph, which give it a rough and villous look; the omentum has a somewhat rosy tinge, and there is usually a good deal of reddish fluid poured out into the sac. When *gangrene* occurs, the bowel loses its lustre and polish, becoming of an ashy grey, or dull black colour, soft and somewhat lacernable, so that its coats readily separate from one another; the serous membrane especially peeling off. The omentum is dark purplish, or of a kind of dull yellowish grey; and there is usually a considerable quantity of dark turbid serum in the sac, the whole contents of which are extremely offensive. Most usually, when gangrene occurs in a strangulated rupture, inflammation of the sac and its coverings takes place, accompanied, after a time, by a reddish-blue or congested appearance and some tenderness on pressure; and, if the part be left unreduced, eventually by emphysematous crackling. If the case be left without being relieved,

gangrene of the skin will at last take place; the sac giving way, and the fecal matters being discharged through the softened and disintegrated tissue. Under such circumstances as these—which, however, are very rarely met with at the present day—the patient usually eventually dies of low peritonitis from extension of the inflammation to the serous membrane. No effusion, however, of feculent matter will take place into the peritoneal cavity, even under such unfavourable conditions; the portion of bowel immediately within the stricture becomes adherent by plastic matter to the peritoneum on its internal surface, and thus the escape of any extravasation into the cavity of the abdomen is prevented. It does not always follow that there is any external evidence of the occurrence of gangrene within the sac; and the bowel is frequently nipped to such an extent as to prevent its regaining its vitality, without any unusual condition being presented until the sac is actually laid open and the intestine examined.

In the more advanced cases of strangulated hernia, the peritoneum always becomes inflamed, usually to a considerable extent; the disease affects a diffuse form, and is accompanied by the effusion of turbid serum, often of a very acrid and irritating character, and mixed with flakes of lymph, sometimes to such an extent as to give it a truly puriform appearance. The glutinous lymph mats together contiguous coils of intestine, often appearing to be smeared over them like so much melted butter.

SYMPTOMS.—The symptoms are of two kinds: 1. Those affecting the Tumour; and 2. Those influencing the Constitution generally.

1. *Local Symptoms.*—The tumour, if the hernia be an old one, will be found to be increased in size; or it may have appeared for the first time. At the moment of strangulation it will generally be found to be hard, tense, and rounded, more particularly if it be an enterocele. When, however, the hernia is in a great measure omental, it is not infrequently soft and doughy, though strangulated. It seldom increases in size after strangulation has occurred, as no fresh protrusion can take place below the stricture, but it may have known it to be greatly augmented in bulk after the strangulation has existed for some hours, by the effusion of serum into the sac. If the hernia have previously been reducible, it can no longer be put back; and there is no impulse in it, nor increase in its size on coughing, the stricture preventing the transmission of the shock to the contents of the tumour; and in this way, as pointed out by Luke, the situation of the constriction may sometimes be ascertained by observing at what point the impulse ceases.

2. *Constitutional Symptoms.*—So soon as the strangulation has occurred, intestinal obstruction takes place, and the patient becomes uneasy and restless. If the constriction be of an active character, he will be seized with acute pain in the part, which speedily extends to the contiguous portion of the abdomen, assuming the characters of peritoneal inflammation. The first thing that happens when intestine is strangulated, whether a large coil be constricted, or a small portion only of the diameter of the gut be nipped, is an arrest of the peristaltic movement of the part implicated, and the occurrence of obstruction to the onward course of the intestinal contents is followed by constipation, vomiting, and colicky pains. The constipation is always complete, neither feces nor flatus passing through; the bowels may sometimes act once after the strangulation has occurred from that portion which lies below the seat of constriction, but they cannot, of course, empty themselves thoroughly, nor from above the strangled part. Vomiting usually sets in early, and is often very severe and continuous, with much retching and straining, at first the contents of the stomach are ejected, with some bilious matters, but afterward the vomiting becomes feculent, or stercoraceous, owing to inverted per-

staltic action extending as far down as the constricted part of the gut. These symptoms are attended by colicky and dragging pains about the navel. They are more severe in their character when the strangulation is acute and the hernia is intestinal, than when it is passive, and the rupture omental. They occur equally in the incomplete as in the complete forms of the disease; indeed, it not unfrequently happens that the hernial tumour may be so small as to have escaped observation; the occurrence of the above-mentioned symptoms being the first indication of the probable nature of the mischief. Hence, it is well always to examine for hernia when called to a patient suddenly seized with constipation, vomiting, and colicky pains, even if told that no tumour exists.

After the strangulation has existed for some time, the inflammation that occurs in the sac extends to the contiguous peritoneum, accompanied by the ordinary signs of peritonitis, such as tension of the abdominal muscles, tenderness, with lancinating pains about the abdomen, and tympanitis. The patient lies on his back with the knees drawn up, has a small, hard, quick, and perhaps intermittent pulse, a dry tongue, which speedily becomes brown, and a pale, anxious, and dragged countenance, with a good deal of heat of skin, and inflammatory fever. In some cases, this is of a sthenic type; but, in the majority of instances, especially in feeble subjects, it assumes the irritative form. When gangrene of the rupture takes place, hiccup usually comes on, with sudden cessation of pain in the tumour, an intermittent pulse, cold sweats, pallor, anxiety, rapid sinking of the vital powers, usually with slight delirium; and death speedily occurs.

Modifications of Symptoms.—The symptoms just described are those which are usually met with in strangulated hernia. They may, however, be modified in some important respects.

1. There may be little or no tension in a strangulated hernia, the tumour continuing soft and lax; this is especially the case when the hernia contains omentum, and in congenital hernia when strangulated. It may also occur in the case of double hernia on the same side, in consequence of the outer sac being empty, or merely filled with serum, and the posterior one being protruded against this and strangulated, but its tension being masked by the lax state of the outer one.

2. Vomiting sometimes does not take place from first to last, there being at most a little retching; at other times the patient vomits once or twice, and then there is no recurrence of this symptom so long as he remains quiet, and keeps the stomach empty; but on moving or taking nourishment of any kind, even fluids, it comes on again, and thus the surgeon may elicit this symptom, should it be necessary in a diagnostic point of view.

3. Extensive peritonitis, with copious effusion of a puriform liquid, may occur without any pain, and with but little tenderness; the anxiety of countenance and sharpness of pulse being the only symptoms that lead to a suspicion of its existence.

4. Death may result from exhaustion consequent on vomiting and peritonitis, without any sign of gangrene in the constricted portion of intestine.

Diagnosis.—The diagnosis of strangulated hernia requires to be made from the following conditions

1. *Obstructed Irreducible Hernia.*—In this there are no acute symptoms, and the rupture will generally be found to be a large one of old standing. It may become somewhat tense and swollen, but is not tender to the touch, and always presents a certain degree of impulse on coughing. There is no sign of peritonitis. There may be constipation; but there is no vomiting, or, if there be any, it is simply mucous and bilious, consisting of the

contents of the stomach. The speedy rest by the treatment already indicated as proper doubt as to the nature of the affection.

2. *Inflamed Irreducible Hernia.*—Here it is in the tumour, with pyrexia, and some general vomiting; or, if the patient have vomited, it continues to do so with the same degree of violence he would if the peritonitis were the result of constipation is not absolute and entire, but usually passes.

3. *General Peritonitis conjoined with Hernia.*—This is extremely difficult, especially if the hernia is large. In such cases, however, it will be observed that the tumour is at a distance from the sac; that there will be no tenderness there, that it is simply of mucus and that the constipation is by no means obstinate.

4. In *Double Hernia*, one tumour may be reducible, the other though irreducible. Under these circumstances it is difficult to determine which one is the seat of the inflammation, but may be ascertained by observing greater tenderness at the neck of the strangulated than of the unobstructed.

Besides these various conditions of hernia, there are other tumours of the abdomen with strangulation, there are other tumours of the abdomen: but these we shall have to consider in the chapter on the forms of hernia.

TREATMENT.—The treatment of strangulated hernia is one of the most important subjects in surgery. The object is the removal of the constriction from the stricture, effected either by the Reduction of its Contents, or by the Stricture.

Taxis.—The reduction of the hernia is effected by the taxis, by which is meant the various manual means of reducing the rupture back. The taxis, when properly employed, is attended by any serious consequences to the patient, but is attended by death; and, out of 293 cases of hernia reduced by the taxis in the London Dispensary, it was unfrequently followed, however, by rather serious consequences, which might probably, in some instances, have been avoided by very abundant bleeding, probably owing to the rupture of some of the vessels of the gut. In using the taxis, it should be employed, and no undue force should ever be used, and no undue force should ever be effected by violence: the resistance should be overcome by forcible pressure; and a vast deal of time is lost in fighting against it the tender and inflamed gut, and in so doing to be bruised, or even perhaps torn. The taxis should not be continued beyond half an hour; if it be properly employed, if reducible, will probably go back. If it be employed improperly, for a lengthened period, and by the protruded part becomes ecchymosed, inflammation; and the chances of recovery after it is reduced are lessened. When the parts are much inflamed, it should be reduced with great caution; and, if it have been reduced,

surgeon, it is better not to repeat it. When gangrene has occurred, the taxis should never be employed; as the putting back of the mortified gut into the abdomen would be followed by extravasation of feces and fatal peritonitis.

In using the taxis, it should be borne in mind that there are two obstacles to overcome; the resistance of the parts around the ring, and the bulk of the tumour. The first may be somewhat lessened by relaxing the abdominal muscles, and consequently diminishing the tension exercised upon the tendinous apertures and fasciæ of the groin. In order to effect this, the patient should be placed in a proper position, the body being bent forwards, the thigh adducted, and semi-flexed upon the abdomen; the surgeon may then, by employing steady pressure on the tumour, endeavour to squeeze out some of the flatus from the strangled portion of intestine, and thus to effect its reduction. In doing this, the neck of the sac should be steadied by the fingers of the left hand; whilst, with the right spread over the tumour, the surgeon endeavours to push it backwards, using a kind of kneading motion, and sometimes in the first instance drawing it slightly downwards, so as to disengage it from the neck of the sac. The direction of the pressure is important; it should always be in the line of the descent of the tumour. These means may be employed as soon as the patient is seen by the surgeon, when, by steadily carrying on the taxis for a few minutes, he will perhaps hear and feel a gurgling in the tumour, which will be followed by its immediate reduction. If the patient be thin, and the outline of the aperture through which the hernia escapes tolerably defined, I have succeeded in reducing the protrusion, after failure of the taxis in the ordinary way, by passing the tip of my finger or the nail under the edge of the ring, and pulling this firmly and forcibly on one side, so as to steady and at the same time dilate it, pressure being kept up on the tumour with the other hand. This manoeuvre can be practised with more facility and success in femoral hernia, where the upper edge of the saphenous opening is sharply defined, but may also successfully be had recourse to in inguinal and umbilical protrusions. In some cases reduction appears to have been facilitated by placing the patient on his head and shoulders, and raising the body in the vertical position whilst the taxis was being employed. Should, however, reduction not ensue, it will be desirable to have recourse at once to further means, the object of which is, by relaxing the muscles and lessening the bulk of the tumour, to enable the hernia to be reduced.

Auxiliary Measures.—The means to be employed must be modified according to the condition of the strangulation, whether it be of the active or of the passive kind. If it be very acute, occurring in a young, robust, and otherwise healthy subject, the patient may have about twelve or sixteen ounces of blood taken away from the arm; he should then be put into a hot bath, where he may remain for twenty minutes or half an hour, or until he feels faint; and, whilst he is in the bath in this condition, the taxis should be employed. If it do not succeed, he should be taken out, wrapped up in blankets, and have chloroform administered. When he is fully under the influence of this agent, which is certainly the most efficient which we possess for relaxing muscular contraction, the taxis may be tried once again. Should it still fail, operation should be immediately proceeded with. No good can possibly come of delay in these cases, and repeated attempts at the taxis should be carefully avoided. If the hernia do not admit of reduction in the early stage of the strangulation, it will necessarily be much less likely to do so when the parts, squeezed and bruised by much manipulation, will have had their congestive condition greatly increased. The frequent employment

of the operation without opening the sac, of late surgeons much less averse to early division of the case.

When the strangulation is less acute, or occurs in a robust subject, it is well to omit the bleeding, and use chloroform.

When the strangulation is of a passive character in elderly people, other measures may be adopted to reduce the bulk of the tumour; which, rather than the taxis, is the chief obstacle to reduction in these cases. Especially when the tumour is large and not very tender, it is well to dispense with the hot bath, which has sometimes a congestive effect that may already exist in the hernia. In some cases seen a strangulated rupture enlarge considerably under the influence of the bath. In such cases, more time may be spent in reduction than in very acutely strangulated hernia. As a first practice to commence the treatment by the administration of an enema, which, by emptying the lower bowel, will alter the contents, and may materially facilitate the reduction. The best enema is one of gruel and castor-oil, with a little opium added to it; it should be injected through a catheter, and run up into the gut, and with a moderate degree of pressure. Great care must be taken that no injury be done to the rectum. It is not necessary to give such a caution as this, were it not for some years ago, by two very excellent practitioners, in a case of strangulated femoral hernia, to whom an enemata of water had been administered; and as this had not appeared to have gone up the bowel, they suspected it had passed out of the rectum into the surrounding cellular tissue. However, did not seem to be suffering from this. In the case of strangulation were urgent, I operated on the day it occurred, apparently from exhaustion, in about an hour after the hernia was found. On opening the body, it was found that the rectum had been pushed up and fluid injected into the meso-rectum, separating the hernia from whence it had extended into the general subperitoneal space, which contained a quantity of the liquid; some of the liquid had entered the peritoneal cavity.

In the large hernia of old people, more especially in the male, in which there is a good deal of flatus, after the taxis has been tried, a bladder of ice may be applied for three or four days, and then Chloroform may then be given, and the taxis continued. Of late years, indeed, I have been in most cases almost solely to chloroform as a relaxing agent, and have dispensed with the use of the warm-bath. If the taxis is conveniently used without too much delay, it should be continued until a patient with strangulated hernia at once yields to the taxis for a period not exceeding half an hour, and then once proceed to operation without any further delay. The taxis is not only useless, but injurious by bruising the hernia.

Persistence of Symptoms after Reduction.—In some cases of hernia, the symptoms of strangulation may occur again. The recurrence toward occurrence may arise from three distinct causes. First, the hernia may have been reduced in mass (*vide p. 999*); secondly, the sac may have existed within the sac—the taxis having over-

the failing to influence that within the sac; 3. The gut may have been so severely nipped that, although all constriction has been removed, the peristaltic action is not restored, the constricted portion of bowel falling into a state of gangrene. The diagnosis of these several conditions may possibly be made by attention to the following circumstances. In the reduction of *mass* the tumour has slipped up without any gurgle; the canal is very open, and no trace of sac can be felt in it, but a rounded tumour, possibly at the upper part, on coughing. In the case of *internal adhesions* there will have been no gurgling, but the canal is still filled by the sac; the abdominal apertures are not preternaturally patent and distinct. In the case of *extreme nipping* and consequent paralysis of a portion of the gut, gurgling will have been felt and heard in effecting the taxis, which does not happen in either of the other conditions, and the symptoms of intestinal obstruction will not be quite complete. The vomiting will lose its stercoraceous character, and probably some flatus will pass.

The *Treatment* of these different conditions is full of difficulty and of anxiety to the surgeon. As a general rule, I think that the proper practice in all cases when the symptoms of strangulation, especially stercoraceous vomiting, continue *unrelieved and undiminished in severity* for some hours after the apparent reduction of the hernia, is to cut down upon the canal, expose the sac, and, if that be found still strictured, as will be explained at p. 1001, divide the constriction. Should the hernia not have been reduced "in time," it might possibly be found that a small knuckle of intestine is still gripped at the inner and deeper ring; but should that not be the case, it will, I think, be safer not to push any exploration into the abdominal cavity with the view of discovering the possible existence of unrelieved internal strangulation, the presence of which would be highly problematical, and, if existing, could scarcely admit of discovery. The safer and wiser plan under such circumstances appears to be, to leave the wound open, with a poultice and a light compress over it, and to give the patient the chance of the formation of an artificial anus on the sloughing of the strangulated or badly nipped knuckle of intestine; a result that I have more than once witnessed about the fourth or fifth day, the patient ultimately recovering.

In some cases, where the nipping of the strangulated intestine has been severe, yet not sufficient to arrest permanently the peristaltic action or to destroy its vitality, constipation and retching, with nausea, may continue; and the tumour, if the hernia have been small and deeply seated (more particularly if femoral), may continue to be felt, though less tense than before; consisting simply of the thickened and inflamed sac, with serous fluid in it. Under these circumstances, we must be careful not to operate. I have, on two or three occasions, seen an empty sac operated on, to the annoyance of the surgeon and danger of the patient. The mistake may be avoided by observing that the symptoms gradually lessen in severity by waiting, and that the tympanitis subsides, the abdomen becoming flat and supple.

The length of time during which the congestive condition of the bowel will continue after a strangulated portion of intestine has been reduced, is very considerable. In a case of strangulated femoral hernia which was some time ago under my care, reduction was effected, but, strangulation recurring at the end of twelve days, an operation became necessary; this was performed, and the patient died on the eighth day after it, or the twenty first from the first strangulation. On examination, the small intestine was found *concreted in two distinct portions*, each of which was about eight inches in

length; several feet of healthy gut intervening between them. One of the congested portions lay opposite the wound, and was evidently the intestine that was last strangulated. The other was altogether away from the seat of operation, but was equally darkly congested, being almost of a black colour, and was clearly that portion which had been constricted some time previously, and which, although twenty days had elapsed, had not as yet recovered itself.

After the taxis has been fairly employed for a sufficient time, and has not succeeded in reducing the hernia, the operation must be proceeded with. It is impossible to lay down any definite rule as to the time that it is prudent to continue efforts at reduction; but it may be stated generally that, after the different adjuvants of the taxis which the surgeon may think it desirable to apply have been fairly tried and have failed, the operation should be undertaken without further delay. There are few surgeons who will not at once acknowledge the truth of the remark of the late Mr Hey of Leeds—that he had often regretted performing this operation too late, but never having done it too early. It is true that cases are occasionally recorded, in which after four or five days of treatment the hernia has gone up; but it is very rare to meet with such cases in practice; and, in all probability, in delaying the operation in the hope of finding one such case, the lives of dozens of patients would be sacrificed. Luke has shown, as the result of the experience at the London Hospital, that the ratio of mortality increases greatly in proportion to the length of time during which the strangulation is allowed to continue. Of 69 cases of strangulated hernia operated upon within the first 48 hours of strangulation, 13 died, or 1 in 5·7; whilst of 38 cases operated on after more than 48 hours had elapsed, 15 died, or 1 in 2·5. Indeed, one chief reason of the greater mortality from operations for hernia in hospital than in private practice, probably arises from the fact that much valuable time is frequently consumed before assistance is sought, or in fruitless efforts to reduce the swelling before the patient's admission. Not only is time lost in this way, but the bowel is often bruised and injuriously squeezed, so that the inflammation already existing in it is considerably increased.

OPERATIONS FOR STRANGULATED HERNIA.

The operation for strangulated hernia may be performed in two ways, either by opening the sac, exposing its contents, and dividing the stricture wherever it is situated, *from within*; or it may be done by dividing the stricture *outside*, without opening the sac. In either case the great object of the operation, the division of the stricture by the knife, is the same, but the mode in which it is effected is different. We shall first describe the operation in which the sac is opened; afterwards that in which it is not, and then briefly compare the two procedures.

OPERATION IN WHICH THE SAC IS OPENED.—*Exposure of the Sac*.—The patient having been brought to the edge of the bed, or placed on a table of convenient height, the bladder is emptied, and the parts that are the seat of operation are shaved. An incision of sufficient length is then made over the neck of the sac, this may be best done by pinching up a fold of skin, pushing the scalp through its base with the back of the instrument turned towards the hernia, and then cutting upwards (Fig 385). A linear incision is thus made, which may be extended at either end if necessary; the dissection is then carried through the superficial fascia and fat with the scalpel and forceps. If any small artery spout freely, it had better be tied at once, lest the bleeding obstruct the view of the part in the subsequent steps.

of the operation. As the surgeon approaches the sac, more caution is required, particularly if the subserous cellular tissue be dense, opaque, and innervated. The surgeon must pinch this up with the forceps, make a small incision into it, introduce a dissector, and lay it open upon this, or on the finger (Fig 385). If it be thin and not opaque, so as to admit a view of the subjacent parts, he may dissect it through with the unsupported hand. In this way he proceeds until the sac is reached, which is usually known

Fig. 385.—Operation for Hernia. Division of the Skin.

by its rounded and tense appearance, its filamentous character, and by the arborescent arrangement of vessels upon its surface. In some cases the surgeon thinks that he has reached the sac, when in reality he has only come upon a deeper layer of condensed cellular tissue in close contact with it; here the absence of all appearance of vessels, the dull and opaque character of the tissue and its more solid feel, together with the absence of the peculiar tension that is characteristic of the sac, will enable him to recognise the real state of things. In other cases, it may happen that the sac is so thin, and the superficial structures are so little condensed, that the surgeon lays it open in the earlier incisions before he thinks he has reached it.

Under these circumstances, a portion of the intestine protruding might be mistaken for the sac. This dangerous error may be avoided by observing the peculiarly smooth and highly polished appearance presented by the dark and congested gut, the absence of arborescent vessels, and the non-existence of any adhesions between its deeper portions and the tissues upon which it lies. If the sac be prematurely opened and omentum protrude, the granular appearance and peculiar feel of this tissue will at once cause its recognition.

Fig. 386.—Operation for Hernia. Incision of 8 baserous cellular tissue.

Opening the Sac.—The sac, having been exposed, must be carefully opened; this should be done towards its anterior aspect; and if it be a small one, at its lower part. It may best be done, if the sac be not very tense, by seizing a portion of it between the finger and thumb, and thus feeling that no intestine is included; a small portion of it is then pinched up by the forceps, and an opening is made into it by cutting upon their points with the edge of the scalpel laid horizontally. If the sac be very tense, it cannot be pinched up in this way, and then it may best be opened by introducing the point of a fine hook very cautiously into its substance, raising up a portion of it in this way, and then making an aperture into it. *There is little risk of wounding the gut in doing this; for, as the tension of*

the sac arises from the effusion of fluid into it, posed between it and the gut. In these cases out in a full jet, and occasionally exists in a vein have seen at least a pint of slightly bloody serum of an old strangulated inguinal hernia. Most not more than from half an ounce to an ounce; is considerably less than this. In some instances then it becomes necessary to proceed with external sac, as the gut or omentum is applied closely cases as these the sac is not unfrequently sufficient the surgeon to see its contents through it: opposite to the omentum, or to any small mass slitting through it. The opening, having opened

Fig 387.—Director on which the Sac is

may be extended by the introduction of a broach which it is to be slit up to a sufficient extent to its contents.

Division of the Stricture.—The next point is of the stricture; and this requires considerable the neighbouring parts of importance, or the gut structures in the vicinity of the stricture are proper direction, in accordance with ordinary which will be described when we come to operation. All injury to the intestine is prevented finger of the left hand up to the seat of stricture underneath it, and dividing the constriction by

Fig 388.—Hernia knife

having a very limited cutting edge (Fig. 388), guide the knife, the intestine will be in contact with the instrument may be slid under that portion of it which

Fig 389.—Mode of using the Hernia knife.

finger, upon its flat side, as represented in Fig. 389, keep the bowel out of the way, and detect the stricture posed between the edge of the knife and the finger.

During the division of the stricture, the gut must be protected from injury by the knife.

hand over them in such a way that they cannot be touched by the edge of the instrument; or they may be protected by an attentive and careful assistant.

In some cases, the stricture is so tight that it is at first almost impossible to get the edge of the nail underneath it. The surgeon will, however, generally succeed in doing so, by directing his assistant to draw down the oil of intestine, so as to loosen it, as it were, from underneath the stricture; he will then usually succeed in passing his finger up in the middle of the oil, where the mesentery lies. So soon as the blunt end of the hernia-knife has been passed under the stricture, its sharp edge must be turned up, and the constriction divided in a proper direction, to a very limited extent, from the one-eighth to the quarter of an inch.

Reduction.—The intestine and omentum, having been examined, must be dealt with according to the condition in which they are found; as will be described at pp. 989-992. If these structures be sufficiently healthy to admit of reduction, the intestine should first of all be replaced. This must be done by pushing it back with as much gentleness as possible, and chiefly by using the index-fingers. When it has slipped up into the abdomen, the omentum must be returned in the same way. In reducing the hernial protrusion, after the sac has been laid open, care should be taken that the margins of this are firmly held down by means of a pair of forceps; lest it, together with its contents, be returned *en masse*, the stricture being undivided. After reduction, the surgeon should pass his finger up into the canal through which the hernia has descended, and feel that all is clear. A suture or two should next be applied through the lips of the wound, with a few cross strips of plaster between them, a long pad of lint laid over it, and a spica bandage to retain it all in proper position, and to prevent the protrusion of the hernia again during a fit of coughing, or a muscular effort. I have, however, seen the pressure of the pad occasion so much venous hemorrhage, by producing congestion of the venous tissues in the neighbourhood of the wound, as to require to be laid aside, and the wound to be simply dressed. About the third or fourth day the sutures may be removed, and water-dressing applied. If inflammation or suppuration should set in, the part must be well poulticed; and care should be taken to leave the most dependent aperture free, as otherwise the pus formed in the external incisions may flow back through the internal aperture into the peritoneal cavity, and occasion fatal inflammation. Indeed, I think it desirable that union of the lips of the wound after the operation for hernia should not take place by the first intention; as it not unfrequently happens when this occurs, that the pus and other discharges, not finding a ready outlet, may either be diffused between the muscular planes of the abdominal wall, occasioning sloughing and abscess; or, returning into the peritoneal cavity, may excite inflammation of it—a result which I have more than once seen occur.

After-Treatment.—The patient should be kept quiet in bed; and, if there be no sign of peritonitis, should have an opiate given him. The bowels will probably act in the course of the first twenty-four hours; should they not do so, a castor-oil and gruel enema may be thrown up. It is, I think, of very great importance not to administer any purgatives in these cases, and to take little heed of the bowels not acting, even for three or four days after the operation. If the mechanical obstacle have been removed, will be sure to recover their proper action; though, in consequence of the gut having been severely constricted and almost wounded by the pressure of the stricture, it may require to be left quiet for a few days before it

recover its peristaltic action. The administration of further irritating it, will increase the risk of doing so, and probably do much harm. The patient, of course, on the simplest and most unirritating diet--indeed, barley-water and ice for the first day or two, and but no solid food must be given till the bowels and peritonitis has passed.

ACCIDENTS AND MODIFICATIONS OF THE DISEASE. Having been thus described, we have next to consider the accidents attending it, or modifications which it may assume. Peritonitis, the Management of the Intestine, the Management of Adhesions and of the Omentum, the Management of Arteries, Sloughing of the Sac, Fistula.

Peritonitis after Operation.--The great danger attending operations for hernia is the supervention of peritonitis, which existed before the operation, may be impending, or at all events greatly increased by the operation of the peritoneum. Two distinct kinds of peritonitis for hernia; the active or acute, and the passive.

Acute Peritonitis is commonly met with in otherwise healthy, who are the subjects of the disease. The ordinary symptoms of acute idiopathic inflammation is tenderness of a diffused character, with lameness on his back, with his knees drawn up, his pulse quick, hard pulse, a dry tongue, and much difficulty of respiration is principally thoracic, and tympanic bowels are usually constipated, though sometimes of this form of herniary peritonitis is best combated by phlogistic principles; the disease is an active inflammation, and means must be taken to subdue it. This may be done by section and the application, perhaps repeated, of blisters to the abdomen; calomel (gr. ij.) and opium (gr. i.) administered every fourth or sixth hour, and barley-water and ice. As the inflammatory action continues which is occasioned by it will be relieved by administering any purgatives. The tympanic bowels are relieved by turpentine enemata, and any lurking tenderness by blisters.

Latent or Passive Peritonitis appears to be of a different character. It chiefly occurs in old people, or in those who are especially apt to follow upon inflammation of the bowels, or sequent suppuration; or it may occur in consequence of a diseased action from the cutaneous wound, and in a morbid condition induced by the strangulated hernia, especially, in whom all disease is apt to assume a chronic form. It is peculiarly liable to occur. In some cases, the appearance of any marked local symptoms or uneasiness in the abdomen, but, two or three days after the operation, the patient becomes depressed, with a quick and feeble pulse, a tumid and tympanic abdomen, and loss of strength. In the majority of cases, however, the signs of peritonitis are present. After death the abdomen is found to contain a quantity of turbid serous

lymph ; in many instances in such quantity as to give it a puriform appearance, and not unfrequently matting together the coils of intestine. In the *Treatment*, it is necessary to support the patient, and in some instances even to administer stimulants, such as ammonia, the brandy-and-egg mixture, &c. Depleting measures of all kinds are quite inadmissible ; and, indeed, the remedy that offers most prospect of benefit to the patient is opium, in full doses, one grain being given every third or fourth hour until some effect is produced upon the constitution. Opium not only acts as a useful stimulant in these cases, but has a tendency to allay the increased vascular action. At the same time, a blister to the abdomen, to be dressed with mercurial ointment, may be advantageously employed ; and turpentine enemata may be administered, with the view of removing the tympanitis, which is a source of much distress to the patient.

Management of Congested Intestine—The condition in which the contents of the sac are found in a case of hernia, determines greatly the course which the surgeon should pursue after the division of the stricture. Most frequently the intestine is deeply congested, being of a reddish purple, a claret, or chocolate colour. This congested state must not be confounded with gangrene of the part, which might happen if the surgeon were to content himself simply with judging of its condition by the colour. However dark this may be, the gut cannot be said to be gangrenous so long as it is polished and firm, free from putrescent odour, and without a greenish tinge. In cases in which there is much doubt as to whether its vitality continues or not, it has been proposed to scarify its surface lightly with the point of a lancet. If blood flow from the punctures, this may be taken as a proof of the continuance of the vitality of the part. Such a procedure as this, however, is certainly attended by some degree of danger, and can seldom be required.

When the intestine is merely congested, however deeply this may be, the rule is, that it should be returned into the cavity of the abdomen in the hope of its ultimately recovering itself. This it will generally do if it have not been too much handled after the sac has been opened ; but in some cases it will slough a few days after it has been reduced, and, the faeces being discharged through the wound, a fæcal fistula will be formed ; this may happen as late as the eighth or tenth day after the operation.

Management of Tightly Constricted Intestine.—When the intestine has

been very tightly nipped by a sharp-edged stricture, so that a deep sulcus or depression is left upon it, it seldom, I think, recovers itself, whether the whole of the coil of gut have been thus affected, or the constriction have been limited to a small portion of the diameter of the intestine. It is remarkable how very quickly changes which are incompatible with life may ensue in a portion of gut that has been very tightly strangulated. I have known a coil of intestine, that had been but eight hours strangulated before the operation was performed, so tightly constricted as not to regain its vitality after reduction (Fig. 390). In such cases, the patient usually

Fig. 390.—Gangrened Intestine from Strangulation.

recover its peristaltic action. The administration of purgatives, by further irritating it, will increase the risk of inflammation, and it will probably do much harm. The patient, of course, must be ~~kept~~ kept on the simplest and most unstimulating diet—indeed, he should only be given barley water and ice for the first day or two, and afterwards even coffee, but no solid food must be given till the bowels have acted, and the peritonitis has passed.

ACCIDENTS AND MODIFICATIONS OF THE OPERATION.—The nature having been thus described, we have next to consider in this article accidents attending it, or modifications which may be required, such as Peritonitis, the Management of the Intestine according to its position, the Management of Adhesions and of the Omentum, Wounds of the Intestine and of Arteries, Sloughing of the Sac, Artificial Anus, and Pilon Fistula.

Peritonitis after Operation.—The great danger to be apprehended after operations for hernia is the supervention of *peritonitis*. This may have existed before the operation, may be impending at the time, and may be occasioned, or at all events greatly increased by the necessary *wound of the peritoneum*. Two distinct kinds of *peritonitis* commonly follow operations for hernia, the active or acute, and the passive or latent.

Acute Peritonitis is commonly met with in strong and robust persons otherwise healthy, who are the subjects of the operation. It presents the ordinary symptoms of acute idiopathic inflammation of the abdomen: there is tenderness of a diffused character, with lancinating pains. The patient lies on his back, with his knees drawn up, has an anxious countenance, a quick, hard pulse, a dry tongue, and much inflammatory fever; the respiration is principally thoracic, and tympanitis soon comes on. The bowels are usually constipated, though sometimes irritated. The treatment of this form of herniary peritonitis is best conducted upon ordinary antiphlogistic principles; the disease is an active inflammatory one, and vigorous means must be taken to subdue it. This may be best done by free incision and the application, perhaps repeated, of two or three dozen leeches to the abdomen; calomel (gr. ij.) and opium (gr. $\frac{1}{2}$ or gr. j.) in pill must be administered every fourth or sixth hour, and the patient confined to barley-water and ice. As the inflammatory action is subdued, the constipation which is occasioned by it will be relieved without the necessity of administering any purgatives. The tympanitis may best be removed by turpentine enemata, and any lurking tenderness by the application of blisters.

Latent or Passive Peritonitis appears to be of the diffused or erysipelatous character. It chiefly occurs in old people, or in weakly subjects, and is especially apt to follow upon inflammation of the omentum and its consequent suppuration; or it may occur in consequence of the extension of diseased action from the cutaneous wound, and in other cases from the morbid action induced by the strangulated gut. In hospital patients especially all diseases tend to assume a low character, this inflammation is usually mild. In some instances, it sets in without any of the symptoms of inflammation, such as pain, tenderness, or swelling, and on the third or fourth day a quick, weak pulse, an anxious countenance, and a sinking strength. It is usually fatal, and is found to be the cause of death in a large number of cases.

ough; in many instances in such quantity as to give it a puriform appearance, and not unfrequently matting together the coils of intestine. In the treatment, it is necessary to support the patient, and in some instances even to administer stimulants, such as ammonia, the brandy and egg mixture, &c. Depleting measures of all kinds are quite inadmissible; and, indeed, the remedy that offers most prospect of benefit to the patient is opium, in full doses, one grain being given every third or fourth hour until some effect is produced upon the constitution. Opium not only acts as a useful stimulant in these cases, but has a tendency to allay the increased vascular action. At the same time, a blister to the abdomen, to be dressed with mercurial ointment, may be advantageously employed; and turpentine enemata may be administered, with the view of removing the tympanitis, which is a source of much distress to the patient.

Management of Congested Intestine.—The condition in which the contents of the sac are found in a case of hernia, determines greatly the course which the surgeon should pursue after the division of the stricture. Most frequently the intestine is deeply congested, being of a reddish purple, a claret, or chocolate colour. This congested state must not be confounded with gangrene of the part, which might happen if the surgeon were to content himself simply with judging of its condition by the colour. However dark this may be, the gut cannot be said to be gangrenous so long as it is polished and firm, free from putrescent odour, and without a greenish tinge. In cases in which there is much doubt as to whether its vitality continues or not, it has been proposed to scarify its surface lightly with the point of a lancet. If blood flow from the punctures, this may be taken as a proof of the continuance of the vitality of the part. Such a procedure as this, however, is certainly attended by some degree of danger, and can seldom be required.

When the intestine is merely congested, however deeply this may be, the rule is, that it should be returned into the cavity of the abdomen in the hope of its ultimately recovering itself. This it will generally do if it have not been too much handled after the sac has been opened; but in some cases it will slough a few days after it has been reduced, and, the faeces being discharged through the wound, a fecal fistula will be formed; this may happen as late as the eighth or tenth day after the operation.

Management of Tightly Constricted Intestine.—When the intestine has been very tightly nipped by a sharp-edged stricture, so that a deep sulcus or depression is left upon it, it seldom, I think, recovers itself, whether the whole of the coil of gut have been thus affected, or the constriction have been limited to a small portion of the diameter of the intestine. It is remarkable how very quickly changes incompatible with life may in a portion of gut that has been tightly strangled.

I have a coil of intestine, that had been but eight hours strangled before it was performed, so tightly constricted as not to regain its reduction (Fig. 390). In such cases, the patient usually

Fig 390.—Gangrenous Intestine from Strangulation

and firmly tying down the gut. On dissecting this carefully through the constricted portion of intestine subjacent to it sprang up to its full diameter, all constriction being removed, and was then very readily reduced.

Management of Omentum.—If the omentum be small in quantity, healthy in character though congested, and apparently recently protruded, not having undergone those changes that occur in it when it has been a long time in a hernial sac, it should be reduced after the intestine has been put back. If, however, its mass be very large, or if it be hypertrophied, indurated, or otherwise altered in structure, or if it be closely adherent to the sac, at the same time that it is congested, I think the best surgeons are agreed that it should not be returned into the abdominal cavity; as inflammation of it, *Epiplitis*, will probably set in and terminate fatally with effusion into the peritoneal sac. So also, if the omentum be in large quantity, and have become inflamed in the sac, it should not be returned, as the inflammation in it is very apt to run on to a kind of sloughy condition of the whole mass. If gangrenous, it should certainly not be reduced. In all these cases of hypertrophied, inflamed, or gangrenous omentum, the best practice consists in cutting off the mass, as recommended by Sir A. Cooper and Lawrence. If it be left in the sac, inflammation or sloughing of it may occur, and the patient can derive no corresponding advantage to the danger he will consequently run. Excision of the mass is usually practised by seizing and cutting it off at a level with the external ring. As the arteries of the stump, which are sometimes pretty numerous, are apt to bleed freely they must be tied singly by fine ligatures, which should be left hanging out of the wound. There is often a tendency to the retraction of the stump of the omentum into the abdominal cavity; in which case the ligatures dropping into the peritoneum, and acting as setons, may become sources of great irritation: in order to prevent this, the better plan is to knot them together, and to fix their ends by a piece of plaster upon the forepart of the abdomen. Surgeons formerly were in the habit of including the constricted neck of the omentum in a tight whipcord ligature, cutting off the mass below this, and leaving the stump in the inguinal canal or ring. This practice has been generally abandoned, from dread of peritonitis being induced by the constriction of the ligature. It may, however, be safely followed in some instances, in those particularly in which the protruded mass is very much indurated, having a narrow neck. I have of late years employed it with excellent effect, and indeed now generally prefer it to the method just described, over which it possesses the advantages of freedom from hemorrhage and impossibility of deep retraction of the cut edge of the omentum into the cavity of the abdomen, provided moderate traction be kept up in the ligatures. The constricted stump of omentum sloughs away in a few days, and separates with the ligatures. When this practice is adopted, the wound should not be closed, but must be lightly poulticed. The quantity of omentum that is cut off varies considerably; the mass removed usually weighs from four to six ounces, but in some instances it may amount to a pound or more.

Sacs or Apertures are occasionally formed in the omentum, in which a knuckle of intestine may become enveloped, or by the margins of which it may be strangulated. These envelopes of omentum around the gut, which have been especially described by P. Hewett, may occur in all kinds of hernia, at least in the inguinal, the femoral, and the umbilical, and sometimes acquire a large size, completely shutting in the gut. It is of importance to bear the possibility of their existence in mind, and in all cases to unravel

omentum before removing it, lest it contain a knuckle of intestine, which might be wounded in the operation.

Cysts, usually containing pellucid serous fluid, though sometimes filled with blood, are occasionally met with in the omentum. They are globular, elastic, and closely resemble in form a knuckle of intestine, occasioning not a little embarrassment to the surgeon: by a careful examination and travelling, however, of the omentum, their true nature will be made out; their fluid contents may then be discharged, and the omentum dealt with according to the rules already given.

Wounds of the Intestine may accidentally occur at two periods of the operation; either from the surgeon cutting too freely down upon the sac, and opening this before he is aware of what he is about; or else, at the time of the division of the stricture, from a portion of the gut which lies beneath it, getting into the way of the edge of the knife, and being nicked by it. The first kind of accident can only happen from a certain degree of carelessness; but it is not always so easy to avoid wounding the gut, when the stricture is so tight that the finger-nail cannot be slipped under it as a guide to the hernia-knife. In cases of this kind, a very narrow director must be used; and this is a most dangerous instrument, as, in passing it deeply out of sight under the tight stricture, a small portion of the gut may curl up over its side into the groove, and thus become notched by the knife as this is slid along it. This accident has happened to the best and most careful surgeons. Lawrence relates two cases that occurred to him; and Sir A. Cooper, Cloquet, Jobert, and Liston have all met with it. It may be known to have occurred by the bubbling up of a small quantity of flatus and liquid feces from the bottom of the incision. The *Treatment* of a wound of the gut must depend upon its size. When it is very small, rather resembling a puncture than a cut, the practice recommended by Sir A. Cooper should be adopted; viz., to seize the margins of the incision with a pair of forceps, and to tie a fine silk thread tightly round them, the ends of which should then be cut off, and the gut returned into the abdominal cavity. Such a proceeding as this does not appear to give rise to much, if to any, increase of danger. In a case that occurred to me at the Hospital, in which, owing to the excessive tightness of the stricture, a very narrow director only could be passed under it, the gut immediately above it was notched and opened by a kind of punctured wound; this was tied up in the way mentioned, and, after the death of the patient, which took place on the fourth day after the operation from gangrene of the strangulated portion of bowel, the silk ligature was found to be completely enveloped in a plug of plastic matter. If the wound be of larger size, it must be closed by the glower's stitch.

Wound of one of the Arteries in the neighbourhood of the sac may occur during the division of the stricture, either in consequence of some anomaly in the distribution of the vessel, or from the surgeon dividing the parts in a wrong direction. This accident usually happens to the epigastric or obturator arteries; and Lawrence has collected fourteen recorded cases in which it has occurred. The result in these has been very various; in some the patients have died; in others, after much loss of blood, and consequent faintness, the bleeding ceased spontaneously. The proper *Treatment* would certainly consist in cutting down upon and securing the bleeding vessel. In the event of the surgeon operating on a case of hernia, without having been able previously to satisfy himself as to its precise character, or if from any cause, in dividing the stricture, he have reason to dread the proximity of an artery, he may safely and readily divide the constriction with a knife

that would not easily cut an artery ; and had of his hernia-knife by drawing it over the still be keen enough to relieve the strangled it any artery that may happen to be in the v

Sloughing of the Sac is of rare occurrence, mostly attended by fatal results ; it is not, I twice happened in my practice ; and in both an old woman on whom I operated for femoral sac sloughed away, exposing nearly the whole as much distinctness as if it had been diseased danger for a time from an acute attack recovered.

Artificial Anus and Fæcal Fistula — When the bowel by which the whole of the intestinal condition is denominated an *artificial anus*, escapes, the greater part finding its way through a fistula is said to exist. The quantity of depends upon the extent of destruction of character on the part of the gut that is injured involuntarily, and is usually continuous.

This condition may occur in several ways. It may be accidentally wounded during the operation, and continue to be discharged through the aperture. It may have been gangrenous, and have given way into the peritoneum, the surgeon may have intentionally laid open the gut, so as to facilitate the escape of the feces. The bowel has been severely nipped, and is dark, but not actually fallen into a state of gangrene. It may itself after its return into the abdominal cavity, in the course of three, four, six, or even ten days, become gangrenous, a small quantity of feculent matter is discharged, and gradually a greater discharge appears, until a completely established. In such cases, it is usually the case, although the bowel gives way within the peritoneum, but escape of feces become extravasated into this, but escape of feces. The circumstance is owing to the fact of the peritoneum losing its peristaltic action, and consequently the parts in the neighbourhood inflaming, the parts being consolidated to each other and to the peritoneum, the gangrenous portion of the gut, and consequently of great importance, in cases of this kind, to disturb the adhesions that have formed between the gut and the neck of the sac.

The *Pathology of Artificial Anus* is connected with the aperture in the gut are glued by plastic matter, and, whether the whole or a portion only of the gut is destroyed, the apertures of the upper and lower gut almost in a continuous line, soon unite at the neck. These are at first similar in size, and present a similar shape or appearance : as the disease becomes more extensive, the transmission of feces, gradually becomes narrowed, it may be almost completely obliterated, while the upper becomes dilated (Fig. 392 a), in consequence

light obstruction to the outward passage of the fæces. The mesenteric portion, opposite the aperture, becomes drawn out into a kind of prolongation or spur, the full importance of which was first pointed out by Dupuytren. This spur-like process projects between the two apertures, and, being deflected by the passage of the fæces, has at last a tendency to act as a kind of valve, and thus to occlude the orifices into the lower portion of the gut. The integuments in the neighbourhood of such an aperture as this usually become irritated, inflamed, and excoriated, from the constant passage of the fæces over them. In some cases, the mucous membrane lining the edges becomes everted, and pouting; and, in others, a true prolapse takes place, large portions of the membrane protruding. An artificial anus fully formed in this way never undergoes spontaneous cure. Besides this, which is the ordinary form of artificial anus, we must, I think, recognise at least two other varieties, both of which I have met in practice. In one of these, the angle formed by the gut is adherent to the upper extremity of the sac which has been returned, and thus lies at some distance from the surface, so that the fæcal matter traverses a long canal before it reaches the external aperture. In the other variety the angle of the gut is fixed at a higher point within the abdomen, and the fæces find their way out through a channel bounded by agglutinated coils of intestine and layers of lymph. In both of these forms, there is a considerable distance between the external opening and the aperture in the gut. Thus, then, there are three forms of artificial anus, differing from one another according to the situation of the angle of the gut in relation to the external opening and to its connections.

When a *Fæcal Fistula* has formed, the condition of parts is somewhat different. The aperture in the intestine consists of merely a small perforation in its coats, unattended by any considerable loss of substance, through which a quantity of thin fluid and feculent matter exudes, giving rise to a good deal of irritation of neighbouring structures. In some cases, there are several apertures communicating with the gut, and extending through the skin. Fistulous openings of this kind not unfrequently undergo spontaneous cure after existing for a few weeks or months.

Treatment.—If the aperture be merely a small one, with a narrow fistula leading into the gut, the chief inconvenience suffered by the patient often arises from the irritation of the skin around the opening by the continued moisture of the feculent matter. In such cases the skin should be protected by means of zinc ointment, spread on lint; and the patient should wear a pad to restrain the discharge. By the pressure of this pad the aperture may sometimes be made to close. In other cases, the occasional application of the galvanic cantery or of a red hot wire will induce contraction of its edges; and in other instances, again, a plastic operation of some kind may be required. But I confess I have not usually seen much advantage result from such operations, which are often followed by erysipelas. As the existence of an artificial anus, by interfering with nutrition, commonly gives rise to considerable emaciation, it becomes necessary to support the patient's strength by a sufficient quantity of good and nourishing food; thus is of greater consequence the higher the fistula is, as the interference with the earlier stages of the digestive process, and the loss of nutritive material by the discharge of the chyme, is proportionally great. Spontaneous cure will occasionally take place, even though a perfect artificial anus exist. In a case under my care at the Hospital, a whole knuckle of intestine was gangrenous, and sloughed away, leaving an artificial anus, which discharged the greater part of the intestinal contents, but gradually

contracted and closed without any local attention to cleanliness.

If the aperture become a permanent artificial anus, if possible, be adopted in order to effect a cure. The important indications have to be fulfilled. In the projecting valvular or spur-like process the continuity of the canal; and, after this has been secured, the anus may be closed, by paring its edges, and bringing the lips together.

The first object is best accomplished by (Fig. 91); this consists of an instrument somewhat like a pair of blunt but serrated blades, which may be brought together by a screw that traverses its handle. One blade

Fig. 91. Deviser's instrument.
Blunt blades.

into the upper, the other (b) into the lower part of the intestine, and then approximated slowly, and fixed by means of a screw. To compress on each side the spur-like process of the intestine, day by day, this screw is tightened so as to bring the edges of the blades into contact, and cohesion of its serous surfaces. Attention caused by the instrument will occasion the formation of a fistula in the angle formed by the intestine, so that the anus may become consolidated, and all opening into the intestine. Should the spur-like process be accidentally torn out in sufficient quantity, the patient's death would probably ensue; hence the necessity of great caution. So soon as the blades of the instrument have been removed, the spur-like process has consequently sloughed off, and the closure of the artificial anus will be removed. The canal being thus re-established, its lips may be brought together by hare-lip pins and sutures. In some cases

has elapsed—many years, possibly—the fistula continues permanently patent, and no treatment is available for its erasure. Its existence is not incompatible with good general health. I have at present two cases under my constant observation, in one of which the whole of the intestinal contents have been discharged for four years through an aperture of the umbilicus, in a woman about 50 years of age, consequent on the sloughing away of a large coil of intestine in an umbilical hernia; and another case is a lady of 80, who has for upwards of thirty years had a faecal fistula in the right groin, consequent on an operation for femoral hernia.

OPERATION WITHOUT OPENING THE SAC.—The possibility of removing the stricture in strangulated hernia without laying the sac open, naturally suggested itself when it was known that in many cases the stricture was seated in the tendinous and cellular tissues outside the neck of the sac, and that, when these were divided, the protrusion was readily reduced. This operation was performed by Petit as long ago as 1718, but was seldom practised until it was revived of late years by Aston Key and Luke. The great advantage sought to be gained by this operation is that, as the peritoneum is not interfered with nor its cavity opened, the risk from peritonitis will be proportionately lessened. The wound made by the operation being altogether superficial, and the sac not opened, its risk has been compared to that of the taxis, with the addition of that which would result from a superficial wound. This argument would be conclusive in favour of the operation without opening the sac, if it could be shown that, in all cases of strangulated hernia, peritonitis is occasioned by interfering with the peritoneal cavity; it must, however, be admitted, even by the keenest advocates of Petit's operation, that this is not the case. In many instances the inflammation exists before any operation is performed, being evidently produced by the stricture of and consequent injury to the gut. But it cannot with fairness be argued that, though the peritonitis may exist before the operation, the incision of the peritoneal cavity does not increase it; even in healthy persons, laying open the abdomen, handling the gut and omentum, and pushing the fingers into the peritoneal sac, would always be followed by intense, often by fatal, peritonitis. It is only reasonable to believe that the same procedures in an already inflamed peritoneum would be followed by equally disastrous results.

That the opening made into the cavity of the abdomen in reality adds to the frequency of the peritonitis, cannot, I think, be doubted by any surgeon. It not unfrequently happens in strangulated hernia, that no sign of peritoneal inflammation sets in until one or two days after the operation is performed; and then it occurs evidently as the result of this procedure. That the fatality of the peritonitis, even if existing before any operation be practised, must be greatly increased by interference with the serous sac, is evident from the fact already mentioned, that death very rarely occurs (not more than once in many hundred cases) after the reduction of a strangulated hernia by the taxis. Fully admitting, therefore, that in many cases the peritonitis exists before the operation, and is occasioned by causes independent of it; it is, I think, impossible to deny that the inflammation is frequently directly occasioned by opening the peritoneal cavity, and handling the viscera; and that, when already existing, its fatality must be greatly increased by this procedure. In fact, there are two causes for peritonitis in cases of operated strangulated hernia—viz., the constriction of the stricture, and the wound of the peritoneum. That peritonitis which arises from the pressure of the stricture is equally liable to happen, whether Petit's operation or that by opening the sac be practised, and often precedes the operation; whilst the peritonitis which arises from wound of the serous membrane does

not occur in Petit's operation, but is necessary when the sac is opened.

There are, however, two objections that operation with more justice than that it does
rence of peritonitis. The first is, that if the
sometimes be returned in a gangrenous con-
the gut may possibly be returned still stran-
by incision in an omental aperture. With
it may be stated that, if the intestine be in-
usually be some evidence of this, either in t

objections against the operation without open-
have followed this practice. Luke, who has
subject, states that he has operated in 84 ca-
the sac was opened; in 59 the sac remained un-

operations is most favourable, when contrasted
was opened.

The operation without opening the sac may be performed in some cases, but is much more readily done in some than in others. It is especially applicable in cases where the stricture is commonly outside the sac, as will be seen in that form of the disease. Of 31 cases of this kind, Luke, the sac required to be opened in 7 cases, and it was not so easy to perform Petit's operation; in 24 cases the surgeon will fail to remove the stricture, the constriction being usually seated in the neck of the observable in congenital hernia. Of 20 cases of this kind, Luke, the sac required to be opened in 13 cases.

For the various reasons that have been in opinion that this operation should always be an ordinary one of opening the sac, in those cases having been long strangulated, presents no sign in it, and more especially when it is femoral or inguinal, in completing Petit's operation, in consequence of the stricture in the neck of the sac, or the constriction of the intestine.

have resulted; for the sac, after being exposed, may at any time be opened in the ordinary way, and the operation completed by dividing the stricture from within.

When the hernia is of large size and irreducible, it is of especial importance to avoid opening the sac. If it be opened, the contents will inflame, and fatal peritonitis commonly ensues. In these cases, as Luke has pointed out, it rarely happens that the old adherent parts are seriously strangled, but the whole mischief seems to be occasioned and to be received by the new protrusion that has taken place, and that gives rise to the tension; and if this can be liberated and reduced, the surgeon has done all that need be accomplished. The evidence of the reduction of the recent protrusion, although the old adherent and irreducible hernia be left is usually sufficiently obvious; the portion of gut returning with a slip and a gurgle, with considerable diminution in the general tension of the tumour.

Operation.—With regard to the mode of performing Petit's operation, little need be said here, as it is precisely identical with the steps of the other operation up to the period of the exposure of the sac; except that, when it is not intended to open this, the incisions should be carried more directly over its neck. The stricture, if situated outside the sac, will then be found either in some of the tendinous structures surrounding it, or else in the subserous cellular tissue lying upon it. After the division of the constricting bands in this situation, by means of a probe-pointed knife carried underneath them, or by dissecting down upon them, an attempt at the taxis may be made by compressing the tumour in the usual way, at the same time that its neck is steadied by the fingers of the left hand. If the contents can be reduced, the incision in the superficial structures is brought together by a few strips of plaster, over which a pad and bandage may be applied. Should peritonitis come on, as the result of the strangulation, it must be treated in the usual way. If, after the surgeon has fairly divided all the structures outside the sac, he find still that the return of the hernia is prevented by some constriction in its neck, it will be necessary to lay this open and divide the constriction in the usual way.

REDUCTION IN MASS.—The reduction of the hernia in mass consists in the return of the sac and its contents into the abdomen still in a state of strangulation. When it is said that the parts are returned into the abdomen, it must not be understood that they are pushed back into its cavity, but that the external protrusion is caused to disappear by being pushed into the subserous cellular tissue behind and underneath the parietal peritoneum, between it and the abdominal muscles. This remarkable accident, which was first described by the French surgeons of the last century, received but little notice from practitioners in this country until attention was drawn to it by Luke, by whom its pathology has been carefully studied. Birckett, who has investigated this condition with much care, is of opinion that the sac is not torn from its connections in the scrotum or canal, and pushed back, but that it is ruptured, usually at its posterior part at its neck, and that thus the contents of the sac are forced through this rent into the subperitoneal cellular tissue; whilst the mouth of the sac, still constricting the hernia, and thus keeping it in a state of strangulation, is pushed back from the internal ring. It appears to me that both explanations are correct, and that we must admit two forms of reduction in mass; the sac being pushed back intact in a state of strangulation, in one form as described by Luke; whilst in the other, as observed by Birckett, the sac is ruptured, and the hernia, strangulated by the displaced mouth of the sac, is forced out through the rent.

Cause.—The reduction in mass has been observed only in inguinal hernia and has chiefly occurred from the patient's own efforts in reducing a strangulated rupture. It is a remarkable fact that, in most of the instances in which it has occurred, only a very slight degree of force appears to have been employed in the reduction of the tumour; and the accident would seem to have resulted from the adhesions between the sac and the neighbouring parts being much weaker than natural, so that a moderate degree of force caused the whole to slip through the canal. It may, however, occur from the surgeon's efforts, if these be too forcible or long continued.

Symptoms.—The symptoms indicative of this accident are constitutional and local. The constitutional symptoms consist in a continuance of those that are indicative of the existence of strangulation, notwithstanding the disappearance of the tumour. The vomiting and constipation persisting, the patient speedily becomes much depressed in strength, being seized with hiccup and prostration of all vital power, signs of gangrene then evince themselves within the sac; and death ensues.

An examination of the parts in hernia will usually enable the surgeon to recognise the nature of the accident; he will ascertain that a tumour has previously existed, and will learn from a description of its general character and the symptoms occasioned by it, that it was in all probability a strangulated rupture. He will then find, on examining the part, that there is a total absence of all that fulness which is occasioned by the presence of the sac, even after its contents only have been reduced; the sac, in such cases, always giving rise to a feeling of fulness and roundness in the part. He will, on the contrary, find that the abdominal ring is peculiarly and very distinctly opened; it is much larger than usual, and somewhat rounded. On pushing the finger into the canal, this will be felt quite empty; but in some cases, on deep pressure with the finger, especially when the patient stands or coughs, a rounded tumour may be indistinctly felt behind the ordinary seat of the hernia. In many cases, however, the most careful manual examination will fail to detect any prominence of this kind.

Treatment.—If, after careful examination of such a case as this, in which the symptoms of strangulation continue, the surgeon learn by the previous history that a tumour has existed, but that it has suddenly gone up, and further, if he find that the seat of the supposed hernia presents the negative evidence that has just been described, it will then be necessary for him to push his inquiries a step further by an exploratory incision. Such an incision as this may first be used as a simple means of diagnosis, and, if it does not penetrate the peritoneal cavity, there is no danger attending it; and if the hernia be found, it will serve the purpose of the ordinary incision required in the operation, and may be used for the relief of the strangulation. The first incision should be made so as to expose the abdominal ring; if this be found peculiarly round and open, it would increase the probability of the existence of the condition sought for. The inguinal canal must next be laid open, and the parts contained within it carefully examined. If no appearance of hernial sac be found, but the cord be distinct and clearly seen, still further presumptive evidence will be afforded of the accident having been effected in mass; for, if the hernia have been reduced in the usual way, the sac will necessarily be left in the canal, and will preserve its usual relations to the cord. This supposition will be strengthened almost to a certainty if it be found that the "condensed cellular capsule immediately investing the sac," as it is termed by Luke—in other words, the condensed and laminated subserous cellular tissue—has been left in the canal. An opening made into this will, as that surgeon observes, allow

finger to be brought into contact with the hernial tumour itself. Should, however, this condensed cellular tissue not be found, it must not be concluded that no hernia is present, inasmuch as this investment may have been accidentally absent. The finger should then be passed into the internal ring, which will probably be found open, and should be carried from side to side; the tumour, if present, will be detected lying externally to the peritoneum behind the abdominal wall. When found, it must be brought down into the canal by enlarging the ring; it must then be opened, its contents examined, and the stricture in its neck divided. The intestine that has been so strangled must be dealt with in accordance with the rules already laid down. If the tumour cannot be readily brought down so as to admit of an examination of it and its contents, the patient should be desired to make some propulsive efforts, so as to cause it to protrude. If it still do not come down, it must be opened, and the stricture cautiously divided within the abdomen with a sheathed bistoury.

HYDROCELE OF THE HERNIAL SAC is a rare condition, the pathology of which has already been adverted to. In the *Treatment*, two lines of practice are open, the palliative and the curative. The first consists in merely tapping, and thus withdrawing the fluid; and the other, in freely laying open the lower portion of the sac, and endeavouring to secure its closure by granulation. This operation, which, however, is not devoid of danger, has been performed with success by Pott and others.

CHAPTER LXII.

SPECIAL HERNIE.

INGUINAL HERNIA.

By *Inguinal Hernia* is meant that protrusion which occupies the whole or a portion of the inguinal canal, and, when fully formed, passes out of the external abdominal ring into the scrotum. Many varieties of this hernia are recognised by surgeons. Thus it is said to be *Complete*, when it passes out of the external ring, *Incomplete*, or *Interstitial*, so long as it is contained within the canal; *Oblique*, when it occupies the whole course of the canal; *Direct*, when it passes forwards through a limited extent of it; *Congenital*, when it lies in the sac of the tunica vaginalis; and *Encysted*, or *Infantile*, when it lies behind this. Inguinal hernie constitute the commonest species of rupture, and would be much more frequent than they are, were it not for the obliquity of the canal, and the manner in which its sides are applied to one another, and closely overlap the spermatic cord. They occur with most readiness in those cases in which the canal is short and the apertures wide. Although these hernie are commonly incomplete in their early stages, it is seldom that they come under the observation of the surgeon until the protrusion has passed beyond the external abdominal ring.

Oblique INGUINAL HERNIA, often called *External*, on account of its relation to the epigastric artery, passes through the whole length of the canal, from one ring to the other; and usually protrudes through the external one, constituting one of the forms of *Scrotal Hernia*.

Coverings.—As it passes along the canal, it necessarily receives the same investments that the spermatic cord does; although these are often greatly modified by being elongated, hypertrophied, and otherwise altered in appear-

ance. If we regard the inguinal canal as consisting of a series of invaginations of the different layers of the abdominal parietes, the outermost being the skin, and the innermost the fascia transversalis, with the peritoneum applied to this, it is easy to understand how the hernia in its descent through these prolongations drawn over it, thus becoming successively invested with the same coverings as the spermatic cord. Thus it first pushes before that portion of the peritoneum which lies in a fossa just external to the epigastric vessels; it next receives an investment from the fascia transversalis, which often becomes thickened and laminated, constituting the *fascia propria* of the sac; as it passes under the internal oblique, it receives some of the fibres of this muscle, in the shape of the cremasteric fascia; and, lastly, when it reaches the external abdominal ring, which it greatly distends and renders round and open, it becomes covered by the intercolumar fascia, receiving also a partial investment around its neck from some of the expanded and thickened fibrous bands that lie near the ring, and which are always most marked upon its outer side.

Relations.—The relations of the spermatic cord and testes, and of the epigastric artery, to an inguinal hernia, are of great importance. The spermatic cord will almost invariably be found to be situated behind or rather underneath the oblique inguinal hernia; and the testis will be found to lie at its lower and back part, where it may always be distinctly felt. In some cases the elements of the spermatic cord become separated, the vas deferens lying on one side, and the spermatic vessels on the other. In other rare cases, as an instance of which there is in a preparation in the University College Museum, the hernia lies behind the cord, and has the testis in front. In other cases, again, it may happen that the elements of the cord are all separately spread out on the forepart of the hernial tumour. The epigastric artery has the same relations to the oblique inguinal hernia that it has to the spermatic cord, lying to the inner side of and behind its neck. The pressure of large and old inguinal herniæ has, however, a tendency to modify somewhat the relations of this vessel. By distending the rings, and dragging the posterior wall of the canal downwards and inwards, they shorten the canal, and cause a great deflection of the artery from its natural course, which is changed from an oblique direction to one curved downwards and inwards, under the outer edge of the rectus muscle.

DIRECT INGUINAL HERNIA.—This does not pass out like the oblique through the internal abdominal ring, but pushes forward through a triangular space, which is bounded by the epigastric artery on the outer side, the edge of the rectus on the inner, and the crural arch at its base, through this the hernial tumour protrudes, pushing before it or rupturing the posterior wall of the inguinal canal.

Coverings.—These vary according to the length of the canal that the hernia traverses, and the portion of the posterior wall through which it protrudes. In fact, there are at least two distinct forms of direct inguinal hernia, which differ according as they are situated above or below the remains of the umbilical artery. One, the most common variety, is situated below the cord-like remains of this vessel, between it and the outer edge of the rectus. The other, which is of less frequent occurrence, is situated above this vessel between it and the epigastric artery.

In that form of direct inguinal hernia, which lies below the umbilical artery, the protrusion takes place through that part of the posterior wall of the inguinal canal which is situated almost behind and opposite to the external ring. In this situation, the investments successively received by the hernia are, first, the peritoneum and the fascia transversalis; it then

comes into contact with the conjoined tendons of the internal oblique and transversalis muscles, which it may either rupture or push before it, thinned out and expanded. Most frequently these are ruptured, constituting a partial investment to the protrusion, which is most evident on the innermost part of the sac, that which is nearest the mesial line. As the hernia passes through the external abdominal ring, it receives from it the inter-columnar fascia and fibres, and lastly is invested by the common fascia and integuments.

In the direct inguinal hernia which lies above the umbilical artery, which is of rare occurrence, the protrusion may pass under the lower edge of the transversalis muscle, and then receives a partial investment of cremasteric fascia, especially on its iliac side, as it comes into relation with the internal oblique. This form of direct inguinal hernia, therefore, receives very nearly the same covering that the oblique does, though its investment by the cremaster is not so perfect. It does not come into relation with the conjoined tendons.

Relations.—In the direct inguinal hernia, the spermatic cord lies to the outer side of the sac; and its elements are never separated from one another, as occasionally happens in the oblique. The epigastric artery also is on the outer side, but usually arches very distinctly over the neck of the sac, sometimes indeed completely encircling the upper as well as the outer margin (Fig. 393).

INCOMPLETE OR INTERSTITIAL HERNIA is usually of the oblique kind; but Lawrence has observed that it may be of the direct variety. It often escapes notice, but may not unfrequently be observed on the opposite side to an ordinary inguinal hernia.

DOUBLE INGUINAL HERNIA, on opposite sides, are of very common occurrence, and they may be of the same, or assume different forms. In some instances, the two forms may be observed on the same side (Fig. 394).

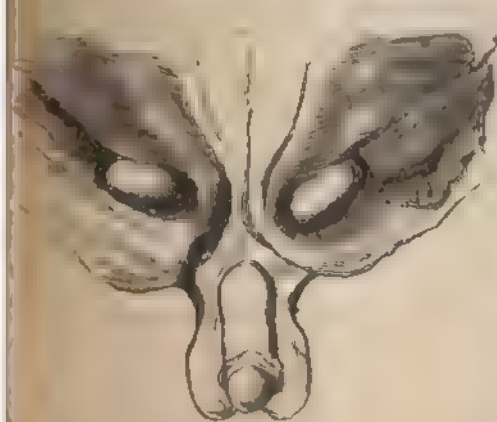

Fig. 393.—Double Direct Inguinal Hernia: Neck of Sac crossed by Epigastric Artery

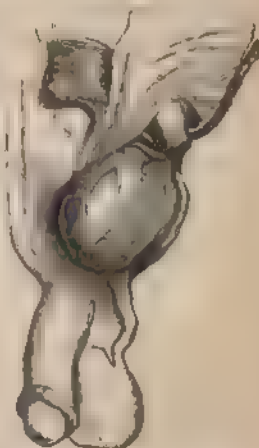

Fig. 394.—Double Inguinal Hernia on the same side. The upper sac, etc. etc. separated by epigastric vessels

In females, inguinal hernie are not very common, except at advanced periods of life; they will then be seen to have the same relations as in the male, except that the round ligament is substituted for the spermatic cord.

The obturator artery, when arising in the normal manner from the iliac, does not come into relation with the neck of the sac; but when it takes its origin, as it not unfrequently does, from the external or common femoral, or the epigastric, it may have important relations to part of the hernia. Most commonly, under these circumstances, it is to the iliac or outer side of the neck, but occasionally it winds round the inner or pubic side, coming into rather close relation with it, and this will immediately be mentioned, it may be in considerable danger during operation. The combination, however, of this particular variety of obturator artery and femoral hernia, is uncommon, because, in the first, this internal division of the artery is rare, when it does occur, it passes directly over the portion of the crura through which it would protrude, and is thereby strengthened, and so diminishes the chance of rupture.

Fig 399.—1, Femoral Hernia, 2, Femoral Vein, 3, Femoral Artery, giving off, 4, Common Trunk of Epigastric and Obturator Arteries, and 5, Epigastric Artery, 6, Spermatic Cord.

Contents. The contents of a femoral hernia are usually intestine, most commonly a portion of the small intestine. Occasionally omentum is contained within, but seldom in large quantity. I have, several times had occasion to operate in cases of old femoral hernia, when it became necessary to remove large portions of adherent omentum; ten and a half ounces, and in the other, about seven. In each case was a small knuckle of intestine strangulated behind the omentum. Ovaries, Fallopian tubes, &c., have been known to be strangulated in a variety of hernia.

Symptoms.—The symptoms of femoral hernia are usually well marked. They consist of a tolerably firm, tense, and unyielding tumour, of a pear shape, situated in the groin, to the inner side of the femoral vessels, having its neck under Poupart's ligament, though, as it increases in size, it may be turned above this structure; sometimes, though rarely, it passes upwards upon the thigh. Its size varies considerably; most commonly it is larger than a walnut or a pigeon's egg, and then is deeply seated at an angle between the body of the pubes and the femoral vessels, but occasionally it may attain a considerable bulk, as large as the fist or a small roll. When large, this hernia usually rises up above Poupart's ligament and extends outwards in a direction parallel to it, so that it assumes an elongated shape; it is then usually somewhat doughy and soft, even when strangulated; very different from the excessively tense feel that it has when small.

In some rare cases the femoral hernia has been found lying external to the vessels, the mouth of the sac being between them and the iliac vessels. In these cases the hernia is usually small, and the contents are usually intestine, but occasionally it may contain a large portion of the small intestine, and in some cases it may contain a large portion of the large intestine. In these cases the hernia is usually small, and the contents are usually intestine, but occasionally it may contain a large portion of the small intestine, and in some cases it may contain a large portion of the large intestine.

In some rare cases the femoral hernia has been found lying external to the vessels, the mouth of the sac being between them and the iliac vessels. In these cases the hernia is usually small, and the contents are usually intestine, but occasionally it may contain a large portion of the small intestine, and in some cases it may contain a large portion of the large intestine.

may be distinguished from hernia by being always of the same size, by not being reducible into the cavity of the abdomen, by the absence of all gurgle, and by its very defined outline. In the *diffused hydrocele* of the cord, the absence of distinct impulse on coughing, the impossibility of returning the swelling completely within the abdominal cavity, and of feeling the cord in a free and natural state, will prevent the disease from being confounded with hernia. *c. Hematocele of the Cord.* Here the soft and fluctuating nature of the swelling, the ecchymosis, the impossibility of complete reduction, and the absence of gurgling, will indicate its true nature. *d. Fatty or other Tumours* occasionally form on the cord; but the circumscribed character and limited size of these swellings, the absence of impulse on coughing, and of reducibility into the cavity of the abdomen, will point out that they are not hernia. *e. Lodgment of the Testis in the Inguinal Canal* will give rise to a tumour, which closely resembles incomplete inguinal hernia, and if it should happen to become inflamed in this situation, the difficulty of the diagnosis from strangulated hernia may be very considerable. In the ordinary undescended testis, the absence of that organ in the scrotum on the affected side, the peculiar sickening pain occasioned by the pressure of the tumour, the absence of gurgling, and of all possibility of reduction, will enable the diagnosis to be effected. *f. Inflamed undescended Testis.* From this it is not always at once easy to effect the diagnosis of incomplete inguinal hernia in a state of strangulation, with which, indeed, it may be complicated. This diagnostic point will be more fully treated of in speaking of congenital hernia. In the meanwhile it may be stated that the absence of *persistent and continuous* vomiting and constipation, the feel of the tumour, hard below, elastic above, and the peculiar pain when it is compressed, will enable the surgeon to recognise the true nature of the tumour as being a retained and inflamed testis.

2. When the hernia has descended *into the scrotum*, it may be confounded with—*a. Hydrocele of the Tunica Vaginalis.* In this disease there is an oval or pyriform tumour, usually translucent, unchangeable in size or shape by pressure, and having the cord clear and distinct above it, with an absence of impulse on coughing, or of gurgling in attempts at reduction. In cases of congenital hydrocele in children, in which there is still an opening communicating with the peritoneal cavity, the tumour may be diminished in size by steady pressure, but gradually returns again, fluctuates, and is translucent. In these cases its translucency, and the gradual manner in which the sac is emptied and is refilled, so different from the sudden slip up and protrusion of a hernia, enable the surgeon to establish the diagnosis. It not unfrequently happens that *hernia is complicated with hydrocele of the tunica vaginalis.* In these cases the two separate tumours can usually be distinguished, there being some degree of constriction, or of consolidation, between them. The hydrocele will present its ordinary characters of translucency, irreducibility, and circumscribed outline, and is commonly placed anterior to the hernia, which lies towards the back of the scrotum, and may be distinguished by its reducibility and impulse on coughing. It sometimes happens, as in a case which once fell under my observation, that a *hydrocele of the cord is associated with one of the tunica vaginalis and a hernia*; under such circumstances, the diagnosis requires a little care, but may be effected readily enough by separately determining the characters of the different swellings. *b. Varicocele.* Here the diagnosis may be effected in the way pointed out by Sir A. Cooper. The patient should be placed in the recumbent position, and the swelling reduced; the surgeon then presses upon the *external ring with his fingers*, taking care to cover the whole of it, and

finger-nail under it, and cautiously sliding the hernia-knife along this. It is an established rule in surgery, that this division should be effected in a direction immediately upwards, so that it may be parallel with the epigastric vessels, whether it be situated upon the inner or outer side of these. It is true that, if the surgeon could be sure that he had to do with an oblique inguinal hernia, he might safely divide the stricture outwards; or, if he were certain that the protrusion was of the direct kind, he might make the section inwards; but, as it commonly happens that he cannot determine with absolute certainty upon which hernia he is operating, he adopts the safer plan recommended by Sir A. Cooper and Lawrence, of cutting upwards from the middle of the ring parallel to the epigastric vessels.

The seat of stricture in inguinal hernia will thus be seen to differ in different cases; and in some instances it exists in two situations. I think it most commonly occurs in the neck of the sac, owing to contraction and elongation of it, with condensation of the subserous cellular tissue lying immediately upon it. In other cases, though much more rarely, it seems to be formed by a thickening of the transversalis fascia at the inner ring, but altogether outside the sac; occasionally it is met with in some part of the canal, at the lower edge of the internal oblique, but much more frequently at the external abdominal ring. In many cases there is very tight constriction in this situation, as well as in the deeper portions of the canal, or at the inner ring; hence, after the division of any stricture at the external abdominal ring, the deeper portions of the canal should always be carefully examined before any attempt is made to put the hernia back.

The operation for an *Incomplete Inguinal Hernia* requires to be conducted in the same way as that which has just been described, except that the incision need not be quite so long, and should not extend beyond the external ring. After this has been laid open, and the tendon of the external oblique shut up, a flat director must be passed under the lower edge of the internal oblique and transversalis muscles, which must be carefully divided; should the stricture not be relieved in this way, and the sac require to be laid open, the deep section must be made in the same way and in the same direction as has already been described.

In *Inguinal Herniæ*, containing either the *Cæcum*, the *Sigmoid Flexure of the Colon*, or the *Urinary Bladder*, the protruded viscera are only partially covered by peritoneum; hence, in operating upon such herniæ, when strangulated, care must be taken that the intestine be not wounded, which is apt to occur if the surgeon divide the parts without due caution, not suspecting himself to have reached the neighbourhood of the gut, but believing that he has met with a sac which does not exist. As the protruded parts are generally adherent in these cases, the surgeon must content himself with leaving them unreduced after the division of the stricture; under such circumstances, it has happened that the protrusion is ultimately drawn back into the abdomen by some natural action of the parts.

Operations for strangulated inguinal hernia are required during a greater range of ages than those for any other kind of protrusion. I have operated successfully for congenital hernia in infants less than six weeks old, and for an ordinary oblique inguinal hernia in one four months of age; and the operation has been done on centenarians. When small and recent, the protrusion usually consists of intestine only; when large, it commonly contains omentum as well. The treatment of these contents, and the after-management of the case, must be conducted in accordance with the rules laid down at pages 1189 et seq.

HERNIA IN THE TUNICA VAGINALIS: In case the hernia descends inside the tunica sac. It is always oblique, and takes the commonly descending into the scrotum, but canal, out of which, perhaps, the testis has differs from an ordinary oblique hernia in the sac, and in the protruded parts lying in the

Fig. 39. A congenital Hernia.

That prolongation tried down around the divided into two parts testicular. The funic to the cord, extend the scrotum; the tun the tunica vaginalis.

in consequence of the funicular prolongation normal condition, converted into a filament remaining pervious, and thus serving as between the general cavity of the peritoneum along the open channel thus left the congenit why in many cases the hernia is not truly congen is that the funicular portion is only partially under a sudden effort, the septum is broken into the tunica vaginalis.

Hernia of the tunica vaginalis, though rarely so in reality; the tendency is congenital not unfrequently happens, it is true, that early in life, in infants a few weeks or months even the funicular prolongation of the peritoneum is occluded, that the hernia which occurs is of Not unfrequently, however, the hernia does not appear until a considerably later period of life than this, and may thus, Velpeau relates instances in which it occurs at the ages of eighteen and twenty-five. I have seen it in a man of thirty-five years of age, in whom this kind of hernia first appeared at a time when he was twelve years old; and seen it in a man of the Hospital, on a man about fifty, in whom, it would appear that the protrusion had not appeared until thirty years of age.

Symptoms.—The symptoms of hernia in the tunica vaginalis resemble those of the ordinary oblique; most of the time the tumour is much rounded, and the neck is small. The testis, also, cannot be felt distinct and is surrounded by, and, as it were, buried in the tunica vaginalis through which it may sometimes be felt at the scrotum. On inquiry, also, it will usually be found that it has existed in childhood, or the testis has de

is usually partly doughy and partly tympanitic to the feel, has a distinct impulse on coughing, and is readily reducible ; not unfrequently it happens, however, that a portion of the rupture continues irreducible, owing to the existence of adherent omentum. The coverings of an umbilical rupture are usually extremely thin, consisting merely of the peritonæum, a layer of condensed fascia, which is often perforated at several points by circular openings through which the hernia protrudes, and the integuments containing the umbilical cicatrix, which is expanded over the part. The sac generally contains both intestine and omentum, but the stomach and other viscera have been included in it ; and Murray has recorded a case in which the gravid uterus, at the eighth month of pregnancy, formed the contents of an umbilical hernia.

Treatment.—The treatment consists, if the hernia be reducible, in wearing a properly constructed truss ; if irreducible, in applying a hollow cup-shaped pad supported by a bandage over the part. It not unfrequently happens that, in consequence of an indigestible or flatulent meal, an irreducible umbilical rupture in old persons becomes obstructed, the symptoms consisting of tension of the protrusion, with nausea and constipation. In these cases, much discrimination will be required to avoid confounding this passive condition of the tumour with acute strangulation of it. This may be done by attention to the rules laid down (p. 979). By local bloodletting, fomentations, calomel and opium, and enemata, relief may usually be afforded. Should, however, the bowels not speedily act, and stercoraceous vomiting come on, the tumour continuing irreducible, it will be better to cut down upon it, and treat it as a strangulated hernia, dividing adhesions, and reducing the swelling ; for, if it be left obstructed and unrelieved, the whole tumour may run into a state of gangrenous inflammation, and then operative interference will be of little use. In such circumstances death usually results ; but I have known the patient to survive the gangrene, the whole of a coil of intestine and much mesentery and omentum sloughing away, and an incurable artificial anus resulting.

When an umbilical hernia becomes strangulated, as often happens in old irreducible tumours of this description, the symptoms are not usually very acute at first ; but no time should be lost in effecting reduction, if possible, by the taxis, as they speedily assume an active and urgent character. If the taxis fail, the plan that I have usually found to succeed best has been to give the patient three doses of calomel, gr. ij, and opium, gr. j, every second hour ; at the administration of the second dose to apply an ice-bladder ; to keep this on for four hours ; and then to employ the taxis again, when reduction of some portion of the swelling will rarely fail to occur. Should this not succeed, the operation must be proceeded with without further delay, lest gangrene of the tumour set in.

Operation.—The stricture should, if possible, be divided without opening the sac. This may usually be accomplished by drawing the tumour well down, and then making an incision in it about two inches in length over the neck at its upper part in the mesial line. If the tumour overlap here, it may be more convenient to make the incision by the side or even between ; but as a general rule, the upper part is the best. After the division of the integumental structures, and often of a deep layer of fat, the end of the nail may be slipped under the edge of the sharp circular margin through which the protrusion has occurred, and, the stricture being divided away from the sac, and if possible in the mesial line, reduction may be readily and safely accomplished. Should the strangulation not be thus relieved, the sac must be opened, and any stricture divided from within. But the surgeon should

and examine its composition. If it be hard, it will require division, the intestine must be freed from the canal.

Treatment.—The treatment of congenital hernia of the tumour, and the application of a proper compress the whole length of the inguinal canal. A radical cure may be effected in this way ; if a desirable result, the truss must be worn for a long time. The application of a truss with an air-pad will be especially useful, more particularly in children, as it gives greater exactness than an ordinary incompressible pad.

When strangulated, congenital hernia does not require division, and thus necessarily renders an operation more commonly required for this kind of hernia. The operation is the same as that for oblique hernia. When the tunica vaginalis is concerned are usually thinner, the tunica vaginalis requires more caution than usual is required in its dissection, as it contains a large quantity of clear or dark fluid. In fact, a hydrocele conjoined with the hernia is always found in the neck of the sac, is elongated, and narrowed ; hence it is useless to attempt to relieve the strangulation, without laying open the sac from within. As the congenital hernia is often associated with vessels, the section of the stricture may be made in a direction upwards and outwards ; though, there is some doubt as to the exact nature of the case, the stricture directly upwards. The reduction of the hernia will often be prevented by adhesions in the neck of the sac and the testes. I have found both the spermatic cord incorporated with this organ, and requiring its division. In operating upon infants of a very young age, it is necessary to be required, on account of the tension, and the small size of the aperture of the spermatic cord, the veins of which are often found much congested, and of a black or blue color.

A species of congenital hernia has been met with

in children, in which the hernia is in the canal of Nuck, which is a small canal. In one instance I have met with it in a girl of five years old. It is a rare disease, and requires the same treatment as the corresponding disease in the adult.

ENCYSTED HERNIA.

INFANTILE HERNIA, as it is termed, occurs in the upper portion of the tunica vaginalis, or by the insertion of a septum, or by the protrusion of the tunica vaginalis, but in such a manner that it is protruded through the vaginalis, so that it is not in communication with the external opening.

Fig 396.—Infantile Hernia.

can be distinguished from the ordinary congenital hernia. If it becomes strangulated, it must be borne in mind that the tunica vaginalis will first be opened, and the contents of the sac will be exposed.

but the tumour lies behind this sac, and requires to be dissected into through the double serous layer of which it is composed. The stricture will probably be in the neck, and requires to be divided in the usual way.

FEMORAL HERNIA.

By *Femoral Hernia* is usually meant a protrusion that escapes under Poupart's ligament, and enters the sheath of the vessels internally to the femoral vein. This hernia passes down into the innermost compartment of the sheath, which is occupied by fat and lymphatics, and usually contains a gland or two. It passes first of all through the crural ring, where it has Gimbernat's ligament to its inner side; the septum which separates the femoral vein from the inner compartment of the sheath of the vessels, to its outer aspect; Poupart's ligament in front; and the bone behind (Fig. 397). After passing through the crural ring, it enters the crural canal,

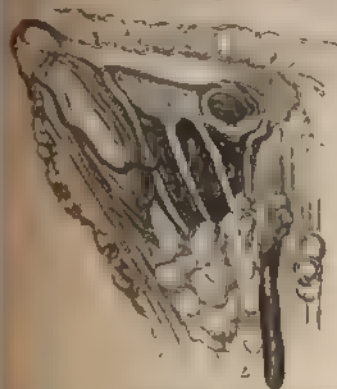

Fig. 398.—Femoral Hernia turning upwards.

Fig. 397.—1. Femoral Artery; 2. Femoral Vein; 3. Innermost Compartment of the Sheath of the Vessels, into which a small Hernia is protruding; 4. Saphenous Vein.

which extends for about an inch and a half down the thigh on the pectineus muscle, and is covered by the iliac prolongation of the fascia lata. As it approaches the lower corner of the saphenous opening where the canal terminates, it passes under the falciform process of the fascia lata, and out upon the thigh through the saphenous aperture; here it expands, becomes rounded, and has often a tendency to turn upwards over Poupart's ligament (Fig. 398), lying in this way upon the iliac region, and sometimes even ascending to some distance upon the anterior abdominal wall. In the descent of the hernia through this course, it first of all pushes before it the peritoneal sac, and then receives an investment of the subserous cellular tissue. It next comes into relation with the *septum crurale*, a mass of dense cellular tissue, containing fat and lymphatics, occupying the crural ring. This septum often becomes incorporated and matted with the contiguous portion of the sheath, thus constituting the *fascia propria* of this hernia, which is commonly thickened, laminated, and of an opaque fatty structure, like omentum. As the hernia continues to descend, it comes into relation with the cribriform fascia, which occupies the saphenous opening, and, lastly, pushes before it the integumental structures.

As the tumour descends through this course, it necessarily comes into relation with very important parts (Fig. 399, p. 1012). Thus it is separated from the femoral vein solely by the septum of the sheath of the vessels. It has the epigastric artery above and to its outer side; and the spermatic cord in the male, or round ligament in the female, almost immediately above it.

The obturator artery, when arising in the normal manner from the internal iliac, does not come into relation with the neck of the sac, but when it takes its origin, as it not unfrequently does, from the external iliac, or common femoral, or the epigastric, it may have important relations to the part of the hernia. Most commonly, under these circumstances, it passes to the iliac or outer side of the neck, but occasionally it winds round the inner or pubic side, coming into rather close relation with it, and then, as will immediately be mentioned, it may be in considerable danger during the operation. The combination, however, of this particular variety of the obturator artery and the femoral hernia, is a very uncommon occurrence, because, in the first place, this internal distribution of the artery is rare, and when it does occur it passes directly over the portion of the femoral vein through which the hernia would protrude, it necessarily strengthens this, and so diminishes the chances of rupture.

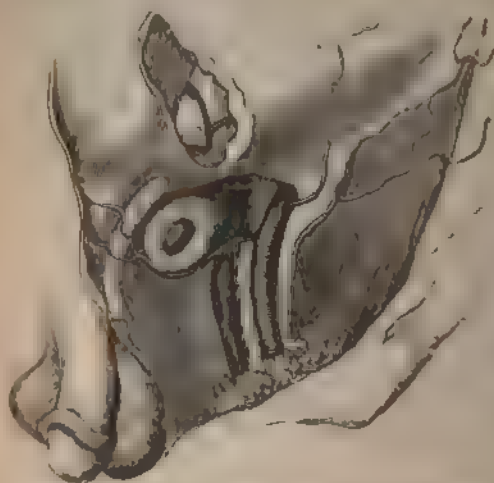

Fig. 599.—1, Femoral Hernia; 2, Femoral Vein; 3, Femoral Artery, giving off; 4, Common Trunk of Epigastric and Obturator Arteries; and 5, Epigastric Artery; 6, Spermatic Cord.

Contents. — The contents of a femoral hernia are usually intestinal, and most commonly consist of a portion of the small intestine. Occasionally omentum is contained within the sac, but seldom in large quantity. I have, however,

several times had occasion to operate in cases of old femoral hernia, in which it became necessary to remove large portions of adherent omentum, in ten and a half ounces, and in the other, about seven. In each case there was a small knuckle of intestine strangulated behind the omentum. The ovaries, Fallopian tubes, &c., have been known to be strangulated in this variety of hernia.

Symptoms.—The symptoms of femoral hernia are usually well marked. They consist of a tolerably firm, tense, and unyielding tumour, of a rounded shape, situated in the groin, to the inner side of the femoral vessels, having its neck under Poupart's ligament, though, as it increases in size, its base may be turned above this structure; sometimes, though rarely, it passes upwards upon the thigh. Its size varies considerably; most commonly it is larger than a walnut or a pigeon's egg, and then is deeply seated in the angle between the body of the pubes and the femoral vessels, but occasionally it may attain a considerable bulk, as large as the fist or a small roll. When large, this hernia usually rises up above Poupart's ligament, and extends outwards in a direction parallel to it, so that it assumes an elongated shape; it is then usually somewhat doughy and soft, even when strangulated; very different from the excessively tense feel that it has when small.

In some rare cases the femoral hernia has been found lying external to the vessels, the mouth of the sac being between them and the iliac space.

Under these circumstances strangulation cannot well occur, inasmuch as the mouth will be the widest part of the sac; but, as Hesselbach has observed, if the fascia laca be torn by the pressure of the tumour, the rupture may be strangled in the aperture thus formed. Should an operation ever be required under such circumstances, it must be borne in mind that the circumflex iliac artery may be in some danger.

Diagnosis.—The diagnosis of femoral hernia is not always easy. When the hernia is large, and more particularly when it rises up above Poupart's ligament, which some herniæ, even of very moderate size, are apt to do, it might at first be mistaken for an inguinal rupture. The diagnosis, however, may usually be effected by ascertaining the relation that the neck of the sac has to Poupart's ligament, the inguinal hernia being situated *above*, the femoral *below* this cord. When, however, a small femoral hernia in a fat man rises upwards, so as to overlie Poupart's ligament, it resembles very closely an incomplete inguinal hernia; but its characters may be determined by the passage of the finger up the inguinal canal, which will be found to be free, and the hernia can only be felt through its posterior and inferior wall. In the female the finger cannot be passed up the canal, but the inguinal hernia will descend into the labium, and may thus be recognised from the femoral, which lies in the upper and inner part of the thigh. After reducing a femoral hernia, the finger also can usually be pushed into the inferior aperture of the crural canal, when the situation and sharp outline of the falciform process will determine the nature of the opening through which the protrusion has occurred.

The diseases occurring in the groin, with which femoral hernia may most readily be confounded, are—1. *Enlarged lymphatic glands* in this situation. From these it may be distinguished by the absence of impulse in the glandular tumour, and by the simultaneous enlargement of several glands. A small strangulated hernia may, however, co-exist with these; being subjacent to, and covered in by them. When this is the case, and the local signs of hernia are obscure, whilst the symptoms of strangulation continue, an incision should be made into the part, and the dissection carefully carried through and underneath the glands, with the view of determining whether the hernia exist or not. 2. *A small fatty growth* has been met with in the crural canal, simulating closely a hernia. The want of impulse on coughing, together with its limited and doughy character, and the absence of circumscription in the tumour, will enable the surgeon to distinguish it from hernia. 3. *Psoas abscess* not unfrequently points very nearly in the situation of femoral hernia. From this it may, however, be distinguished by its fluctuating feel, soft, yet semi-elastic character, and by the general history of the case. The impulse on coughing, which is very distinct in the abscess, is commonly more forcible and direct than that of a hernia; and although the purulent collection may in many cases be squeezed back into the abdomen when the patient lies down, yet it returns without a gurgle, and without that distinct slip which accompanies the reduction of a hernia. 4. *Varix of the saphena vein* is in some danger of being confounded with hernia. It may, however, be distinguished from this by the impulse in it being less distinct, and by the enlargement of the lower part of the vein being marked in the varix, but not existing in the rupture.

Femoral hernia most commonly occurs in women, and very seldom under the age of twenty; differing in both these respects from the inguinal rupture. Sir A. Cooper states that he had only seen three cases under the above age. It very seldom becomes strangulated at an early period of life, even when existing. *I have had a girl of nineteen under my care with femoral hernia,*

in whom strangulation had already occurred on four occasions, reduction, however, having been happily effected each time.

Treatment.—The treatment of femoral hernia, when it is reducible, must be conducted in the ordinary way by the application of a proper truss. A cure, however, is never, I believe, effected by the pressure of a pad as sometimes happens in inguinal hernia; owing probably to the rigidity and incompressibility of the tendinous and aponeurotic structures through which this rupture protrudes. It is difficult to keep this form of hernia by means of a truss. The best instrument for this purpose is, I think, the moorain truss, which I have found to succeed when all others have failed. When the hernia is irreducible, it should be supported by means of a truss with a concave pad.

When a femoral rupture is strangulated, reduction should be effected either by taxis or operation as speedily as possible, gangrene more rapidly ensuing in this than in any other form of hernia. In attempting the taxis, the structures in the groin should be well relaxed by bending the body forward and flexing the thigh upon the abdomen; if it do not succeed with the assistance of the means recommended at page 981, the operation should be proceeded with at once. The operation for strangulated femoral hernia may be undertaken earlier and with a better prospect of success than in any other form of rupture; this is owing to the stricture being so commonly seated outside the sac, that the operation usually admits of being completed without unfastening the peritoneum. The advantage of this mode of procedure in femoral hernia has been fully pointed out by A. Key, Luke, and Gay, and is now, I think, pretty generally recognised and practised. Mr. Gay more particularly, in his work on *Femoral Hernia*, has pointed out that the stricture may commonly be divided without opening the sac, by making a very limited incision on the inner side of the neck of the tumour, and he justly observes that the operation undertaken in this manner is done more than the taxis with the addition of a superficial incision.

The stricture in femoral hernia is often found to be occasioned by the pressure of the crural arch. Lawrence states that it may be most effectively relieved by dividing the thin posterior border of this arch near the junction. Other surgeons recommend that the sharp edge of Gimbernat's ligament should be divided; and others again that the division should be made at the junction of Gimbernat's and Poupart's ligaments, through those ligamentous bands which go by the name of Hey's or the ilio-femoral ligament, at the inner edge of the falciform process; and, indeed, it is in this stricture that both Lawrence and Hey direct the incision to be made. In operating for femoral hernia, I have certainly most frequently found the stricture not to continue after the division of these ligamentous structures, and to be occasioned by fibrous bands, often very distinct, narrow, and glistening, lying across the neck of the sac in the fascia propria of the hernia; and I agree with the opinion expressed by Sir A. Cooper, that the neck of the sheath is the common seat of strangulation in femoral hernia; these transverse fibres, which sometimes appear to be partially reticulated, consisting probably of a condensation of the tendinous fibres that are normally found in the sheath of the vessels. In order to expose them, it is commonly necessary to draw the neck of the sac well down, when they will be seen deeply to indent and constrict it.

The operation without opening the sac may most conveniently be performed, when the tumour is small, by making an incision along the inner side of its neck, and then dissecting through the superficial structures until the fascia propria is exposed and carefully opened, and then the sac exposed.

The point of the finger should then be carried to the lower side of this, well under the fascia propria. The finger-nail or a flat director may then be insinuated under the sharp edge of Gimbernat's ligament; which, at the point of junction with Poupart's, may be divided upwards and inwards to the extent of a line or two by means of a hernia-knife. By this incision, not only is the edge of Gimbernat's and Poupart's ligament divided, but also the condensed and compressed fascia propria lying between the sac and the inner side of the crural arch. The reduction may now be attempted, and often effected; should any obstacle exist, the neck of the sac must be well drawn down and exposed, and any transverse bands situated upon it dissected through with the scalpel and forceps, or divided on a director. These bands lie in the fascia propria; and when they are found, it is usually owing to the surgeon not having closed the neck of the sac sufficiently before passing his nail or director under the stricture. It is owing to the incision being confined to the constrictions occasioned by the crural arch only, not including, as it ought to do, the subjacent condensed fascia propria; a point of very great practical importance. Sometimes this condensed and constricting portion of the fascia propria is so closely incorporated with the neck of the sac, that it cannot be divided without opening the latter. The operation performed in this way, without opening the sac, is certainly a very simple procedure, and adds little to the danger of the patient.

If it be thought desirable to *open the sac*, or if it be necessary to do so in consequence of its incorporation with the fascia propria, the operation must be performed in a different manner, the parts requiring to be rather fully exposed; and indeed, if the tumour be of any considerable magnitude, even though the sac be not opened, it will be better to expose the part somewhat more freely in the way to be described. An incision should be made parallel to Poupart's ligament, by pinching up the skin, and then a transverse cut from the centre of this carried over the tumour so as to present the following shape

: the dissection must then be carried through the superficial fascia, when the septum crurale or fascia propria will be exposed; in some cases, especially if the hernia be a large one, this is thin, and requires to be carefully slit up on a director. In many instances, however, it is so dense, laminated, and changed in structure, as scarcely to be recognised for what it is. It not unfrequently happens that, after the superficial fascia has been divided, an oval, smooth, and firm body is exposed, which at first looks like the hernial sac, or a lump of omentum; this is in reality the fascia propria, thickened by the long-continued pressure of the truss, and congested perhaps by the attempts at reduction; and in the midst of it, the sac will at last be found, after the dissection has been carried through several layers of this tissue. In it cysts containing bloody serum may occasionally be found, and then the difficulty in the recognition of the structures is greatly increased. Though the mobility of this mass, the facility of tracing its neck, and the roundness of its general outline, often cause it to be mistaken for sac or omentum, it may be distinguished from the first by the absence of the characteristic vessels upon its surface, and from the second by its more rounded, solid feel, and uniform appearance. When the sac has been reached, it must be very carefully opened, there being usually very little if any fluid between it and its contents; the finger-nail must then be passed under the sharp edge of the stricture, which should be divided in a direction upwards and inwards. The reason why this line of incision is universally chosen by surgeons in this country at the present day, is, that it is the only direction in which the stricture can be

usually partly doughy and partly tympanitic to the feel, has a distinct impulse on coughing, and is readily reducible; not unfrequently it happens, however, that a portion of the rupture continues irreducible, owing to the existence of adherent omentum. The coverings of an umbilical rupture are usually extremely thin, consisting merely of the peritoneum, a layer of condensed fascia, which is often perforated at several points by circular openings through which the hernia protrudes, and the integuments containing the umbilical cicatrix, which is expanded over the part. The sac generally contains both intestine and omentum, but the stomach and other viscera have been included in it; and Murray has recorded a case in which the gravid uterus, at the eighth month of pregnancy, formed the contents of an umbilical hernia.

Treatment.—The treatment consists, if the hernia be reducible, in wearing a properly constructed truss; if irreducible, in applying a hollow cup-shaped and supported by a bandage over the part. It not unfrequently happens that, in consequence of an indigestible or flatulent meal, an irreducible umbilical rupture in old persons becomes obstructed, the symptoms consisting of tension of the protrusion, with nausea and constipation. In these cases, much discrimination will be required to avoid confounding this passive condition of the tumour with acute strangulation of it. This may be done by attention to the rules laid down (p. 979). By local bloodletting, fomentations, calomel and opium, and enemata, relief may usually be afforded. Should, however, the bowels not speedily act, and stercoraceous vomiting come on, the tumour continuing irreducible, it will be better to cut down upon it, and treat it as a strangulated hernia, dividing adhesions, and reducing the swelling; for, if it be left obstructed and unreduced, the whole tumour may run into a state of gangrenous inflammation, and then operative interference will be of little use. In such circumstances death usually results; but I have known the patient to survive the gangrene, the whole of a coil of intestine and much mesentery and omentum sloughing away, and an incurable artificial anus resulting.

When an umbilical hernia becomes strangulated, as often happens in old irreducible tumours of this description, the symptoms are not usually very acute at first; but no time should be lost in effecting reduction, if possible, by the taxis, as they speedily assume an active and urgent character. If the taxis fail, the plan that I have usually found to succeed best has been to give the patient three doses of calomel, gr. ij, and opium, gr. j, every second hour; at the administration of the second dose to apply an ice-bladder; to keep this on for four hours; and then to employ the taxis again, when reduction of some portion of the swelling will rarely fail to occur. Should this not succeed, the operation must be proceeded with without further delay, lest gangrene of the tumour set in.

Operation.—The stricture should, if possible, be divided without opening the sac. This may usually be accomplished by drawing the tumour well down, and then making an incision in it about two inches in length over the neck at its upper part in the mesial line. If the tumour overlap here, it may be more convenient to make the incision by the side or even between; but as a general rule, the upper part is the best. After the division of the integumental structures, and often of a deep layer of fat, the end of the nail may be slipped under the edge of the sharp circular margin through which the protrusion has occurred, and, the stricture being divided away from the sac, and if possible in the mesial line, reduction may be readily and safely accomplished. Should the strangulation not be thus relieved, the sac must be opened, and any stricture divided from within. But the surgeon should

exhaust every means before he opens the s^cially of large size, the patient I believe rare—much less frequently, so far as my experience goes. Sometimes, after the external division, I found that there is an internal strangulation slipped through an aperture formed by the covering the sac; if so, the edge of this requires division. Sir A. Cooper mentions tumours, having a communication between in which the tumour resembled a figure of down the middle of the sac. In such cases uncommon, central constriction may require stricture at the neck of the sac. Adherences be left in the sac in cases of umbilical hernia, omentum must be treated upon general principles. Strangulation of an umbilical hernia occurs; this happen, the operation must be performed not complicate the case much, and instances Lawrence, and others, of its successful performance the division of the strictures and the reduction of the hernia, and be retained in position by a flannel roller.

OTHER VARIETIES OF

VENTRAL HERNIA.—By ventral hernia is meant one which occurs through any part of the abdominal wall, femoral, or the umbilical apertures; they are situated between the recti muscles, the linea alba, in this situation during parturition, and increase in size. A case was once sent to me from the long triangular gap through the upper part of the linea alba from the umbilicus to the ensiform cartilage, which had taken place that was nearly as large as a fistula. I have also been met with in the linea semilunaris and iliac regions; and Cloquet describes a region. When these hernia happen in the abdomen, they are apt to occasion dyspeptic symptoms as Lawrence is doubtless right in thinking that they arise from the implication of the stomach, but sometimes different protrusions have occasionally been met with by which the anterior abdominal wall has been ruptured, seldom, if ever, take place below the umbilicus, and are of traumatic cause.

Treatment.—The treatment of ventral hernia is to reduce the tumour by means of a broad belt and prevent it from becoming strangulated, which I believe very rarely happens. If the width of the neck of the sac, the operation is performed in the same way as for umbilical rupture, care being taken to divide the integuments, any aponeurotic investments, and the stricture should always be divided upwards.

A rare kind of ventral rupture has been described by German surgeons, in which the abdominal wall is ruptured to such an extent, forming a broad and expanded wound.

pedicle. Sometimes this tumour may attain an immense size, stretching perhaps down to the knees, and containing even the gravid uterus.

OBTURATOR HERNIA.—The occurrence of this form of hernia is extremely rare, and its existence has still more rarely been determined until after death; in fact, Lawrence seems to doubt the possibility of the recognition of this complaint during life, in consequence of the small size which the tumour attains, and its being covered in by and compressed under the pectineus muscle. Two instances have, however, been recorded, one by Otre, the other by Bransby Cooper, in which a strangulated hernia of this kind was recognised during life. And these are probably the only instances on record in which an operation has been successfully performed; almost all the other cases mentioned by writers having been accidentally discovered after death, which had occurred from internal strangulation, the precise seat of which could not be detected. In Obré's case, the patient was seized with symptoms of strangulation, but no tumour could be detected in any of the ordinary seats of hernia. "On uncovering the upper part of both thighs at the same time, the eye detected a slight degree of fulness in Scarpa's triangle on the right side; this triangle of the opposite limb was well marked with a hollow, or depression passing down its centre, but this was lost on the affected side, and the whole contour of this part of the limb was visibly fuller than that of the corresponding one. There was no tumour or circumscribed swelling, but on standing over the patient, and using firm pressure with the ends of the fingers over the neighbourhood of the femoral artery, and a little below the saphenous opening, a distinct hardness could be felt (slight in its extent), giving an impression as if the sheath of the vessels were being pressed on." Taking the dangerous state of the patient into consideration, Mr. Obré acted in accordance with the best rules of surgery; and, thinking that there might be a hernia deeply strangulated in the femoral canal, he made an incision downwards in this situation, but was disappointed on finding, when the saphenous opening was exposed, that there was no intestine confined there. As, however, a hardened structure could be deeply felt at the inner border of the opening, the fascia lata was exposed, and the pectineus muscle divided to the extent of about two inches, when a hernial sac of about the size of a pigeon's egg, and containing intestine, came into view. In this operation the saphenous vein gave some trouble, lying in the course of the incision. The sac having been laid open, the structure was divided upwards, during which part of the procedure the vein was accidentally cut, and required ligature; no other vessel was tied. The operation, which reflects the greatest credit on Mr. Obré's diagnostic skill and dexterity, was perfectly successful, the patient making an excellent recovery.

Besides the obturator, various other pelvic herniæ may take place, such as a protrusion into the perineum, the vagina, or through the sciatic notch. These various forms of rupture are of extreme rarity, and present many difficulties in their diagnosis.

PERINEAL HERNIA commonly occurs in the middle line, between the rectum and the bladder in men, or the rectum and vagina in women; but sometimes the protrusion has been known to take place by the side of the anus, or even in front of this. Of these various forms of rupture, many instances have been collected by Lawrence from different writers. The Treatment of such a hernia would consist in supporting the protrusion by means of a pad and bandage; as the mouth of the sac is very large in these cases, it is not probable that any strangulation would occur.

VAGINAL HERNIA has occasionally been met with; the tumour protruding

through the posterior or upper wall of the nary characters of this disease, such as imp It may most conveniently be kept up by m

PERIDENDAL HERNIA has been described, resembling vaginal rupture. The situation be mistaken for an inguinal hernia; but fit the upper part of the labium and the ring tumour presenting the ordinary characters lower part of the labium, and forms a prot of the vagina.

DIAPHRAGMATIC HERNIA.—This form of rence, and, I believe, always results in cons of the diaphragm. It usually attains a la the stomach or the transverse colon, with form a tumour in the thoracic cavity, et pushing the heart to one side. This heral sac, but has been found partially envel believe, only been met with in the left sid the liver on the right side preventing its case affords a very good instance of this ven

A man, seventy-four years of age, was Hospital. About twelve months before, he deep; he believed that he injured his chest had suffered much from shortness of bre suffocation, had a hacking cough, and cou some difficulty in breathing. At the time about three spoonfuls of blood. Ever since from dyspeptic symptoms and constipation, injury he had experienced no inconvenience before admission, the difficulty in breathing he came to the hospital, violent pain in bowels ceased to act, although he took a va had enemata containing croton oil administ

On admission, the abdomen was found in panitic, with pain around the umbilicus; the brown, moist fur; the pulse was small, there was nausea, but no vomiting. The abd anxious; the bowels had not acted for a desire to go to stool. He was ordered an hour. As this had no effect, he was directed pills, and to have turpentine enemata, though they brought away no feces. The skin cold and flabby, the countenance mor

and the abdomen more tympanitic, and he died two days after admission, and nine from the commencement of the obstruction.

Examination of the body twenty-four hours after death.—The abdomen was distended and tympanitic, and the peritoneal sac contained about six ounces of fluid, with here and there patches of recently effused lymph. The small intestines were not distended: the large were greatly distended with æræ, the cæcum extending into the cavity of the pelvis; the ascending and the transverse colon were much distended, and it was found that a large loop of the transverse and of the descending colon had passed through an opening in the cordiform tendon of the diaphragm into the pleural sac, and was there strangulated (Fig. 400). The colon below the stricture was

contracted, and entirely empty. On opening the thorax, the loop of intestine, fourteen inches in length, of a pale slate colour, and distended with gas, was found in the left pleural sac. It reached as high as the fifth rib, touched the pericardium, and was overlapped by the free margin of the left lung. Where strangulated, it was of a darker colour than elsewhere. The opening in the diaphragm, through which it had passed, admitted little more than the point of the forefinger, and had a thin tendinous margin. The tenth and eleventh ribs, on the left side, were found to have been fractured; the latter was united by osseous matter, but the tenth rib, at the seat of fracture, had formed a false joint. Connected with this and with the intercostal space below it, was a firm adhesion about an inch broad, and an inch and a half long, united by its other extremity in the protruded meso-colon and the diaphragm. The protruded meso-colon was firmly adherent to the upper surface of the diaphragm; close to the opening in it, the lungs were tolerably healthy. The right pleura contained three ounces, and the left eight ounces of serum.

Fig. 400.—Diaphragmatic Hernia.

CHAPTER LXIII.

INTESTINAL OBSTRUCTION.

Intestinal Obstructions may be of two distinct kinds, the *Acute* and the *Chronic*, which should not be confounded with one another, as they are usually dependent upon very different conditions, and require different lines of treatment to be adopted for their relief.

ACUTE INTESTINAL OBSTRUCTION.—This may arise from five different causes. 1. It most commonly occurs in consequence of the formation of an internal hernia, which becomes suddenly strangulated, a portion of gut slipping through an aperture in the mesentery, or omentum (Fig. 401), or becoming constricted by bands, adhesions, or diverticula, stretching across

from one side of the abdomen to the other. 2. It may occur from invagination or intussusception, the upper portion of the intestine slipping into

Fig 401.—Intestinal Obstruction from Internal Hernia.

lower. 3. It may be produced by a portion of gut becoming twisted upon itself, and thus forming a volvulus, owing to the mesentery or mesocolon being unusually long, and allowing a half-twist to take place, the consequence of which complete obstruction occurs. 4. In other instances, as Phillips has pointed out, the same train of symptoms may arise in consequence of malignant stricture gradually closing, and then at last becoming suddenly occluded.

It is of much importance

in practice to bear in mind that severe and even fatal intestinal obstruction may occur, simply from spasmodic causes, or as the result of inflammatory affections of the abdomen, without the existence of any mechanical lesion.

Symptoms.—The symptoms of acute intestinal obstruction, when arising from a mechanical cause, such as the formation of an internal hernia, or volvulus, are always characterised by very marked vital depression. The first symptom is constipation, it is true, from the very first; but this symptom is not the most prominent one, and those that result are evidently, as in an ordinary case of strangulated hernia, the consequence of the injury inflicted upon the intestine, rather than of the mere mechanical obstacle to the onward passage of the feces. At the moment of the occurrence of the attack, the patient is usually seized with a sudden feeling of something wrong having taken place in the abdomen; or he is struck with intense pain at one point. There may be sudden syncope, though most usually the depression of vital power does not amount to this. Vomiting speedily occurs; at first of the contents of the stomach, but after a time of a stercoraceous character; sometimes assumes this form almost from the very first. The abdomen becomes swollen and tender, the intestines being blown up with flatus, so as to give rise to immense tympanitic distension, rolling over one another, and occasioning loud rumbling and gurgling noises. If the abdominal walls be thin, the rolling of the intestines may be distinctly felt, and in many cases seen through them: and may sometimes be observed to be continued up to one spot, where it ceases. At this point an intumescence may sometimes be indistinctly felt corresponding to the seat of strangulation. If relief be not afforded, the sufferings of the patient become very considerable, and the mental distress agonising; the vomiting, perhaps, becomes less frequent, but the depression increases, and at last death results, usually about the sixth to the tenth day, though sometimes sooner, from exhaustion, peritonitis, and gangrene conjoined, the mind being clear to the last, and the patient's attention being intently and distressingly riveted upon the possibility of getting relief from the bowels.

CHRONIC INTESTINAL OBSTRUCTION.—This usually arises from one of three causes; viz., 1, the gradual obliteration of the inferior portion of the large intestine, in consequence of the malignant degeneration of its walls; 2, the compression of the gut by a tumour growing near it; or 3, the obstruction

of its cavity by the accumulation of large masses of hardened feculent matters.

The *Symptoms*, in the earlier stages of these cases, are commonly those that will be described as indicating stricture of the large intestine; but, when once complete obstruction has come on, the constipation becomes the most prominent symptom. In some instances this will occur without any antecedent leading to the supposition of the existence of stricture. There may be comparatively little constitutional disturbance at first, but the bowels cannot be made to act, and any attempt at forcing their operation by the administration of purgatives, gives rise to sickness and much distress. During the progress of the attack, eructations, retchings, and even vomiting, are of frequent occurrence, but it seldom happens that this is stercoraceous till the very last; there may be much tympanitis, with rumbling and gurgling of the intestines, but most frequently the abdomen fills slowly and gradually, and these symptoms do not occur until after some days have elapsed. The distress of the patient does not depend so much on the length of time that the obstruction has existed, as on the amount of tympanitic distension of the abdomen. The greater this is, the more urgent will be the symptoms. In many instances, life is prolonged for several weeks, for five or six, even after complete obstruction has set in; and in some cases a recovery may take place even though a very considerable time have elapsed from the occurrence of the obstruction. In a lady whom I attended some time ago, with Mr. Powell, recovery took place, although there had been complete obstruction for upwards of five weeks.

DIAGNOSIS.—I. The diagnosis of the *causes* of the obstruction is of great importance; attention as to whether it assume the acute or the chronic form, will throw some light upon the conditions that occasion it. It is often difficult to determine whether the obstruction is mechanical, or whether it depends upon a spasmodic or inflammatory affection of the intestine. The practice to be adopted in any particular case must at last be determined by a history of the symptoms, by a careful exploration of the abdomen and rectum, and by the light that can thus be thrown upon the question, as to whether the obstruction in the particular case be dependent on causes that are removable or not by medical means. In many instances, the history of the case, the assemblage of strongly marked symptoms, and the result of abdominal and rectal exploration, enable the surgeon to determine, without much difficulty, that the obstruction is dependent on causes that are not removable by any means short of operative interference. But, in other cases, no means that we possess enable us to arrive at a correct or even an approximate diagnosis. Cases are recorded that have ended fatally from obstruction in forty eight hours, without sickness, fixed pain in the abdomen, or tympanitis. These, however, are certainly exceptional, and do not bear upon the question as to the propriety of performing gastrotomy in those instances in which it can be satisfactorily determined that a mechanical obstacle, not removable by medical means, exists. That the diagnosis may so far be effected with tolerable certainty is evident, from the fact that in all those cases of gastrotomy which have been of late years practised in this country, by Luke, Hilton, Avery, and myself, mechanical obstruction, irremovable by any but operative interference, was found.

The most prominent symptoms, and those that will chiefly engage the surgeon's attention, are—1, the Duration of the Constipation; 2, the Occurrence of fixed Local Pain in the Abdomen; and 3, the Character of the Vomited Matters.

1. *The Duration of the Constipation* does not throw much light upon the

cause. Indeed, if patients be naturally costive, constipation may last for considerable number of days, or even weeks, without producing any serious or fatal consequences. Most practitioners must have seen cases in which constipation has continued for three or four weeks, without destroying the patient. Dr. Johnson mentions a case, in which it lasted during forty-six days. In these cases, however, constipation has usually come on gradually, being, as it were, an aggravation of the patient's natural condition. In cases of acute internal strangulation, the constipation is always sudden, and is accompanied or speedily followed by other symptoms, indicating intestinal obstruction.

2. *The Occurrence of Fixed Pain* is common to many conditions of the abdomen; though, when taken in conjunction with the sudden supervention of obstruction to the onward passage of the feces, with more or less tumefaction corresponding to the seat of pain, and more especially with the nausea, a symptom to which I shall advert, it is not without considerable value in the diagnosis of these cases.

3. *The Character of the Vomiting.*—When the obstruction is not dependent on complete mechanical occlusion of the bowel, there may be incessant vomiting, and the stomach may reject its contents as often as anything introduced into it; but the vomiting will not be feculent in the majority of cases, however obstinate the constipation may be, and however long it may last. If, however, there be complete mechanical occlusion, feculent vomiting most commonly sets in early, frequently by the third day, or even sooner, and will continue until the cause of occlusion be removed. The vomiting, however, is not continuous, but will usually occur only after food has been taken into the stomach. It is true that feculent vomiting is not sufficient by itself to determine the diagnosis; and that it may occur in cases of pure spasmodic ileus, in which the obstruction is removable by medical means. A remarkable case of this kind occurred a few years ago at the Westminster Hospital, under Dr. Basham, in the person of a black woman, who was admitted for hæmatemesis, with catamenial suppression. The stomach was very irritable, with occasional colicky pains in the abdomen for the first two weeks. The bowels, although torpid, were not completely occluded for within forty-eight hours of the stercoraceous vomiting. This latter condition continued for five weeks altogether, with an interval in which the bowels acted; indeed, towards the latter period of the case, feculent vomiting occurred on the same day that a small alvine evacuation was obtained. She suffered during a greater part of this period from dysuria. There was also frequent spasmodic constriction of the rectum; and altogether much hyæmia was mixed up with the symptoms. The stercoraceous vomiting gradually abated, the natural order of things returned, and she left the hospital sufficiently well to walk to Portsmouth in three days. It is, therefore, necessary to bear in mind the occasional dependence of feculent vomiting on pure spasmodic ileus, or on other conditions that are removable by medical aid alone, as that it may be absent in cases in which the obstruction, whether seated in the small or in the large intestine, is not under the influence of medical treatment, and can only be relieved by surgical assistance. But I believe that a careful exploration of the abdomen and rectum, and a proper inquiry into the history of the case, will most generally prevent the surgeon from being led into any serious error by trusting too implicitly to the presence or absence of this one symptom.

The following may be given as a summary of the general diagnostic signs.
1. In *internal hernia* the suddenness of the symptoms, the prostration or syncope, fixed pains and vomiting, will throw light on the condition. 2. In *int-*

absorption, the early age, the fixed pain, with elongated tumour, to be chiefly felt on palpation, and possibly through the rectum, with bloody mucous stools and tenesmus, are the chief signs. 3. In *Volvulus* the signs of internal strangulation, with very unequal distension of the abdomen, great tympanitis on one side and flattening on the other, are met with. 4. In *Chronic structure* suddenly occluded, the sudden aggravation of the previous long-continued difficulty in defecation will clear up the diagnosis.

2. After determining whether the obstruction be dependent on causes that are removable or not, the next most important point is doubtless to ascertain whether the obstruction is seated in the large or in the small intestine. In general, there may be no great difficulty in coming to an accurate opinion on this point, if it be borne in mind that, with the exception of volvulus, obstructions of the large intestines are most generally chronic, whilst those of the small are, in by far the majority of cases if not invariably, acute in their character. The earlier occurrence of feculent vomiting when the obstruction is in the small intestine, the greater tympanitic distension and bulging in the course of the cæcum and colon when it is seated in the large intestine; the amount of urinary secretion, being, as was pointed out by Hilton and G. Bird, less in the former than in the latter case; and the result of careful exploration of the rectum, will most commonly enable the surgeon to decide this question with sufficient precision to guide him in the choice of an operation. Yet cases do occur in which, though the obstruction be seated in the large intestine, the symptoms are acute, and evidently not dependent on chronic obstructive disease, the vomiting is of early occurrence, the distension of the abdomen slight, and exploration by the rectum yields no result; and it is in cases of this description, presenting a train of symptoms of mixed and uncertain character, that the diagnosis of the precise seat of the obstruction cannot be made.

The question as to whether the cavity of the peritoneum should be opened or not, will altogether turn, in any given case of intestinal obstruction dependent on causes that cannot be removed without operative interference, on the point, whether such obstructing cause implicates the bowel above or below the lower end of the descending colon.

a. When the obstruction is situated *below the descending colon*, exploration of the rectum will usually determine to what cause it is more immediately referable. Thus it may be owing to strangulation of internal piles; to compression of the rectum by an over-distended bladder; or to an enlarged uterus, engorged and tilted backwards so as to compress and constrict the rectum, and thus to lead to the supposition of the existence of tumour. If the intestinal obstruction be owing to one or the other of these causes, it may readily be relieved by appropriate treatment. It, however, more commonly proceeds from other conditions in this situation, that do not admit of relief except by operative interference; as from constriction, simple or malignant, of the upper portion of the rectum, or of the lower part of the sigmoid flexure of the colon, in consequence of the pressure of a pelvic tumour, or of a stricture from fibrous or cancerous degeneration of this part of the wall of the gut. Under these circumstances, the obstruction may be as complete as in a case of internal strangulation, and the patient will inevitably perish unless relieved by operation. But there is this important difference between the operative interference that may be called for by these obstructions that are situated below the descending colon, and those at a higher point in the intestinal canal—that in the latter case the peritoneum must be opened; whilst, in the former, relief may be given without interfering with the cavity of the peritoneum, by the operation of opening the

descending colon in the left, or the cœcum in the right lumbar region between the reflexions of the peritoneum at the part where the gut is covered by that membrane.

β. When the obstruction is situated *above the descending colon*, it almost always occurs in the small intestine, rarely in the cœcum or transverse colon, and may be dependent on various causes, some of which are removable, others not, and of which preparations may be found in all the large pathological collections in London. Thus, it may be the result of internal strangulation, either occasioned by the small intestine falling into a pocket formed by the meso-colon, or by the constriction of the gut by the passage across it of adventitious bands of fibres. It may be occasioned by intussusception, by the lodgment of biliary or other similar concretions, or by mere spasm of the small intestine, which may be so persistent as to prove fatal. This is, doubtless, a rare occurrence; but cases of the kind are on record, in which the only *post mortem* appearance that could be discovered has been a spasmodically contracted ileum. The great practical difficulty in all these cases of obstruction, above the sigmoid flexure of the colon, is to determine the cause of the obstruction, whether it be of such a nature that it may be removed by operation or not. In some of the cases mentioned there may be special symptoms, which lead to a tolerably correct diagnosis. Thus, in intussusception, bloody and mucous stools and the existence of a long oblong indurated swelling may give a clue; and in children, as the intussusception usually takes place through the ileo-colic valve, the mass of prolapsed intestine may often be felt in the rectum. In malignant or fibrous degeneration of the colon, the chronic nature of the disease, the history of the case, and the appearance of the patient, may indicate the nature of the obstructing cause.

TREATMENT.—*Treatment of Acute Obstruction.*—This must necessarily in a great measure be determined by the diagnosis that is made as to its cause. Before proceeding to the employment of any measures, whether medical or surgical, in these cases, the surgeon should never omit to institute a careful examination of the various abdominal and pelvic apertures for some of the more obscure forms of external hernia; for in cases of supposed internal strangulation, it has occasionally turned out, after death, that the patient had been labouring under a small femoral, obturator, or sciatic hernia. If such a condition be detected, it must of course be relieved by proper operative means. In the event of no such protrusion being detected, and from the general obscurity of the symptoms in these cases rendering an exact diagnosis in the earlier stages almost impossible, it is generally expedient to try the effect of proper medical treatment, which will sometimes, even in apparently hopeless cases, afford relief. The only plan of treatment that appears to me of any value is the continued administration of calomel and opium, with the free application of leeches to the abdomen, followed by fomentations; this will be of considerable service, and in some cases, even the most hopeless and complicated, will afford satisfactory results. In a very complicated case of intestinal obstruction which I attended with Dr. Garrod, this plan was eminently successful. A patient was admitted into the hospital under Dr. Garrod, having symptoms of internal strangulation; he had at the same time double inguinal hernia, and a small umbilical rupture, as well as the remains of a fatty tumour, which had been partially removed from the abdominal wall many years previously. There were peritonitis with tympanitis, stercoraceous vomiting, and much depression of power; but, as there was no strangulation existing about any of the external apertures, and as there was no evidence as to the precise locality of the

internal mischief, it was not thought advisable to have recourse to operation. The patient was accordingly treated with calomel and opium, together with other antiphlogistic means, when, on the tenth day, the obstruction gave way and the bowels acted, the case ultimately doing well.

Inflation of the Obstructed Intestine, by the injection of air into the rectum, has been recommended in cases of intussusception, and has occasionally been practised with success. In two instances I have successfully had recourse to it. One was the case of an infant, a few months old, seized with symptoms of intussusception, whom I attended with Mr. Cousins. The other patient was a young lady about ten years of age, to whom I was called in to consultation with Drs. Murphy, Watson, and West; inflation was performed on the fifth day after the setting in of symptoms of acute intestinal obstruction, apparently dependent on intussusception. The proceeding was followed by perfect success: the child felt "as if a bone broke" in the abdomen, the obstruction was removed, and motions followed in three hours, though all the previous treatment had been unavailing. For the convenient performance of this operation, I have had an apparatus constructed, consisting of a circular double-action bellows, with a long vulcanised India-rubber tube, furnished with a stop-cock and rectum-tubes of different sizes for children and adults. Should this not be at hand, a well-fitted stomach-pump will answer the purpose. When the air is pumped in, it is doubtful whether it passes beyond the ilio-cæcal valve; but this is of little consequence, in children especially, in whom the inflation of the large intestine alone may be quite sufficient, the obstruction often consisting of the slipping of a portion of the small intestine through the ilio-cæcal aperture.

If, however, for any of the various reasons that have already been mentioned, an internal strangulation of some kind be diagnosed, attended by urgent symptoms, and threatening the life of the patient, the great questions to be determined are, whether it is advisable to have recourse to operative interference; and if so, when it is proper to undertake it? The solution of these questions is fraught with difficulty, and must always be a matter of the most anxious consideration to the surgeon. It is not only that he knows that if the patient be left unrelieved, he must necessarily die; but that he is aware that the only means of relief, gastrotomy, is probably nearly as fatal as the disease for which it is undertaken; no case in which this operation has hitherto been performed for internal strangulation having recovered. But the difficulties that present themselves in the solution of the question are much increased by the great obscurity in diagnosing the cause of the obstruction, for in many cases it is absolutely impossible to determine with certainty whether it be dependent on ileus, or arise from mechanical causes; and by the fact that apparently desperate cases occasionally recover without operation. If, however, by attention to any of the points that have been pretty fully adverted to, it can be satisfactorily made out that there is an internal strangulation, and more especially if the intumescence occasioned by it can be felt, it will evidently be the duty of the surgeon to give the patient his only chance by the division of the stricture. With regard to the time at which this should be done, the only general rule that can be laid down is probably the conclusion arrived at by Mr. Phillips; that operation is justifiable when three or four days have passed without any relief from ordinary means, constipation being complete, and vomiting of fecal matters continuing.

Gastrotomy may be performed in the following way. The room being well warmed, the patient should be laid on a high table, his legs being allowed

to hang over the end of it, so as to afford a full view of the abdomen. The bladder having then been emptied, chloroform should be administered to the patient, the surgeon, taking his stand between the legs of the patient, proceeds to make the incision through the abdominal wall. If a tumour can be felt, the seat of obstruction in any way diagnosed, the cut must be made in a longitudinal manner directly over the seat of mischief, if there is evidence to show where the obstruction is situated, it had best be made in the mesial line. It must be carried through the abdominal wall until the peritoneum is reached; this must then be slit up by means of a sharp pointed bistoury guided by the fore-finger of the left hand. The constricted intestine will now probably protrude through the wound, curling over its edges; they must be drawn to one side, and be carefully supported by an assistant, who should press upon them with a soft towel, whilst the surgeon searches for the obstruction. This he does by very carefully and patiently tracing upwards the contracted and empty coils, which must necessarily be below the seat of obstruction, or by following downwards the dilated intestine. If there be a hernial constriction, he may divide the tumour which constitutes the stricture by means of the scalpel, or break it through with the finger; or he may withdraw, from the aperture in the omentum, the mesentery into which it had slipped, the constricted coil of intestine, and if it be a case of volvulus, the gut may be untwisted, as in a case of hernia, and operated. The intestines having been returned, the wound should be closed by the interrupted suture, and the application of some transverse strip of plaster; the patient must then have his knees bent over a pillow, and should be kept principally upon ice and barley-water. Opium must be administered, and the case generally treated on the ordinary principles of an abdominal wound.

Treatment of Chronic Intestinal Obstruction.—This must be conducted upon different principles. Here the great point is to remove the obstruction. With this view the rectum should be explored; and, if it is found to be blocked up by rounded masses of impacted feces, as may sometimes happen, these must be broken up and removed by means of an iron lithotomy scoop, and copious enemata administered. At the same time purgatives may be tried, and a drop or two of croton oil may be given. The constipation, however, arising from other causes, purgatives will induce vomiting, and will always considerably increase the patient's distress, and should not be repeated; the patient should be kept quiet in bed, have a nourishing diet, one leaving little residue is to be preferred, the best consists of beef-tea, eggs, and a small quantity of brandy, and the passage should be opened by enemata, and the introduction of the tube stomach-pump. If these means do not succeed, and if the obstruction is almost always the case in these chronic instances, be seated in or below the sigmoid flexure of the colon, the intestine must be opened at a point above the seat of disease. This may be required for acute as well as for chronic obstruction; for it may be observed that although, in the former, the obstacle is usually situated in the small intestine, yet it is occasionally met with in the colon. But in chronic obstruction it is almost always the large intestine that is affected. The operation required to give exit to the intestinal contents is of two kinds; in one the intestine is opened in the iliac fossa, by cutting through the peritoneum covering it. In the other it is opened in the left loin by cutting between the layers of the mesocolon, and thus opening it where it is uncovered by peritoneum.

The first operation, or *Littre's*, as it has been called, was proposed by the surgeon of that name, in 1710, who advised that in those cases the

Alexander of the colon should be opened from the left iliac region ; but it was not until the year 1776 that any operation of the kind was performed, when Fallore, a surgeon of Rouen, was the first to make an artificial anus on the adult, for relief of retention of feces ; this he did, not according to Littré's method, but by opening the cæcum from the right iliac region. Fine, of Geneva, in 1797, opened the transverse colon from the umbilical region, in a case of retention of feces produced by scirrhus of the upper part of the rectum.

Although these operations serve to fulfil the indication of relieving the retention of the feces, they are all defective in one most important respect ; for, as the peritoneum must in all of them of necessity be wounded, an intense and frequently fatal peritonitis is the inevitable consequence. It was to avoid this serious complication that Callisen, in 1796, proposed opening the colon from behind, in the left lumbar region, where it is not covered by peritoneum. He once attempted this operation on the dead body of a child ; but, failing in his endeavour to reach the intestine without wounding the serous membrane, he seems to have relinquished all further idea of it ; and it was subsequently rejected as impracticable by all writers on surgery who treated of this subject.

Amussat, at the time when he was attending the celebrated Broussais for that scirrhus affection of the rectum of which he ultimately died, was led to reflect on the resources that Surgery offers in similar cases ; and after making some experiments on the dead body, with the view of contrasting the merit of the different operations that have been proposed for the formation of artificial anus in cases of obstruction of the large intestines, he became convinced that the operation proposed by Callisen, if somewhat modified, was not only practicable, but safe. He soon had an opportunity of putting this opinion to the test of experiment in 1839, in a private case, at which he kindly invited me, then a student in Paris, to be present ; and since this time the operation has been performed at least nearly fifty times.

The following is the way in which Amussat's operation may be performed. A transverse incision is to be made two finger-breadths above and parallel to the crista ili of the left side, or rather in the middle of that space which is bounded by the false ribs above and by the crista ili below ; the incision should commence at the external margin of the erector spinæ, and extend outwards for about four inches. The spinous processes of the lumbar vertebrae, the crest of the ilium, and the last false rib, are the principal guides. The superior margin of the crista ili is, however, the safest of these ; and the transverse incision may be said to correspond to the middle third of this part of the ilium. After the skin and the more superficial tissues have been divided, the muscular layers are next to be incised as they present themselves ; if necessary, the external border of the quadratus lumborum may also be cut across. The dissection is then very carefully to be carried through the fine but firm layers of cellulo-adipose tissue, which lie immediately upon the intestine. When the patient is fat, these are loaded with adipose tissue ; when thin, they are semi-transparent and membranous, closely resembling peritoneum, for which, indeed, they may readily be mistaken. These layers immediately overlie the colon, which may usually be felt and seen to bulge through them. After their division, the colon will, in general, readily present itself, and may at once be recognised by its greenish colour and distended appearance (Fig. 402). The operation may then be completed by passing a tenaculum, or a needle armed with a strong waxed thread, into the most projecting part of the gut, and by this means drawing it to the surface of the wound, in order to prevent it from shrinking.

or sinking back when opened. It is now to be punctured with a large trochar or bistoury; and its contents having been evacuated, the sides of the

Fig. 402. Amussat's Operation.

the operation is proportionately difficult on account of the depth of cellular adipose tissue lying in front of the quadratus, which requires to be very carefully dissected through before the gut can be reached. This step of the

Fig. 403. Arrangement of Openings in Amussat's Operation.

operation will be much facilitated by dividing the deeper seated tissues in a crucial manner so as to give the operator more space. When the operation is practised on the dead body, it will be found on dissection that the following are the parts cut through. After the skin and cellular tissue, the latissimus dorsi will be seen divided towards the posterior third of the incision, and the obliquus externus in the anterior two-thirds of it; the obliquus internus and the transversalis, sometimes the quadratus lumborum, the cellulo-adipose tissue which immediately covers the intestine, and finally the colon itself, come into view. The colon is usually found a little in front of a point that lies midway between the anterior and the posterior spines of the ilium. After the more superficial incisions have been made, the surest guide will be the line of condensed fascia which forms the anterior edge of the sheath of the quadratus, as which lies between that muscle and the transversalis. This line may always readily be distinguished by its buff colour from the surrounding muscular structures. Very few vessels or nerves are wounded, as they for the most part run parallel to the line of incision; whereas, if the vertical incision of Callisen were adopted, they would necessarily be cut across.

Amussat's operation may also be called for in cases of cancer of the rectum, when there is perhaps but little or no distension of the gut, the object being to prevent the feces from passing over and irritating the ulcerated surface. In such cases, the operation is very difficult in execution, for, on account of the contracted state of the colon, that intestine recedes behind the quadratus lumborum, and the folds of peritoneum nearly surround or invest it; and it is so covered in by fat and cellular tissue that a very cautious dissection is required to expose it without wounding the peritoneum.

When we compare the different operations that have been proposed for the formation of an artificial anus, it will be found that Callisen's, as modified

opening in the intestine is to be fixed to those of the incision in the skin by four or five points of suture, as to prevent the contents of the bowel from being effused into the cellular tissue of the wound (Fig. 403).

It is of importance to draw the colon well forwards before opening it, in order to prevent its contents from being effused into the loose cellular tissue of the wound where they may set up considerable irritation and retard the union of the parts.

If the patient be very fat

the operation will be much facilitated by dividing the deeper seated tissues in a crucial manner so as to give the operator more space.

When the operation is practised on the dead body, it will be found on dissection that the following are the parts cut through. After

the skin and cellular tissue, the latissimus dorsi will be seen divided towards the posterior third of the incision, and the obliquus externus in the anterior two-thirds of it; the obliquus internus and the transversalis, sometimes the quadratus lumborum, the cellulo-adipose tissue which immediately covers the intestine, and finally the colon itself, come into view. The colon is usually found a little in front of a point that lies midway between the anterior and the posterior spines of the ilium. After the more superficial incisions have been made, the surest guide will be the line of condensed fascia which forms the anterior edge of the sheath of the quadratus, as which lies between that muscle and the transversalis. This line may always readily be distinguished by its buff colour from the surrounding muscular structures. Very few vessels or nerves are wounded, as they for the most part run parallel to the line of incision; whereas, if the vertical incision of Callisen were adopted, they would necessarily be cut across.

Amussat's operation may also be called for in cases of cancer of the rectum, when there is perhaps but little or no distension of the gut, the object being to prevent the feces from passing over and irritating the ulcerated surface. In such cases, the operation is very difficult in execution, for, on account of the contracted state of the colon, that intestine recedes behind the quadratus lumborum, and the folds of peritoneum nearly surround or invest it; and it is so covered in by fat and cellular tissue that a very cautious dissection is required to expose it without wounding the peritoneum.

When we compare the different operations that have been proposed for the formation of an artificial anus, it will be found that Callisen's, as modified

Amussat, is the one to which the preference must be given ; for by it alone the peritoneum is not wounded, and thus the inflammation of that membrane, which is a necessary and so often a fatal consequence of the other operations, is avoided. Beside this advantage, which is of the very greatest importance, Amussat's operation presents several other claims to our notice. As only one side of the colon can be drawn forwards, and not a knuckle of it, as would be the case if the small intestines were operated upon, it is evident that the spur-like process, which has been described by Dupuytren, must exist to a very small extent ; and consequently, if the artificial anus should ever become useless, the natural passage for the fæces having been re-established, it could readily be closed up. If, however, the peritoneum should be accidentally wounded in the attempt to reach the colon from behind, even then this operation would be preferable to that of Littré ; for, the cavity of the abdomen having been opened at its most depending part (in the recumbent position), the fecal matters would have much less tendency to be effused into it, than if it were opened in front. In respect of not wounding the peritoneum, this operation closely resembles that of puncturing the bladder above the pubes, and below the reflection of that membrane. There is, however, one important difference between the two operations, which may influence the result ; in the one case, as the patient lies upon his back, the urine has a tendency to stagnate in the wound, being obliged, in order to escape, to mount against its own gravity ; whilst, in the other case, the fecal matters find a ready exit from a wound situated in a depending part.

Cæsar Hawkins, in a paper published in the 25th volume of the *Medico-Chirurgical Transactions*, has collected and analysed 44 cases, in which an artificial anus has been formed by opening the intestine ; in 17 of these the artificial anus was made through the peritoneum, and in 27 behind that membrane ; but for various reasons, which are stated at length in the paper, Hawkins excludes 5 of the cases of peritoneal section, leaving only 12 to compare with 26 cases of operation behind this membrane. Of the former, he finds that 7 died and 5 recovered ; the recoveries amounting, therefore to only forty-one per cent. in the cases of this category ; whilst of the 26 cases where the peritoneum was uninjured, 10 died and 16 recovered ; the proportion of recoveries in the cases of this category amounting to sixty-one per cent. Though the large intestine was opened in all these cases, the operation was performed on the *right* side in 10 instances ; in 4 cases the right colon and cæcum were opened through the peritoneum, and of these all died ; whilst of the remaining 6, in which the right colon was opened behind the peritoneum, 4 recovered. The preference, therefore, as Hawkins observes, on the right side, is certainly due to the lumbar operation. It is remarkable, however, that in the operation on the *left* colon, the results are somewhat different ; for, of 8 cases in which this intestine was opened through the peritoneum, 5 recovered and 3 died ; whilst of 20 cases in which the lumbar operation was performed, 11 recovered and 9 died. Mr. Hawkins observes, that the inequalities of the numbers appear, however, to leave the question as to the mode of operating on the descending colon still undecided ; and that an operator is justified in selecting whichever situation he thinks best for the formation of an artificial anus on the left side of the body ; still, for the reasons that have already been given, I should very decidedly prefer Amussat's to Littré's operation. In those cases in which death has resulted from Amussat's operation, peritonitis does not appear to have exercised any material influence ; and the fatal result seems rather to have depended on the influence of previous disease on the constitution of the

patient, or on changes taking place in the diseased bowel, than on the operation itself, which appears occasionally to have been uselessly done at the extremity. We should, therefore, have less hesitation in performing the extraperitoneal operation in an early stage of those cases in which it is called for, than we should if the section itself were attended with any serious risk to the patient's life.

CHAPTER LXIV.

TAPPING THE ABDOMEN.—TUMOURS OF THE GROIN

TAPPING THE ABDOMEN.

THE abdomen often requires *Tapping*, either for ascites or of encysted dropsy. This operation, which is perhaps the simplest in surgery, may be performed as follows. The bladder having been emptied, the patient is seated at the edge of the bed or of a large chair, or if very weak lies on the side, under a broad flannel roller, split at each end to within six inches of the ends, passed round the body in such a way that the untorn part covers the front of the abdomen, whilst the ends, which are crossed behind, are drawn up by an assistant on each side, who must draw tightly upon them as the water flows. The surgeon then, seating himself before the patient, makes a small incision with a scalpel into the mesial line about two inches below the umbilicus, and through the opening thus made, he thrusts the trochar; as the fluid escapes, the patient often becomes faint, but this may commonly be guarded against by continuing to draw upon the bandage so as to keep up good pressure on the abdomen. After all the fluid has escaped, the aperture must be closed with a strip or two of plaster supported by a pad and bandage.

The incision through which the trochar is thrust need not enter the peritoneum, though if it do it matters little. The trochar itself must be of full size with a well-fitting cannula. Sometimes it is convenient to have one fitted with a stop-cock, to the end of which a vulcanised India rubber tube may be adapted, by which the fluid is carried quietly and without splashing into the pail destined to receive it. Should the particular character of the accumulation of fluid in encysted dropsy not admit of its withdrawal by an aperture below the umbilicus, the abdomen may be tapped in any other convenient situation, except in the course of the epigastric vessels.

TUMOURS OF THE GROIN.

Tumours of various kinds may develope primarily in the groin, or descend into it from the abdomen. They are of the following kinds—1. Enlargement of the Lymphatic Glands. 2. Abscess in or around those glands. 3. Abscess descending into the groin from the abdomen—Psoas, Iliac, Perinephritic, &c. 4. Varix of the Saphena Vein at its entrance into the femoral. 5. Aneurisms of all kinds. 6. Osteo-Aneurisms. 7. Cystic Tumours, bursal, and developing in the muscular structures. 8. Solid Tumours, as fatty, fibro-cellular, fibro-plastic, and fibroid. 9. Malignant Tumours, primarily developing in the soft structures in this region, extending into it from the bones, or secondarily from contamination of the glands. 10. Hernia of different kinds—inguinal, femoral, and oblique.

DIAGNOSIS.—In effecting the diagnosis of these various tumours, we must

first distinguish the pulsating from those that do not pulsate. The *Pulsating* must either be aneurism, osteo-aneurism, and cancers or abscesses with communicated pulsation. The diagnosis of these different forms of disease has already been so fully given at pages 589 and 734, that I need not enter upon it here.

The *Non Pulsating Tumours* are to be divided into two great classes, viz., the *Reducible* and the *Irreducible*.

The *Reducible Tumours* of the groin are either hernia, varix of the saphena vein, or abdominal abscess, presenting under Poupart's ligament. The diagnosis of these diseased conditions is given at p. 1013. These have all an impulse communicated to them in coughing.

The *Irreducible Tumours* of the groin have further to be divided into those that contain *Fluid* and those that are *Solid*.

The irreducible tumours containing *Fluid* are either abscess in or around the lymphatic glands, or cystic growths of various kinds. The diagnosis here is easy: the irregular hardened outline of glandular abscess, its rapid development, and softening from a previously indurated state, will distinguish it from the tense, clearly defined outline, smooth and elastic feel of the slowly developing and very chronic cystic growth. In irreducible hernia the impulse on coughing, and the peculiar signs characteristic of that disease, will prevent the possibility of error in diagnosis.

The *Solid* tumours in the groin may either be simple or malignant. The history of the case, the feel of the tumour, the rapidity of its progress, the extent of contamination of neighbouring parts, and the other signs that serve as diagnostic differences between simple and malignant growths, will enable the surgeon to effect the diagnosis with sufficient accuracy.

The *TREATMENT* of many of these tumours, such as abscess of various kinds, aneurism, varix, and hernia, has already been so fully considered in the various chapters devoted to these diseases, that I need not enter upon it here. But the question of operating for the removal of *cystic and solid tumours* of the groin, is one that presents several special points for consideration. These are, the relations of the morbid mass to the femoral vein, to the femoral artery, and to the abdominal cavity. If the tumour lie upon or compresses the femoral vein, oedema of the foot and leg will be the result; and, should the compression have been prolonged and very chronic, this oedema may assume a semi-solid character, so as to occasion a condition of the limb closely resembling elephantiasis. Although an intimate relation such as this between the tumour and vein would obviously inculcate the necessity for extreme caution, it need not necessarily preclude the idea of operating for the removal of the tumour, which may possibly be altogether above and unattached to the sheath of the vessels. I once successfully removed a tumour of many years standing of a nœvoid and lipomatous character, in which the limb was in a state of spurious elephantiasis from compression of the femoral vein, but in which the vessel was not involved in the growth. If the femoral artery be compressed to such an extent as to interfere with the circulation through the lower part of the limb, it will most probably be found that the tumour dips under or surrounds the vessel so as to render removal impracticable. The mere overlying of the artery by a freely moveable mass, without any compression of the vessel, need not preclude operation. The growth figured p. 822, was of this kind. The connection of the tumour with the abdominal or pelvic cavities under Poupart's ligament, or through the obturator foramen, must be carefully examined. Should this exist, or even be strongly suspected, operation is necessarily not admissible.

CHAPTER

DISEASES OF THE LARGE IN

CONGENITAL MALE

Congenital Malformations of the anus—unfrequent occurrence, and are of considerable importance, as they must necessarily be the cause of asphyxia. They may exist in various degrees, which may be arranged under the following heads.

NARROWING AND PARTIAL CLOSURE OF THE ANUS.—The anus is pervious, but not sufficiently so to allow of the stool being expelled, the contraction usually merely forcing it into the rectum. In some cases the obstruction appears to depend upon a partial closure of the orifice, in others upon an imperfect septum.

Treatment.—This consists in notching the perineum with a pointed bistoury, and then introducing a bougie of the proper size, to which it must be kept.

COMPLETE CLOSURE OF ANUS.—The anus is closed by a membranous septum stretching across it, in the middle line, and a slight depression, through which the stool may be seen, and on which an impulse can be felt. This is the most common form of malformation that is met with.

Treatment.—In this variety an incision is made along the middle line, and this again causes the meconium to freely escape. The four corners of the septum are removed, and the aperture kept open by the use of a bougie.

OCCLUSION OF RECTUM ABOVE THE ANUS.—The anus may remain open; but, at a distance from its aperture, the rectum will be found closed by a membranous septum stretching across it. This is a variety of malformation, as in it the infant will be born with obstruction, and yet, on examination, the anus will be found formed, and thus the surgeon may be misled. He will, however, detect it by introducing his finger into the anus. In several cases of this kind, to me, I have opened the septum by puncturing it with a needle, after the lapse of a few days, dilated the rectum with a bistoury, the cases ultimately doing well.

COMPLETE ABSENCE OF ANUS.—The anus is blocked up by a dense mass of fibro-cellular tissue, an inch in thickness, above which the rectum is found.

Treatment.—An incision about an inch long is made, from the point of the coccyx forward, down until the gut is reached; this may be done, and the meconium allowed to escape. If the cut is made, a plug of lint merely interposed between the rectum and degenerate into a fistulous opening, the stool will escape with difficulty; and, as this track

case, the probability is that the irritation set up along it by the intestinal matters will ultimately prove fatal to the child. Indeed, it commonly happens in these cases that death results in a few days, from irritation occasioned by the absorption of the excreted fluids. In order to obviate this source of danger, Amussat thought of bringing down the mucous membrane of the bowel to the anal orifice, and fixing it there by sutures, so as to afford the meconium a mucous canal to pass through, and thus to prevent the diffuse inflammation which is apt to take place in the cellular tissue of the pelvis, by the contact and absorption of the effused matters. In many cases it is by no means easy to do this, but it should always be attempted, as I believe the whole safety of the child depends upon this being carried out. For some considerable time after the operation, the aperture should be kept dilated by means of bougies; a gum elastic or pewter tube, through which the feces are allowed to escape, may be fixed in the part.

CLOSURE OF ANUS WITH ABSENCE OF RECTUM.—The anus may be closed and the whole of the rectum absent; the intestine (colon) terminating in an expanded pouch, situated high up at the brim of the pelvis. A case of this kind differs from the last only in the extent of the occlusion, and cannot indeed be distinguished from it until the surgeon has made an incision in the wall of the anus, and has failed to reach the gut at the usual distance from the surface.

Treatment.—In these cases three courses present themselves to the surgeon.

1. The colon may be opened in the left iliac region; 2. It may be reached in the left lumbar region; and, 3. An opening may be made into it through the perineum.

1. *Iliac Incision.*—The only *advantages* that the iliac incision, or Littre's operation presents, are, that it is an operation easy of performance; and that, whether the surgeon reach the colon or not, he is certain to hit upon some part of the intestinal tube which may be drawn forwards and opened.

The *objections* to this operation are, the inconvenient situation of the artificial anus; the great danger that must necessarily result from wounding the peritoneum; the chance of not finding the sigmoid flexure; and, as has often happened, of being obliged to open that portion of the small intestine which first presents itself.

The *mortality* after this operation is very great. Amussat states that, of twenty-one children thus operated on, only four ultimately recovered; and it is worthy of remark, that all the successful cases occurred in the town of *Genoa*.

2. *Lumbar Incision.*—The lumbar incision, or Amussat's operation, has now been several times successfully practised on imperforate children.

The *advantages* of this operation consist not only in the artificial anus being situated at a more convenient spot than in Littre's operation, but more especially in the possibility of opening the colon in this situation without wounding the peritoneum.

The *objections* to this operation, as applied to imperforate children, lie in the frequent coexistence of malformation or malposition of the colon with absence of the rectum, and in the impossibility in many cases of determining, before proceeding to operate, whether the anus is only occluded by a membranous septum, or whether the rectum is absent as well. If it could be ascertained beforehand that, though the rectum be absent, the descending colon occupies its normal position in the left lumbar region, I think it probable that the lumbar incision would be attended with less danger than any other operation that could be practised; but in the absence of this

knowledge, it would scarcely appear to be as the colon might not be found, and the a dense membranous septum.

3. *Perineal Incision.*—The perineal incision is the natural situation of the anus, and of be successful in all those cases in which the an being present. It is in those cases only in of the rectum that this operation is difficu in its results. The dissection requires to siderable depth along the mesial line; the sacrum and coccyx for his guide, and, bea bladder and large vessels in the neighbe search of the gut, which may be found at surface. Danger of wounding the bladde may be materially lessened by emptying pubes before commencing the operation. which I have operated, it was necessary t one and a half or two inches before the account of the narrowness of the wound a relations of the parts, is not an easy matter. proceeding to operate, that the rectum is al for the bowel in the lumbar region. But, ascertaining, before making his incision, w three inches from the surface, he must ob obtain the necessary information; and if o depth as to pass beyond the levator ani in this situation, a great portion of the immed have been incurred, and few would think operation unfinished, and expose the child the colon in the lumbar region. Yet, if h venture, and have not encountered the bow open the intestine through the abdominal fate. In this alternative, Amussat's operatio actually been done, and with success. I sa Mr. Bryant, a young gentleman, eight years c on in Mexico for congenital absence of the had first been made in the perineum, but, colon was opened in the left lumbar regio well nourished, had no great trouble with covered with a truss pad, and only suffer prolapse of the mucous membrane. Ther action in the muscles about the orifice, by

There is one point in connection with th of much importance especially to attend, n result of the operation, but as regards the I mean the bringing down of the mucous it to the lips of the external wound. Unles between the termination of the gut and the degenerate into a fistulous canal; which, lik to contract, and will be a source of endle and to the patient. If the mucous mem fixed to the opening in the integument, the removed, and the patient will be saved al the passage of the meconium over a variou

This, however, can only be done when the intestine terminates at a short distance from the surface. If the perineal incision be two or three inches in depth, there will be little probability of the surgeon being able to bring the intestine down to such an extent. In the case that I have related I attempted to do so, but found that the gut was too firmly fixed to be moved by any traction that it would have been safe to have employed.

ABSENCE OF ANUS: OPENING OF RECTUM INTO OTHER CANALS.—The anal orifice may be absent, and the gut may open into one of the neighbouring mucous canals, as the vagina, the urethra, or the bladder. In such anomalous cases there is usually, I believe, but little to be done, except to restore the anal orifice if possible; but, if this be impracticable, to make a lumbar orifice, and then to take the chance of the other preternatural communication closing. This it will sometimes do; and cases have occurred in which, although the whole of the meconium with flatus had escaped *per urethram*, yet, on opening the rectum, the abnormal communication seemed gradually to close, the feces being directed into their proper channel. In a case in which I was once consulted, there was imperforate anus and rectum, and the bowel protruded as a red, fleshy tube, about four inches in length; from the end of which, in the anterior abdominal wall, just below the umbilicus, and immediately above an extroverted bladder, the meconium escaped. In such a complicated malformation, Surgery could evidently do nothing.

STRICTURE—SIMPLE AND MALIGNANT.

Stricture may occur in any part of the large intestine, but with very varying degrees of frequency in different parts of that gut. Excessively rarely met with in the transverse, of unfrequent occurrence in the descending colon, it becomes more common in the sigmoid flexure, and very frequently occurs at about the junction of this portion of the colon with the rectum. In the rectum itself it is most commonly found either at the upper part, from four to six inches above the anus, or else a little above that aperture.

It is of two kinds; the Simple, consisting of mere thickening of the bowel, with fibrous degeneration of its coats and contraction of its canal; and the Malignant, dependent on cancerous degeneration of, or formations in the bowel.

SIMPLE OR FIBROUS STRICTURE, though occasionally occurring in the transverse or descending colon, is most frequently met with at the junction of the sigmoid flexure and the rectum, or at the upper part of this gut, from four to six inches from the anus. Stricture of the large intestine commonly occurs in elderly people, and with special frequency in women. Not unfrequently a very tight annular stricture is found in otherwise healthy subjects, chiefly in young women, at the lower part of the rectum, about an inch and a half from the anal orifice; appearing almost as if it were the remains of a septum, or a thickened annular fold of the mucous membrane in this situation.

Symptoms.—The symptoms of stricture of the rectum consist at first of some difficulty in defecation, the patient being obliged to strain at stool. The feces will also appear to be flattened or narrowed, and in many cases, more especially as the stricture advances, are passed in the form of small scybala, with occasionally a kind of spurious diarrhoea, consisting of the passage of the more fluid intestinal contents, whilst the solid matters are left behind. At the same time there is very commonly pain in defecation, and the occasional passage of some mucus or blood; and dyspeptic symptoms, with flatulent distension of the abdomen, are apt to come on. If the stricture be within four or five inches of the anus, it may be reached with the

finger, and its precise situation and diameter ascertained. If above the point, it must be examined by the introduction of a well greased bougie, attention being paid to the curve which the rectum makes from side to side as well as from before backwards. In introducing a bougie in order to ascertain the presence of a stricture above the upper end of the rectum, but little information can be gained in many cases, as the point of the instrument is apt to hitch in folds of the mucous membrane, or opposite the peritoneum of the sacrum; and thus, its onward passage being prevented, the appearance of constriction may present itself, which in reality does not occur, and unless care be taken the mucous membrane may actually be lacerated, and the instrument forced through it into the peritoneal cavity. In other cases, the bougie will appear to pass, when in reality its point, meeting with an obstruction, curves downwards into the rectum.

The *Progress* and termination of a simple stricture vary in different cases. In some the contraction of the stricture may go on increasing, until at last complete occlusion takes place, with retention of feces and all the symptoms of obstructed bowels. This condition usually comes on slowly, and, after the obstruction is complete, life may continue for several weeks, but in some instances the obstruction appears to take place rather suddenly, and with all the symptoms of acute intestinal strangulation, death occurring in a few days. Abscess occasionally forms in the neighbourhood of the stricture; and, passing down into the pelvis, may burst either into the ischio-rectal space, or into the vagina, or may present upon the nates. The discharge of pus from this source, as well as from the mucous membrane lining the stricture, which falls into an ulcerated state, may induce extreme emaciation and hectic, to which the impairment of nutrition consequent upon the disturbance of digestion adds materially. In some cases peritonitis will at last ensue, either in consequence of ulcer or abscess communicating with the serous cavity, or else from the extension of the irritation outwards.

Treatment—The treatment of simple stricture of the rectum must be conducted on the principle of dilating the canal at its constricted point. If this be within reach of the finger, the dilatation can be readily carried out. If it be above the upper part of the rectum, and the stricture be tight it is extremely difficult to introduce the proper instruments with certainty. When the stricture is low down, so that the end of the finger can be introduced into it, it may readily be dilated by introducing a rectum bougie every second day, and gradually increasing the size of the instrument. If the stricture yield but slowly, and be very tight and undurated, I have found it a convenient plan to introduce a sheathed probe-pointed instrument into it and to notch it towards its posterior aspect, where this may be done without danger to the peritoneum. A tent of compressed sponge should then be introduced, and left in for twelve hours. On its withdrawal, bougie may more readily be passed; or the dilatation may be carried on by means of tents of compressed sponge. When the stricture is above the reach of the finger, a good deal of management will be required to make the bougie enter it. This is best done by laying the patient on his left side, and using a moderate-sized wax or elastic bougie, which must be passed without the employment of any force. When once the surgeon has introduced one, others can readily be made to follow in the same track. The great danger in introducing a bougie high up, is to mistake the obstruction offered by a point coming into contact with one of the valvular folds of mucous membrane that occur in this situation, for that of the stricture, and, by pushing on the instrument, to perforate it—an accident that would probably

crasion fatal peritonitis. During the introduction of bougies, the bowels must be kept regular by means of lenitive electuary, and the occasional use of emollient enemata. If much pain or irritation should be occasioned by their presence, opium should be administered internally or in the form of suppositories. Though a simple stricture of the rectum may be much relieved by the use of bougies, it is seldom, I think, cured by this means; there being a great tendency in it to contract so soon as the treatment is discontinued.

If complete obstruction occur, an endeavour should be made to relieve the patient by the use of enemata of gruel and linseed-oil, and the strength should be supported by a diet that is nourishing, at the same time that it leaves little or no solid residue; the bowels may eventually act after a considerable lapse of time, the stricture apparently giving way. In a case which I attended with Mr. Powell, and to which reference has already been made, the stricture gave way after obstruction had lasted for about five weeks, some hardened feces with bloody mucus being discharged, which were speedily followed by abundant feculent motions. Should the obstruction, however, continue, and the patient consequently be in imminent danger of death from this cause, the intestine should be opened, if possible, by Amussat's operation, performed in the way already described (p. 1029). This may require to be done either on the right or the left side, according to the seat of stricture. In the majority of instances, this will be situated below the descending colon, so that relief may be given by opening this intestine in the left loin; but if it be impossible or even very difficult to determine the precise seat of the obstruction, the operation may as readily be performed in the right lumbar region. In those rare cases in which the stricture is seated in the transverse colon, there would probably be considerable distension of the right loin, without any corresponding enlargement of the left; under these circumstances, the proper plan would be to open the cœcum.

CANCER AND MALIGNANT STRICTURE.—Cancer of the rectum usually occurs in the form of degeneration or infiltration of the substance of the wall of the gut, giving rise to considerable induration and contraction of the bowel. In other cases, a flat cauliflower growth springs from the inner surface of the intestine, being hard, nodulated, and presenting all the ordinary characters of scirrhus, or fibro-plastic; sometimes it is somewhat pedunculated, so as to resemble a hemorrhoidal protrusion. Lastly, a scirrhus tumour may form in the cellular tissue external to the rectum, and at last press upon and implicate the gut.

Most usually cancerous disease is seated from three to five inches above the anus, and may implicate a considerable portion of the bowel, extending upwards rather than downwards, and giving rise to considerable induration and contraction, with complete occlusion of the interior of the gut.

Symptoms.—The symptoms of cancer of the rectum are pain and weight in the gut, with a sensation as if the bowels had not been completely relieved, together with the discharge of mucus, blood, or pus, and some flattening of the feces. On exploring the parts with the finger, the lower portion of the rectum will usually be found considerably expanded, whilst the tip of the finger will come into contact with the contracted, hardened, and rugged scirrhus mass. The patient experiences most suffering during defecation, in consequence of the passage of feces over the raw and ulcerated surface. This pain is not confined merely to the diseased part, where the sensation is of a hot and burning character, but usually radiates round the loins and down the thighs, and is so severe, that the patient looks forward

to each action of the bowels with the greatest pain, and it as long as possible. The whole nervous system is continually recurring suffering; the coagulable spirits are depressed; sleep and digestive condition is indeed truly miserable, between the times when the bowels act, on the one hand, and when they do not, on the other; and in many instances the patient dies together with the constitutional cachexy, and the system with the cancerous matter. The pain is much increased by the formation of fistulae, either of the bowel, and communications between the bowel, as the vagina, bladder, or urethra, with the rectum, in other instances, though more rarely, death occurs in the case of simple stricture.

Treatment.—The treatment must necessarily be palliative, opium being required after each action of the bowels to relieve distress. Little good can be expected from any other remedy, only irritates the disease, and would tend to the application of caustics, such as potassa fusa, is of no advantage, as only a superficial slough could be produced, at very serious risk to the patient, and it is not to be anticipated. Amussat has proposed to crush and break down the tumour with the finger and forceps; but from such a procedure much is to be anticipated. The recommendation of excision by Lafranco and other French surgeons, is not to be considered good surgery; as it is impossible to extirpate the tumour without either laying open the peritoneal cavity, or the risk of profuse hemorrhage, which could scarcely be avoided, fail in affording the requisite relief, and the patient dies of constitutional irritation during defecation. In several instances much relief of suffering has been effected by an artificial anus in the left lumbar region, but rather in the view of saving life, but rather in the view of lessening suffering by preventing the exertion required to attend the passage of the feculent matter or gas. In several instances much relief of suffering has been effected by this procedure.

CANCER OF THE ANUS.—This is not a very common disease, it usually occurs in consequence of chronic inflammation, and involving the margin of the anal opening. In the early stage, it is usually in the form of epithelioma, just as it does at other mucous surfaces. If detected in the early stage, it might admit of cure, in a more advanced period of the disease, it is not to be removed with any prospect of success, in such cases the only remedy is removing the whole of the structures implicated.

FIBRO-PLASTIC TUMOUR of the rectum, is a very common disease, large and somewhat pale tuberoso masses, which may protrude through the anus, or even protruding through the anus, and is characterised by local symptoms as characterise cancer of the rectum, less intense. In such cases as these the tumour, be removed by double whipcord, by the means of this instrument, I have removed tumours of this kind nearly as large as the largest, but the patient will get relief.

POLYPI sometimes form in the rectum, constituting large pendulous tumours of a fibro-mucous character; they may most conveniently and safely be removed by the application of a ligature to their neck.

RECTAL FISTULÆ.

Fistulous openings occasionally occur between the rectum and the bladder in men; or between this gut and the vagina in women.

RECTO-VESICAL FISTULÆ are not of common occurrence, and usually result either from organic disease of a cancerous character, establishing a communication between the rectum and the bladder; or from a wound of the gut during the operation of lithotomy. In these cases the urine escapes *per anum* in greater or less quantity, occasioning constant irritation or excoriation, with a sort of liquid diarrhoea; and the wet state in which the patient is kept by the dribbling of urine gives rise to an offensive ammoniacal odour about him. If the communication between the rectum and bladder be a free one, feculent matter and flatus get admission into the urinary organ, and escape from time to time by the urethra; perhaps even more abundantly than the urine does *per anum*. This is especially the case when the fistula is carcinomatous; and it is remarkable how little irritation is often set up by this admixture of feces with urine in the bladder. The fistulous aperture in the rectum can always readily be detected by passing the finger into the gut, or examining its interior with the speculum ani.

Treatment—If the disease be cancerous, nothing can be done in the way of treatment beyond keeping the parts clean; but if it be traumatic in its origin, of small size, and more especially if it be recent, its closure may not unfrequently be accomplished by touching it with the nitrate of silver, or a red-hot wire through a speculum ani. In these cases, the platinum loop made red-hot by the galvanic current, according to Marshall's plan, might advantageously be employed. If, however, the fistula be of old standing, and the aperture large, cauterisation will probably not succeed; and then perhaps the only mode of treatment that can be adopted will be to introduce a grooved staff into the urethra, and cut through the sphincter upon this, thus laying the parts into one, and converting the anal into a perineal fistula. By keeping the catheter in the bladder, and emptying this, granulations will be allowed to spring up, and deep union be accomplished.

ENTERO-VAGINAL FISTULA.—It has happened that a communication has been set up between the small intestine and the vagina, an artificial anus in fact forming in this cavity. These cases, however, are very rare, and may indeed be looked upon as incurable; for though some of the French surgeons, as Roux and Casamayor, have endeavoured to establish, by a deep and difficult dissection, a communication between the small and large intestine, the operation, as might have been expected, has proved fatal.

RECTO-VAGINAL FISTULÆ are usually the result of sloughing of the posterior wall of the vagina, in consequence of some undue pressure exercised upon it during parturition. They are of two kinds; viz., the simple, and those complicated with more or less extensive laceration of the perineum. The size of these fistulous openings, when uncomplicated with rupture of the perineum, varies greatly; in some cases there is merely a small perforation, in others there may be loss of the greater portion of the posterior wall of the vagina. Whatever their size, they are necessarily sources of very great discomfort and annoyance, both physical and mental, to the patient. The recognition of the disease is of course at once made; the escape of the feces and flatus into the vagina being obvious, and digital or ocular examination

through the two-bladed speculum at once detecting the seat and extent of the aperture. As there is just the possibility of the communication existing between the vagina and the small intestine, it may be useful to bear in mind that, in this case, the feculent matter that escapes has been found to be yellowish and less stercoraceous than when the rectum is opened.

The Treatment will vary according as the fistula is simple or complicated with lacerated perineum.

Simple uncomplicated Recto-Vaginal Fistula, if it be small and recent, may occasionally be closed by attention to cleanliness, at the same time that its edges are touched with the nitrate of silver, a hot iron wire, or the platinum loop. If it be very large, the greater part of the posterior wall of the vagina having been destroyed, it will probably be incurable; but even here the patient should not be left to her fate, and some operation should be attempted which may lessen its size, even if it do not completely close it. The kind of fistula which is here most commonly met with usually consists of a circular aperture, that readily admits the point of the finger, as it is situated just above the sphincter ani. The operation for the closure of a recto-vaginal fistula of this kind consists, after emptying the patient's bowels by purgatives and an enema, and the bladder by the catheter, in introducing a duck-billed speculum into the vagina, and freely paring the edges of the aperture. As the fistula is always low down, this is readily done by placing the patient on her back, and tying the hands and feet together, as in lithotomy. The vaginal mucous membrane should be dissected off towards the fistula. The next point is to bring its edges into apposition, in a direction transverse to the axis of the vagina; and in doing this, the recommendation made by Copeland and Brown, of dividing the sphincter ani, should always be acted on, as it is a most important auxiliary to the success of the operative procedures that are required; for, as there is always loss of substance in these fistulae, there is necessarily a tendency to tension on their sides when any attempt is made to draw them together; and it is also of importance that any muscular movement about the parts in the neighbourhood of the fistula should be arrested, as this might otherwise break down union after it had taken place between the edges. The sides of the fistula must then be drawn into apposition by silver sutures introduced by means of the hollow needle. I have generally found that these sutures are most easily introduced if passed *from above downwards*—the mucous membrane being then drawn upon by the needle, which more readily transfixes it than if it is introduced from below upwards, when it is left to push the membrane before it. The wires are then passed across the fistula and out through the vaginal mucous membrane, half an inch beyond the freshened surfaces, care being taken not to include the rectal mucous membrane. They may then be twisted, or brought through a leaden plate and clamped by shot. The success of the procedure depends not only on the proper completion of the steps of the operation, but greatly on the after-treatment. This should consist in the administration of opium, to prevent the bowels from acting for ten or twelve days; indeed, until firm union has taken place between the edges. They may then be moved by means of laxatives and oleaginous enemata carefully given. During the treatment the parts should be disturbed as little as possible, the patient lying on her side with a gum catheter tied in the bladder. The parts should be well syringed twice a day with cold water. The patient must be kept upon a very moderate diet, and the stitches may be left in for eight days, when they must be cut out and carefully removed. Should any point of the fistula not be closed, the application of the nitrate of silver may induce proper union of it.

If, as very commonly happens, the *Recto-Vaginal Fistula* be complicated with *lacerated Perineum*, the operation for that condition, described at p. 412, must be performed, and the edges of the fistula, being deeply pared, brought together at the same time. Sometimes in these cases it happens that the perineum unites, leaving an aperture above this in the recto-vaginal septum: if this aperture be but small, it may be closed by its edges being touched from time to time with the actual cautery; if it be large, so as to allow the introduction of the finger, I believe that it is generally useless to attempt to close this aperture by itself; but the perineum should again be divided, and the whole operation repeated.

ULCER AND FISSURE OF THE ANUS.

This disease, though trivial in point of size and in its pathological relations, is of great practical importance, on account of the excessive local pain and great constitutional irritation to which a patient labouring under it is often subject. Ulcer and fissure commonly exist together in this situation, though it by no means unfrequently happens that the two conditions occur separately. The ulcer is usually of small size, seldom larger than a silver threepence, of a circular or a longitudinal shape, situated between the folds of the mucous membrane in the upper part of the anus, or rather the lower part of the rectum, just above the ring or ledge formed by the sphincter, and is usually met with towards the posterior part of the gut on one side of, or opposite to, the point of the coccyx. Occasionally more than one ulcer exists in this situation. If a fissure accompany the ulcer, it commonly leads from this across the face of the sphincter to the verge of the anus; but in many cases one or two fissures, sometimes even three or four, exist without any ulcer. The fissures are usually slightly indurated and cord like, extending merely through the mucous membrane, scarcely, if at all, implicating the deeper structures; and not unfrequently their external termination is concealed by a small red pile or flap of integument.

The existence of the ulcer may usually be determined by exploring the rectum with the finger, which, if practised in these examinations, will detect a small, soft, and velvety patch at the diseased spot; on touching thus the patient will usually complain of acute and burning pain. In some cases the

Fig 404.—Anal Dilator

Fig 405.—Speculum Ani.

ulcer may be brought into view by examining the rectum with the speculum ani, as here delineated (figs. 404 and 405). The fissure may always readily

be detected by everting the mucous membrane of the anus, and by turning up or turning aside the pile that covers the lower end of the crack. In this examination, it will usually be found that the sphincter is in a more or less spasmodically contracted state, admitting the finger and instrument with difficulty.

Symptoms.—The symptoms of ulcer or fissure in the anus are very characteristic. The patient complains of pain, usually of a severe burning character, on the passage of a motion, especially if a hard one; occasionally it occurs at the time of defecation, but more frequently commences a few minutes afterwards, and continues from half an hour to several hours. The pain is very severe, and peculiarly wearing and burning; it is generally most felt opposite the sacro-iliac articulation, but not unfrequently radiates across the pelvis or down the thighs. In many cases it produces a good deal of continued irritation about the genito-urinary organs, giving rise to synchysis or spasmodic stricture; a frequent desire to urinate, tenderness about the prostate, and seminal emissions. The pain is sometimes so severe that the patient avoids defecation as long as possible, and even abstains from it with the view of lessening the necessity for the frequency of this act. Very commonly in women, the pains produced by the rectal disease are attended or occasioned by uterine irritation; and in both sexes they may, after a time, become continuous, and be attended by a good deal of constant uneasiness sitting, so that the patient is obliged to raise the affected hip. There is often a discharge of a streak of pus or blood on the faeces, and commonly a good deal of mucous exudation, with some tenesmus on defecation, but in many instances these symptoms are altogether absent, and the patient never feels any local inconvenience except from the pain.

The constitutional irritation is often very great, the nervous system generally sympathising with the local mischief. The countenance is pale, anxious, careworn, and the patient's expression is indicative of constant suffering.

Causes.—This affection most commonly occurs in women, especially in those of an hysterical temperament and weakly constitution. When met with in men, it is most frequently seen in enfeebled, cachectic, and debilitated subjects, and appears to be the result of a broken state of health. In persons who have been the subjects of the chronic dysentery of hot climates, I have several times noticed a peculiar form of patchy ulceration within the rectum, of an extremely irritable and very intractable character. I have in several instances observed it in women to be of a syphilitic nature, and in such cases it is situated generally towards the side or the anterior part of the anus.

Treatment.—The treatment of fissure or ulcer of the anus, when the disease is met with in the early stages, may sometimes be successfully conducted by the application of nitrate of silver to the fissure, and the use of an astringent suppository. I have found a very excellent and useful suppository in this and many other painful affections of the anus to be composed of 2 grains of extract of belladonna, 2 grains of the acetate of lead, and 1 of tannin, made up to a proper consistence with a little suet. This may be introduced into the rectum every night and allowed to dissolve there, the bowels should at the same time be kept gently open with castor oil, or the lenitive electuary. In those cases in which the disease has been of long standing these means will not suffice, and it becomes necessary to have recourse to a very simple operation to effect a cure. This consists in turning the affected mucous membrane through the ulcer or fissure, with pressure on some of the subjacent fibres of the sphincter muscle, by which the part is set at rest, and cicatrization speedily takes place. The relief after the operation

is usually immediate; indeed, after its performance, a patient who has been suffering severely for months or years, will often get complete and almost instantaneous relief. The merit of introducing this plan of treatment for the cure of ulcer and fissure of the anus into surgical practice is due to Sir B. Brodie. Boyer had previously recommended that the sphincter should be cut completely across, in order that its action might be paralysed; but Sir B. Brodie found that the ulcer could be made to heal as readily by the limited incision above mentioned. The operation is readily done by introducing the left fore-finger into the rectum, guiding along it a probe pointed bastoury, and then cutting downwards and outwards, carrying the knife about the eighth of an inch in depth. The section may either be made through the ulcer and fissure, or on each side of the coccyx. It is doubtless better, when practicable, to cut through the diseased structures, though it is not necessary to do so; and it is always better to make an incision on both sides of the sphincter, so as to be sure that the muscle is set at rest. No dressing is required after this operation; but, if the incision do not readily heal at the end of a fortnight or three weeks, it should be touched from the bottom with the nitrate of silver. The patient's bowels should be well opened before the operation, and a dose of castor-oil may be given on the second or third day after it. During the process of cicatrisation it will often be advantageous to give iron, and to put the patient on a very nourishing diet.

Spasmodic Contraction of the Sphincter Ani is usually associated with fissure or ulcer of the anus; but occasionally it occurs without this complication, and in all cases it may be connected with a neuralgic condition of the part. In hysterical women, this neuralgia and spasm are especially apt to occur; though it is not improbable that in many of the so-called cases of neuralgia of the anus, some positive disease, such as a small ulcer or fissure, may be detected on close examination, as I have had several occasions to verify.

The Treatment of spasm of the sphincter, whether associated with neuralgia or not, consists in the employment of local sedatives, enemata, and laxatives, with, if necessary, the division of a few of the muscular fibres, together with the mucous membrane.

ABSCESS AND FISTULA.

ABSCESS not unfrequently occurs in the vicinity of the rectum and anus. It may either be superficial, being confined to the muco-cutaneous structures, and presenting the ordinary characters of acute subcutaneous abscess; or it may be deeply seated, forming in the ischio-rectal fossa. It is these rectal abscesses that are of most practical importance. They may be of two kinds—*Acute and Chronic*.

Acute Ischio-rectal Abscess.—This forms deeply in the fossa, with throbbing, shooting, and stabbing pains through the anus, rectum, and perineum; on examination, a hard brawny substance may be felt in the cellular tissues by the side of the gut, either by examination from without, or by exploration through the rectum, which speedily softens, and will, unless an outlet be made for it, either burst externally, or into the cavity of the gut, or both ways. This acute form of abscess usually occurs in persons of otherwise strong and healthy constitutions.

Chronic Ischio-rectal Abscess, on the other hand, occurs insidiously in persons of cachectic, broken, or phthisical constitutions. Without much pain or local inconvenience, it forms a collection of pus, which is usually limited to one side of the ischio-rectal fossa, but in other cases acquires con-

siderable magnitude, denuding the gut to a considerable extent, in the almost surrounding the rectum, and then spreading widely on the outside of the hip, presenting all the ordinary characters of a chronic abscess. The mass of purulent collection may form in this as in any other situation in the body, as the result of congestion or of some local irritation. I have seen it follow kicks, blows, or bruises of the lower part of the body, or the consequence of the lowering of the vitality of the mass of cellular and fatty tissue on the ischio-rectal fossa by weakly persons sitting on a cold stone or standing for a long time on the ice or snow. In other cases the abscess appears to originate around the prostate, and an abscess forming in this situation may bud its way down by the side of the rectum. Mr. Keen attributed these abscesses, and the consequent fistulae, to perforations of the mucous membrane of the gut, and although I think he exaggerated the frequency of this mode of production of the abscess, yet there can be no doubt that, in some instances at least, it occurs as the result of perforation of the gut; either by ulceration from within, by the formation of a tumor, or by some foreign body, as a fish-bone, transfixing it, and thus inducing inflammatory action in the cellular tissue outside the rectum.

Treatment.—In the treatment of these abscesses, the principal point to be attended to is to prevent the extensive denudation of the gut. In doing this the abscess must be opened, so soon as the formation of pus can be ascertained to have taken place, by making a free, and, if necessary, a deep incision into the ischio-rectal space by the side of the bowel. Unless this is done, it may either burst into the interior of the gut, or spread away upon the nates, and then give way. The pus that is let out of these abscesses is always extremely offensive, even though not mixed with any feculent matter; the near neighbourhood of the bowel appearing to determine a change in it that renders its smell peculiarly stercoraceous. After the evacuation of the abscess the patient feels easy, and thanks that air is vented, the discharge gradually lessening and the cavity contracting; but it does not close, and a fistula will be left, which continues to exude a thin watery pus, in which feculent matter, perhaps, accumulates from time to time, giving rise to fresh outbreaks and extensions of the disease.

FISTULA IN ANO.—The sinus left by the contraction of the cavity of an ischio-rectal abscess constitutes a *fistula in ano*; an affection that has attracted a good deal of attention from the frequency of its occurrence, and from the difficulty of curing it without having recourse to operation.

Extent.—Some fistulae are very limited, being merely the sinus left in the submucous cellular tissue of the anus after the bursting of a superficial abscess in this situation, extending to a short distance up the gut inside the sphincter. This form of fistula constitutes, however, a kind of spurious variety of the disease; for the true fistula in ano is outside the sphincter in the surrounding cellular tissue, extending always as high as the upper margin of that muscle, and frequently stretching to a considerable distance up the side of the gut. Most frequently the lower and external aperture of the fistula is single, and is situated by the side of the anus in the ischio-rectal fossa, just beyond the sphincter; but not unfrequently the aperture is in the perineum, or posteriorly in the coccygeal region. Occasionally there is a fistulous opening on each side of the gut; or several openings may exist, and then sinuses extend from these outwards to a considerable distance, undermining the integuments about the buttocks, even stretching away towards the trochanters, and opening at a great distance from the bowel. These extensive fistulae and sinuses are frequently connected with structure of the gut; but they may occur without this in old and neglected cases.

Varieties.—Fistula in ano is said to be *Complete* when it communicates by one end with the interior of the rectum, and opens by the other upon the external surface. It is said to be *Incomplete* when it has only one aperture, whether that be external or internal.

Complete Fistula is the most common form. It probably arises in the majority of cases from some source of irritation seated within the bowel, by which the mucous membrane of the rectum has been perforated, and an abscess has formed in the cellular tissue outside the gut. The external opening in this form of fistula is usually from half an inch to an inch from the margin of the anus; though it may be seated at a greater distance than this, as upon the hip. It is commonly small, and has a vascular granulation projecting from or occluding it; and a thin purulent discharge usually drains away from it in small quantities, moistening the surrounding integuments. The internal opening is usually situated just above the sphincter, where the rectum begins to expand. But the fistula does not terminate at this internal aperture; for in the majority of cases it runs up into a kind of *cul-de-sac*, to a considerable distance further. The internal aperture may readily be detected by introducing a blunt curved probe into the fistula; when, by a little management, it may be carried through the inner opening. In some cases, the existence of this may be ascertained by examining the interior of the bowel with a speculum ani, and by injecting water into the external opening.

Incomplete or Blind Fistula may be of two kinds, and commonly arises from constitutional causes. When there is no internal perforation, a mere sinus having been left by the bursting of an abscess, the fistula is termed *blind external*. When there is only an internal aperture, it is called *blind internal*. The blind external fistula is readily recognised by its being found that the probe does not penetrate the interior of the gut. The blind internal is not so readily detected; but in this case it will generally be found that the patient suffers from an occasional and tolerably abundant discharge of pus from the interior of the bowel; that there is a good deal of tenderness, with some brawny induration in the ischio-rectal fossa on one side of the anus; and that the pus may be made to well out in some quantity by pressing upon this part. On passing the finger into the rectum, the ragged internal aperture in the gut through which the pus exudes may readily be felt.

Treatment.—Operative interference is usually necessary. It is true that in some rare instances the fistula may be made to close under the influence of constitutional management, aided, perhaps, by stimulating its interior with the nitrate of silver, or by touching it with a probe dipped in nitric acid. This kind of treatment is, however, only successful in the blind external fistula, several instances of which I have seen recover in this way; but it can never be expected to answer in any other variety of the disease. Occasionally in elderly people a blind internal fistula (or fistule) will be found, which, falling into a very chronic state and discharging but little, is a source of but very trivial discomfort, and will continue for years without giving the patient serious local inconvenience, and in no way disturbing the general health. In such cases, I believe, there is often far less risk in leaving the fistula untouched, than in subjecting the patient at an advanced period of life to the hazards of an operation. When the fistula is complete, the only plan of treatment that offers any chance of success is the division of the sphincter; so that this muscle, which tends to prevent the closure of the anus, may be paralysed, and the fistula, being laid open from the bottom, made to heal by granulation. Various plans have been devised for

the division of the sphincter, and much ingenuity has been expended in attempts to discover simpler and less painful modes of effecting this than the knife, but hitherto without success; and the only plan of treatment that deserves any attention is the division of the sphincter with a curved bistoury.

The operation for fistula in ano should not be performed indiscriminately in all cases and at all periods of the disease. If the fistula be dependent upon stricture of the gut, and more especially if this be of a malignant character, it is evident that no operation can be attended by a chance of success, and none should be attempted. So, also, if the patient be cachectic and broken in health, it is well to improve his constitutional powers before undertaking an operation, lest the wound that results may not readily cicatrise. It is also well to wait until the disease has assumed a somewhat chronic form before proceeding to the division of the sphincter; if this be done early after the bursting of the abscess, or at any time if there be much inflammatory action going on, the wound is apt to assume a somewhat sloughy condition, and to heal with great difficulty. The most important question usually connected with the operation for fistula, is the propriety of performing it in phthisical subjects. It is a well-known fact that fistula in ano is especially apt to occur in consumptive individuals, and it is often a nice point to determine whether an operation should be performed or not in them; how far the drain from the fistula may keep up or even generate the tendency to phthisis, or how far it may be salutary in acting as a counter-irritant, and in preventing the morbid condition of the lung from developing itself. Dr. Theophilus Thompson states that the co-existence of fistula with

Fig. 406 —
Fistula in ano.
See text for details.

phthisis appears to retard the progress of the latter disease, acting as a derivative; and doubtless in some instances this may be so. I have, however, in several cases found considerable advantage result from operating for fistula in the early stages of phthisis, or in suspected cases of that disease, the patient's health having considerably improved after the healing of the fistula. In such cases, it may be of use to put an issue in the arm or side of the chest. But in confirmed, and still less in advanced phthisis, no operation should ever be practised; as the wound will not heal, and the patient must be weakened by the additional discharge.

The operation for complete fistula should be performed in the following way. The bowels having been well cleared out the day before with a dose of castor-oil, and an enema administered on the morning of the operation, the patient should be laid on his left side, with the nates projecting over the edge of the bed; a probe must then be passed through the fistulous track into the rectum, and the surgeon, introducing the forefinger into the gut, feel

Fig. 407 — Operation for Fistula in ano

the end of the instrument; he then passes a short strong-bladed probe-pointed bistoury of about the size and shape of that represented in the annexed figure (406), through the fistula, using the probe as a guide, though in some cases this may conveniently be dispensed with. When he feels the end of the knife projecting into the rectum through the internal aperture of the fistula, he withdraws the probe, hooks his forefinger over it (Fig. 407), and by a sweeping and pressing cut, raising the handle of the instrument at the same time that he pushes down its point, brings both finger and blade to the anal aperture, cutting through the whole thickness of parts between the anus and the fistula, so as to lay the two cavities into one. In performing this operation the surgeon should cut with his left hand if the fistula be upon the left side; and in either case should be careful not to wound his own finger, as such cuts often prove troublesome in healing. If sinuses stretch from the fistula along the nates or hip, he may slit these up with a probe-pointed bistoury, before or after dividing the sphincter. If the fistula be a blind external fistula, it must at the time of the operation be made complete, by scratching with the end of the knife through the thinned structures that intervene between its extremity and the interior of the gut; and the operation must then be completed in the way described. If it be a blind internal fistula, a bent probe should be passed up the anus and through the inner opening of the fistula into the canal. The end of this, which can be felt externally, must be exposed by a puncture made through the integuments with a sharp-pointed bistoury, and the operation then concluded in the ordinary way.

When there is an internal aperture into the gut, this will usually be found just above the sphincter; but the fistula does not terminate here, frequently extending up by the side of the gut for an inch or two. Under these circumstances, what should be done with the *cul-de-sac* above the inner aperture? If it be laid open, an extensive and deep wound will be inflicted, which may implicate some of the hemorrhoidal vessels, and thus give rise to a dangerous amount of bleeding. Hence I think it a safer practice for the surgeon to content himself with the division of the sphincter and all the parts intervening between the inner aperture of the fistula and the verge of the anus; the sinus which is left usually contracting and closing without difficulty when this has been done. In some cases it happens, however, that this *cul-de-sac* is not readily obliterated, but gives rise to a good deal of trouble in consequence of the occasional accumulation of pus in it, and the thickening of its aperture into the bowel giving rise to spasmodic contraction of the sphincter and a kind of rectal stricture. This inconvenience gradually subsides in most cases, by the use of astringent injections or the introduction of a probe armed with nitrate of silver.

The after-treatment should be as simple as possible, consistently with securing closure of the wound by granulation from the bottom. A narrow slip of oiled lint should be introduced between the lips of the wound, and this must be left in for forty-eight hours, during which time the bowels are kept confined by the administration of a grain or two of opium immediately after the operation. On the second day a dose of castor-oil may be administered, which will not only act upon the bowels, but bring away the piece of lint. The wound must then be lightly dressed from the bottom, a poultice applied, and care taken at the daily dressing, by the introduction of a probe, to prevent the bridging over of granulations. After the wound has completely united, a notch will usually be left by the side of the anus, which gives rise to some inconvenience for a time by the occasional involuntary discharge of a little intestinal mucus, and some flatus. This especially happens in those

cases in which the incision has been made anteriorly to the anus into perineum, and where incontinence of feces may, for a time, be left. Should an inconvenient or dangerous amount of hemorrhage occur at the time of the operation, the wound should be plugged with dry lint, and a firm bandage applied by means of a T-bandage. Should profuse bleeding, in consequence of the division of some of the hemorrhoidal vessels, come on a few hours after the operation, all coagula should be cleared away, the gut washed with ice-cold water, and then securely plugged either with a piece of compressed sponge, or with a bougie, surrounded by lint soaked in a solution of perchloride of iron.

HEMORRHOIDS OR PILES.

By *Hemorrhoids* or *Piles*, is meant a morbid condition of the blood-vessels of the anus and lower part of the rectum, especially of the veins of the mucous and subcutaneous cellular tissue, giving rise to more or less intolerance of the part, which may or may not be attended with a discharge of blood. Surgeons are commonly in the habit of classifying piles, according as they bleed or not, into *Open* or *Blind*; or, according as they are situated above or below the verge of the anus, into *Internal* or *External*: the internal being always within the gut, the external habitually protruding out of around the anal aperture. The first may either bleed or not, the latter always blind. To this division into external and internal, B. Cooper added an intermediate variety, the *Intero-External*, which is partly within and partly without the anus. These divisions are of much practical importance as the treatment is very materially modified according as the hemorrhoids are situated above or below the anal verge.

PREDISPOSING CAUSES.—We must look to the peculiar arrangement of veins of the rectum as directly predisposing to the occurrence of piles. The lower part of the rectum and the verge of the anus are composed of a plexus of muscular fibre and a muco-cutaneous surface, with an intervening stratum of dense cellular tissue. In this cellular membrane is situated a dense interlacement or net-work of tortuous veins. The blood, from this plexus of hemorrhoidal veins, finds its way into the general system through distinct channels. By far the greatest portion of it is carried into the inferior mesenteric vein, and thence into the vena porta, through the medium of the superior hemorrhoidal vein, which may be looked upon as the extreme end of the portal system; and a certain quantity passes into the internal iliac vein through branches that accompany the middle hemorrhoidal artery. We may, therefore, look upon the hemorrhoidal plexus as being placed midway between the portal and general venous systems, being the point indeed at which they touch; but as belonging rather to the portal than to the general veins. In these arrangements we see all the elements that would predispose to congestion, and consequent dilatation of the vessels of a part. There is a large and intricate plexus of veins in which, as in all similar networks, there is a tendency for the blood to circulate slowly at times; the natural tendency to stasis of the blood being much increased by the dependent position of the part, and by the anatomical fact that, in consequence of the absence of valves in the superior hemorrhoidal vein and in the vessels into which it pours its contents, the whole pressure of the column of blood in the portal system may be brought to bear upon the hemorrhoidal plexus. The circulation through the portal system is likewise subject to much interference in consequence of hepatic and intestinal obstruction, and in these changes the blood in the hemorrhoidal plexus also participates; and were it not for the provision that exists by which this plexus may free itself to a certain extent

from over-distension by its communication with the internal iliac through the medium of the middle hemorrhoidal vein, piles would be much more frequent than they even now are, as a consequence of obstructed portal circulation. Another great cause of hemorrhoidal enlargement is to be found in the want of support that the veins of this plexus experience on their mucous aspect during defecation. Situated as they are in cellular tissue, between a plane of muscular fibres on one side, and yielding mucous membrane on the other, when distended by the constriction which they undergo during and after the expulsion of the contents of the rectum, they necessarily give way on that side on which they have the least support, being forced down and elongated, together with the mucous membrane under which they ramify, and which has a natural tendency to become slightly everted during the act of defecation. It will be found that all the more immediate or exciting causes of piles act by unduly increasing one or other of those natural tendencies that exist in the system, by favouring the local congestion or determination of blood, at the same time that they produce a lax state of fibre.

Age exercises considerable influence in predisposing to piles. This disease is not unfrequently met with in young men of eighteen or twenty years of age; more especially if they be of a relaxed and phlegmatic temperament with languid circulation, and be obliged to lead a more sedentary life than is natural or proper at that age. After this period, the liability to the disease diminishes until middle age is reached, when the tendency to hemorrhoidal affections is again increased, and becomes more marked than at any former period of life, owing to the more active operation of those causes that tend to impede the return of the portal blood.

Sex appears to exercise more influence on the occurrence of hemorrhoids at particular periods of life, than on the general liability to the disease. It certainly appears to be more frequently met with amongst men at an early age, than in young women; but at a later period of life, so far as my observation goes, the disease occurs with nearly equal frequency in both sexes. The comparative exemption of young women is readily accounted for by the periodic discharges from the uterus preventing the congestions that might otherwise occur in the parts in its vicinity. The greater frequency in females at a later period of life is attributable not only to the tendency induced during pregnancy by the pressure of the gravid uterus, but also, after the cessation of the menses, to the determination that is apt to be set up in certain organs of the female economy, and to the retardation of the portal circulation by the accumulation of fat and other causes; these conditions chiefly occur in women of a sanguine and plethoric habit of body.

A *sedentary life* with indolent habits constitutes, perhaps, the most powerful predisposing cause of the disease; more especially if habitual high living be conjoined with want of proper and sufficient exercise. Indeed, the artificial and luxurious habits of the more opulent classes, by diminishing tone at the same time that they occasion plethora and a tendency to abdominal engorgement, exercise a considerable influence on the occurrence of this disease, which is much more frequent amongst them than in persons in the humbler walks of life.

There are a number of minor conditions which are commonly looked upon as predisposing causes of this disease, though it is extremely difficult to determine the precise share that each has in its occurrence. Amongst these may be mentioned intemperance in food and drink; residence in warm, moist, and relaxing climates; the use of soft and warm beds; or the opposite condition of sitting on a cold stone or damp cushion. Over-excitement of the generative organs will also occasion it.

EXCITING CAUSES.—Amongst the exciting causes may be mentioned irritation of any kind. Thus, in some people hard riding will bring on attack of piles. The *habitual use of drastic purgatives*, more especially aloes, rhubarb, &c., is well known to occasion the disease, though it may be observed that individuals, who make habitual use of these remedies, or labour under some of those obstructions of the abdominal viscera that have already been noticed as conducing to piles. The existence of other diseases about the rectum and anus, such as fistula, ulcer or stricture, by inducing local congestion and irritation, may excite the disease; so also uterine and various diseases of the genito-urinary organs may give rise to the affection.

The most direct exciting cause of piles is certainly a *retardation to the return of the portal blood*. Any impediment to the onward current of blood through the hemorrhoidal or mesenteric veins, the trunk or ramifications of the vena porta, exercises a marked influence on the tendency to congestion of the hemorrhoidal plexus. Habitual constipation; the accumulation of hardened feculent masses in the large intestine; the want of secretion from the mucous surface; obstruction to the proper action of the liver, and consequent congestion of that organ; the pressure of abdominal tumours, or of the gravid uterus, are all active exciting causes, interfere as they do with the proper return of the portal blood. In some cases, the existence of an obstacle to the circulation in the systemic veins may occasion this disease; thus it will arise from the pressure of an aneurismal tumour on some of the larger venous trunks within the chest.

STRUCTURE.—A pile, whether external or internal, consists essentially in the first instance of a varicose condition of a portion of the hemorrhoidal plexus, or rather, of the small veins of the submucous tissue that pour their contents into this; this varicose condition, becoming prominently developed at certain points, gives rise to small knots or tumours. A pile in this state is quite soft and compressible, and can readily be emptied by pressure. When cut into, it will be found to be composed of one or more cells filled with blood, and surrounded by areolar tissue. The appearance of cells is, however, deceptive, and is occasioned by a section of the anastomosed and dilated veins that enter into the composition of the tumour. After the piles have existed for some little time, or after they have once become inflamed, the tissues that enter into their composition undergo modifications that induce corresponding alterations in the character of the tumour. The coats of the veins become thickened; their cellular dilatations are filled with coagulated blood; the investing areolar tissue is hypertrophied or thickened by plasma deposit; and, on being cut into, the pile is seen to be composed of a spongy kind of tissue filled with blood. External piles, when examined after removal, often resemble in structure a mass of hypertrophied cellular tissue infiltrated with plastic matter, in which a number of small vessels of unimportant character ramify, but without any appearance of cells. Internal piles, on the contrary, contain more of the venous, and less of the cellular element. They are also commonly furnished with a small central artery, which is liable to bleed freely, or even dangerously, if the tumour be cut across; hence, provided they are not clogged with coagulated blood, they may readily be removed from the inferior mesenteric artery.

In studying the structure of hemorrhoids, it is of importance to observe that they occur under two different forms: one in which there are distinct tumours, within or external to the anus, and another in which there is merely a varicose condition of the veins of this region, without distinct intumescence.

In those cases in which there is merely a general varicose state of the veins of the submucous cellular tissue of the anus, without any distinct tumour springing above the level of the membrane, it will be found that the smaller branches of the hemorrhoidal plexus, and the small twigs that enter these from the submucous cellular tissue, have undergone varicose dilatation, being apparently greatly increased in number, as well as in size. The mucous membrane is of a deep mulberry or port-wine colour, and becomes everted after each motion. There is usually some mucous secretion about the anus, rendering the part moist : and the patient complains at times of weight and of bearing down, with pains either in the part itself, in the sacro-lumbar region, or in the thighs. The motions, more especially if hard, are streaked with blood, and more or less of this fluid drops in a rapid manner after the passage of the feces. There is seldom much blood lost ; but at times there is an exacerbation of all these symptoms, and the hemorrhage, as will more particularly be mentioned hereafter, may become very abundant. This condition of the mucous membrane may precede, and is frequently found to accompany the true pile, whether external or internal, and may be looked upon as constituting the first stage of this disease. If this state of things be allowed to continue unrelieved, the tendency to congestion increases ; more and more of the mucous membrane becomes everted and protruded after defecation ; the submucous cellular tissue becomes stretched and lax, and the case is apt to become one of prolapsus ani.

EXTERNAL HEMORRHOIDS are those that are situated below the verge of the anus, and that are invested by cutaneous, or, at most, by muco-cutaneous tissue. Before appearing as defined tumours, they usually constitute longitudinal folds that surround the anal aperture, or radiate from it as from a centre. In colour, they vary from that of the natural structures to a pink or purplish hue ; and their tegumentary covering consisting of the thin skin of the part, they resemble folds of this tissue rather than of mucous membrane. Their size varies, according to the state of congestion ; and hence the same tumour may at one time be soft, flaccid, and loose, apparently nothing more than a fold of integument, and at another may become tense, tumid, and ready to burst.

Symptoms.—When of small size and recent formation, external piles do not in general give rise to much distress, merely some local heat, pricking, and itching, with a sense of fulness after defecation ; but when of large size, and inflamed or irritated, they may occasion very acute suffering. There is not only deeply seated, dull, aching and throbbing pain in the pile itself, but this shoots up the side of the rectum, through the perineum, and into the nates, and is much increased when the patient stands or walks. After a few days these symptoms subside ; suppuration either taking place in the pile, or the blood contained in it coagulating. The parts are, however, left in a thickened and indurated state, and do not really resume their former soft and flaccid condition, effusion of plastic matter taking place into the cellular tissue, and the contained blood perhaps coagulating, so that the tumour can no longer be emptied by pressure, assuming the form of a broad, rounded, or indurated mass.

INTERNAL PILES.—When the pile is situated altogether within the verge of the anus it is called internal ; of these there are two principal varieties, the *Longitudinal* and the *Globular*.

The *Longitudinal*, or, as it is sometimes called, the *Fleshy* pile, is generally met with about an inch or two up the rectum. It is spongy, elastic, firm, or tough, of a dark reddish, or dusky brown tint, tapering upwards from a broad base. It seldom bleeds or varies much in size ; between the piles are

found small curtains, valves, or folds of mucous membrane, forming sacs or pouches, with their convexities looking upwards. These sacs are liable to become distended and pressed downwards by the force, especially if the motions be hard and the bowels have been constipated, thus giving rise to a tendency to prolapsus.

When the hemorrhoid assumes a *Globular* form, it constitutes the *internal bleeding pile*. It may be situated on a broad base; or, as not unfrequently happens, its point of attachment to the mucous membrane becoming elongated, it assumes a pedunculated shape, hanging downwards into the end of the rectum. It is of a dark bluish colour, and numerous small vessels of a brighter hue than the body of the pile may be seen ramifying on the mucous membrane investing it. Its surface is at first smooth and shining, and may continue so throughout, being covered with a thin coat of mucus, or prolongation of the lining membrane of the gut. Not unfrequently, however, superficial ulceration takes place, and then it has a granulated or berry-like appearance.

Symptoms—Internal piles are usually attended by a sensation of itching, pricking or smarting about the anus, and a feeling as if there were a foreign body within the gut. After defecation these sensations are increased, and are often accompanied by a bearing-down, as if the bowel were emptied of its contents, that is peculiarly distressing and sickening. It is occasioned by the piles, or the elongated and condensed mucous membrane to which they are attached, being protruded during the expulsion of the feces, and not returning sufficiently quickly, being grasped by the sphincter ani and constricted by it. This feeling of discomfort and bearing-down is much increased, if the patient stand or walk much after having had a stool, or if he have a confined state of the bowels. If this state of things is not properly attended to, the symptoms become increased in severity, the bearing-down sensation amounts to true tenesmus, and the act of defecation becomes so painful that the patient defers it as long as possible, and when it does take place, in consequence of the accumulated stores, and their indurated character, the suffering is much increased. Internally, now usually make their appearance, if they have not existed before. The mucous membrane of the rectum becomes prolapsed, and an increased secretion of thin mucus takes place from the orifice of the gut, soiling the part and soiling the patient's linen. Irritation in the neighbouring organs is frequently set up; occasionally to so great an extent as to become the original complaint, the patient referring his principal pain and distress to these sympathetic disturbances. There is often a dull aching fixed at the lower part of the lumbar spine, and more frequently over the sacrum or the sacro-iliac articulations on either side; this is sometimes severe, perhaps down the thigh, or round the groins; irritability of the testicles may come on, or irritation about the neck of the bladder, or frequent desire to micturate, and increasing the patient's suffering by straining that takes place. The general health now suffers, the patient becomes emaciated, and the countenance often presents a peculiarly anxious and drawn, and care-worn look.

The symptom, however, that first of all and most prominently fixes the patient's attention, is *Hemorrhage*. This varies greatly in quantity, and it may merely consist of a few drops falling after the passage of a motion, or the cylinder of feces may be stained on one side by a streak of blood, or it may amount to several ounces or even pints. When moderate in quantity, it often affords relief to the other local symptoms, and seldom proves injurious from the quantity lost at one time; but, if

fuse, and occurring at short intervals, its effects on the constitution may be alarming.

The hemorrhoidal flux is connected with, and in the great majority of cases dependent upon, the existence of distinct hemorrhoidal tumours. Occasionally, however, it appears to occur when there is no distinct separate tumour projecting above the surface of the membrane; but in these cases there is general intumescence and congestion of the whole of the mucous membrane of the lower part of the rectum, from which the blood exudes in drops, or it may even spurt in a distinct jet from the open mouth of a blood-vessel.

It is frequently ushered in by an exacerbation of those symptoms that commonly accompany piles, such as a sensation of fulness, weight, and tension, about the parts. But the symptoms that precede its occurrence are often much more imperfectly marked than is usually stated, and are frequently absent altogether.

The discharge of blood may be periodical, occurring every month, or at intervals of two, three, or six months; and it may be remittent or intermittent. When once it has set in, it usually continues from three to six days, increasing in quantity up to the third or fourth day, and then lessening.

When moderate in quantity and short in duration, it is often a source of relief to the patient; but if a very large quantity be lost at one time, or if it continue for too long a period, more harm is usually done to the patient by its long continuance than by its excessive quantity at any one time. The patient may become much debilitated; nervous headaches, pallor, palpitations, and syncope may result. In some cases, it has been said that this discharge is of service, acting as a derivative, and preventing disease from falling on more important parts; it has especially been looked upon as, and doubtless is in many cases, a safeguard from apoplexy and visceral congestions and obstructions, particularly when it occurs in plethoric and corpulent persons who habitually live too high. In other cases it may be considered as critical; especially when it occurs about the cessation of the menstrual period.

The colour of the blood is most generally florid, as if it came from the small arteries or capillaries of the part rather than from the veins. It would appear that, in consequence of the over-distended and varicose condition of the veins of the part, the onward flow through the arteries and capillaries leading to them was obstructed; and that in consequence of the accumulated pressure on these vessels their parietes gave way, allowing the florid blood to escape from the veins.

Very commonly the internal piles, when brought down, present a somewhat granular surface, in consequence of ulceration having taken place, and the whole surface will be seen to exude blood in drops. In other instances, the blood appears to come from a cavity in one side of the hemorrhoid, as if rupture had occurred from over-distension at that part. Occasionally, however, the flow of blood is so rapid and copious that it cannot be supposed to come from exudation, but would appear to depend on rupture of the vessels of the part.

The hemorrhoidal flux may be accompanied by, or alternate with, a thin glairy mucous discharge from the rectum and diseased structures, this would appear to be nothing more than excessive secretion from the membrane, in consequence of the irritation set up by the pressure of the piles; it is seldom in sufficient quantity to produce much annoyance, or to be of much moment to the patient.

COMPLICATIONS.—Piles are not uncommonly complicated with other diseases of the rectum, such as fissures, fistula, or prolapsus. When connected with fissure, the hemorrhoid often, as Syme has remarked, assumes a peculiar form and appearance, presenting itself as a small red colourless body, like a pea in size, firm, and seated at the base of the fissure, which often conceals; to a practised eye, however, the presence of a pile of the peculiar colour and shape is sufficient to indicate the existence of the fissure.

In that form of fistula in which the aperture is near the anus, one or more external piles of small size are often found situated at the orifice of the fistula; and prolapsus rarely, if ever, is met with in adults, without the simultaneous occurrence of piles.

TERMINATIONS.—Hemorrhoidal tumours may terminate by Subsidence, Coagulation, Suppuration, or Sphacelus.

Subsidence.—Complete subsidence of the pile can only take place when the disease is of recent occurrence. When of long standing, and after has been exposed to successive attacks of inflammation and turgescence, never subsides completely; and the cellular tissue and the muco-cutaneous structures, becoming hypertrophied, form elongated pendulous flaps about the margin of the anus.

Coagulation of the contents of the pile is the result of inflammation having taken place in it, and probably terminating in plastic effusion, by which the vessels leading from it are obstructed. When it takes place, the tumour after more or less active inflammation, becomes hard, incompressible, and indolent, permanent in size, and of a purplish or plum-colour. The coagulum thus formed may remain persistent, may excite suppuration, or may be absorbed, the hypertrophied tissues forming one of the usual anal folds. In some rare instances, the coagula may become converted into structures resembling phlebolites.

Coagulation more frequently takes place in external than in internal piles, owing to the great impediment to the return of the blood from them, and to their greater liability to inflammation, their exposed situation leading them to be bruised or otherwise injured. When it occurs in internal piles, it more commonly affects those that are of a columnar or longitudinal shape, and least frequently the globular variety.

Suppuration is not an uncommon termination, if acute inflammation has been set up in external piles, more especially in those that have previously been coagulated. When the abscess is discharged, small coagula escape with its contents, the cavity granulates and becomes obliterated, and the pile cured.

Sphacelus.—In some cases, when there is much elongation of the mucous membrane from which the pile springs, prolapsus of that membrane and of the piles may take place; and thus being grasped after it has descended by the contraction of the sphincter, the same effect may be produced as if a ligature were applied. The tumour becomes much swollen, hard, livid, and tense, there are much constitutional disturbance and restlessness, but after a few days all the symptoms are relieved by the part that is constricted sloughing and dropping off.

DIAGNOSIS.—The diagnosis must be regarded in two points of view; 1, as concerns the *Hemorrhoidal Tumours*; and 2, with reference to the *Hemorrhoidal Flux*.

1. *Hemorrhoidal Tumours* must be diagnosed from prolapsus ani, polypus of the rectum, and condylomata about the anus. From prolapsus the diagnosis is not always easy; indeed, the two diseases are so generally associated, that it is of little moment to attempt it. In true prolapsus, con-

examination will suffice to distinguish the membranous wall of the intestine, forming a smooth, rounded, and somewhat lobulated annular protuberance, from the isolated tumours of piles. In *polypus*, the history of the case, the pedunculated and solitary character of the tumour, its large size, and comparatively slight tendency to periodical hemorrhage, will enable the surgeon to make the diagnosis. From *condylomata* the diagnosis is easy; the soft, flat, mucous, and wart-like character of these growths, their history, and their occurrence at other points, as the perineum, scrotum, vulva, and buttocks, will enable the surgeon to distinguish them without any difficulty.

2. The *Hemorrhoidal Flux* must be distinguished from other *intestinal hemorrhages*. This may be done by attention to the character of the blood, which will enable us in many cases to determine its source. When it comes from piles it is liquid, of a more or less florid colour; and not unfrequently is quite bright, staining or coating the feces rather than being mixed up with them. When, on the contrary, the blood is poured out at some higher point in the intestinal canal than the usual seat of hemorrhoids, it is of a dark sooty character, mixed up with liquid feces either in a diffused form, or in small black coagula, and no fresh or bright blood will be visible. Digital exploration of the rectum in cases of piles, and the presence of symptoms indicating the existence of mischief at a higher part of the intestine than the anus in cases of melæna, will also serve to point to the seat of the flux.

TREATMENT.—In conducting the treatment of a case of piles, that surgeon will succeed best who looks upon the disease not as a local affection, merely requiring manual interference, but as a symptom, or rather an effect, of remote visceral obstruction and disease, the removal of which may alone be sufficient to accomplish the cure, without the necessity of any local interference; or, should it be thought necessary to have recourse to operative procedure, this must be made secondary to the removal of those conditions that have primarily occasioned the congestion and dilatation of the hemorrhoidal vessels. The treatment of piles, therefore, must be considered, 1, as regards the removal of those Constitutional Conditions or Visceral Obstructions that occasion the disease, together with any Topical Applications that may be considered necessary; and, 2, with reference to the Operative Procedures that may be required for the removal of the affection.

1. The *Constitutional Management* of piles necessarily varies considerably, according to the condition of the patient in which they occur, and the visceral obstruction to which they may be referrible. Thus, when they occur in debilitated persons, apparently from relaxation of the vessels, most benefit will be derived from a mild tonic and nutritious plan, at the same time that the bowels are kept regular by some of the aperients that will immediately be mentioned. In these cases, also, much advantage is often obtained by the administration of the confection of black pepper, which acts as an useful local stimulant to the vessels of the rectum. In the great majority of instances, however, more particularly when occurring about the middle period of life, piles are connected with a plethoric state of system, and obstruction of the abdominal viscera. Under these circumstances, our efforts should be directed to the reduction of the plethoric condition, by putting the patient upon a proper regimen, prohibiting the use of stimulants, and lessening the quantity of animal food that he is in the habit of taking. When piles arise from the pressure of a gravid uterus or other abdominal tumour, little can be done; except, by local palliatives and mild aperients, to moderate the inconvenience attending them.

In all cases of piles, but more particularly in those arising from hepatic obstruction, mild aperients are of essential service; by removing fecal accumulations, and establishing a free secretion from the intestinal surface they tend materially to prevent congestion of the portal system. At the same time, drastic purgatives of all kinds should carefully be avoided. The most useful aperients are the electuary of senna, sulphur, and castor-oil; or other of which should be taken regularly twice or thrice a-week at a time, in as small a quantity as will be sufficient to keep the bowels free. In many cases the confection of senna may advantageously be given in conjunction with precipitated sulphur and the bitartrate of potash, equal parts each of these being made into a mass with twice their quantity of the confection and a little syrup; of this electuary a dessert-spoonful may be taken every night or every second night. If there be a relaxed condition of the rectum and anus conjoined with the piles, as not unfrequently happens, not only in old as well as in young people, the administration of an electuary composed of equal parts of the confectios of senna and of black pepper, or of castor-oil will be found very useful. In fact, in all cases in which the black pepper is administered, an aperient should be given from time to time, to prevent accumulation in the large intestine. When the liver is much obstructed the treatment should be specially directed to the relief of this organ. In this view, a course of Plummer's pill, followed by taraxacum, and, in relaxed constitutions, the mineral acids, will be found especially serviceable, at the same time that the bowels are kept free by gentle aperients.

The habitual use of lavements, consisting either of soap and water or gruel, will be found advantageous in many cases of piles, though in some they appear to irritate, and rather to increase the disease. When they occur in relaxed constitutions, the lavement should be used cold; but in the patient is of full habit of body, a tepid one will usually be found to agree best. In the general management of piles it need scarcely be observed that any habits which favour the disease should be sedulously avoided.

The *Local Treatment* of piles is of considerable importance. The piles should be regularly sponged with cold water, morning and evening. If there be much relaxation, and the piles be internal, benefit may result from the employment of some astringent injection, such as a very weak solution of the sulphate of iron, or of the tincture of the sesquichloride—a grain of the first, or ten drops of the second, to an ounce of water; of this solution two ounces may be injected every night, and left in the rectum. The application of an astringent ointment, such as the unguentum galle compound, or the employment of the anodyne and astringent suppository already recommended, will be attended with much benefit.

If the piles become inflamed, the patient should keep his bed, and ice should be freely applied around, but not upon the tumours. Tepid lotions, poultices, and poppy fomentations, must be assiduously used, a very strict diet enjoined, and the bowels opened by mild saline aperients. If a cancerous form in an external pile, as the result of inflammation, the tumour should be laid open with a lancet, and its contents either squeezed, or turned out by the flat end of a director. If abscess form, it must be punctured in the usual way, and the part afterwards poulticed. Should strangulation of piles take place, the protruded swelling must be returned by gentle external pressure, and the part afterwards well poulticed.

2. *Operation.*—The means above indicated are usually sufficient in ordinary cases of piles; but, if the disease attain an inconvenient size, give rise to general irritation and local uneasiness, or if the abundance of hemorrhage be such as seriously to interfere with the health of the patient,

it will become necessary at last to have recourse to operative interference, with a view of removing the diseased structures. No operation should ever be undertaken whilst the pile is in an inflamed state, lest unhealthy inflammatory action to an undue extent be set up in the part; it is also well to get the patient's health into a good state, as erysipelas may otherwise follow the operation; and before proceeding to perform it, care should always be taken that the bowels have been well opened.

There are three plans of treatment adopted by surgeons for the removal of piles; viz., the excision of the tumour, its strangulation by ligature, or destruction by caustics. These methods of treatment should not be employed indiscriminately. The first is alone applicable to external piles; the last two may be adopted in the internal form of the disease.

Excision.—The removal of external piles is readily effected. The tumour should be seized with a vulsellum or hook, drawn forwards and snipped off with a pair of knife-edged scissors, curved upon the flat. At the same time when the external piles are removed in this way any pendulous flaps of skin in their vicinity should be excised, lest they become irritated, and constitute the basis of a fresh pile. After the excision of external piles, there is usually but trifling hemorrhage, which may readily be arrested by the application of cold hut, or a pad and T-bandage; should any small artery bleed, it may be pinched, and the hemorrhage thus stopped.

Ligature.—Internal piles should be removed by the ligature only; in fact, it may be laid down as a rule in surgery, that all external piles should be cut off, and all internal piles tied. The reason of this difference in the practice to be adopted, according as the pile is situated above or below the margin of the anus, is the liability to hemorrhage in the one case, but not in the other. The bleeding that follows the excision of an external pile is not only small in quantity, but may readily be arrested by cold or pressure. With internal piles, however, it is different; these tumours are not only more vascular, being often fed by a large central arterial twig, but are deeply seated, and do not readily admit of the application of means for the arrest of the flow of blood from them. So difficult is it to stop the bleeding from an internal pile in some cases, that patients have actually lost their lives from this cause after its excision, even in the hands of some of the most distinguished surgeons. The excision of internal piles has consequently been very properly abandoned.

The operation for the ligature of internal piles may most conveniently be conducted in the following manner. The patient, having had his bowels cleared out by a dose of castor-oil on the day preceding that fixed for the operation, should have an abundant lavement of warm water administered about an hour before the surgeon arrives; and he should then be directed to sit for half an hour on a bidet, or over a pan containing hot water, bearing down at the same time, so as to cause the piles to protrude. When all is ready, he should be laid on the bed on his left side, with the nates well projecting; the surgeon then seizes the most prominent pile with a hook, vulsellum, or broad-ended forceps (Fig. 408), draws it well forwards, and ties its base as tightly as possible with a thin whipcord ligature. He does the same to one pile after the other, until all that can be met with have been strangulated in this way. In some cases the pile is so broad at the base, that the ligature will not include it without transfixion; when this is required, it may usually be done readily enough

Fig. 408.—Broad-ended Forceps.

by means of a *novus-needle*, or by the following drawing (Fig. 409), Bushe's needle,

Fig. 409. — Bushe's Needle for Applying Ligature to Piles.

fixed in an ivory handle perforated for the recumbent point. The advantage only is the angle for a very convenient one a pile inside the anus the needle can be directed across the base so withdrawn more easily. If the pile be long it is in a direction upwards the ligature tied in whatever way the ligature taken that they are the piles may be effected this way they separate less pain to the patient all the tumours require

ends of the threads in a strangulated mass pile there be any external piles, these must not be done, they become irritated, swollen, and inflamed, and constitute a source of much distress to the patient, and should keep the recumbent position which usually happens from the sixth to the eighth day the surface will be left, which, however, speedily heals. In some cases this process may be facilitated by the insertion of a silver thread through a speculum ani. On the opening of the bowels may be opened with a dose of castor oil. In the case of the case, care must be taken to prevent the patient from giving rise to the affection in the first instance, more particularly if they be seated towards the rectum there is frequently great irritation set up, and the patient experiences difficulty in defecation, and suffers from complete retention; a warm bath, and *cymus* and nitric ether, will usually relieve. In some cases, when the external piles are large, and the patient debilitated, the ordinary rule of cure must be deviated from, and a combination of ligature be adopted. In such cases an incision is made into the integuments merely, and then the piles tied with a thread. By these means the pain and inflammation are removed, and on the inclusion of a portion of the integument at the same time that the risk of hemorrhage is avoided.

The treatment of piles by ligature is not applicable to persons of broken constitution. I have not seen any pyæmia result in these cases.

Chemical. — In certain kinds of internal piles, it has been recommended by Houston of Dublin, to be advantageously adopted. It must not, however, be used in the intero-external pile, as it will not be looked upon as a substitute for the

is especially in the granular pile, having an ulcerated surface, that this mode of treatment is useful: as in these cases it appears, by destroying a portion of the mucous membrane, not only to cure the pile to which it is applied, but, by producing an ulcer, to give rise to a cicatrix, which, by contracting, consolidates the parts in its vicinity, and so lessens the relaxed state of the rectum, which favours the hemorrhoidal tendency. The acid may most conveniently be applied through a speculum ani, having an aperture on one side (Fig. 110). This should be introduced, well oiled, until the pile project through the opening in it, when it must be freely rubbed with a piece of stick, or a glass rod or brush, dipped in the acid; the surface is then immediately wiped with a piece of lint saturated with prepared chalk and water, and the instrument removed. A thin slough separates, leaving a raw surface, which gradually cicatrises and contracts. The application of the acid occasions but little pain when made fairly within the rectum; but, if a drop of it accidentally come into contact with the muco-cutaneous surface, a vast deal of irritation and inflammation are excited. This plan of treatment, though useful in particular forms of pile, as when the tumour is granular or flat, so as not to admit of ready removal by the ligature, should not, I think, be practised when the ligature can be employed, as it is by no means so certain a mode of treatment. It cannot be considered altogether devoid of risk; for I have known one instance in which fatal erysipelas followed the cauterisation of piles with nitric acid.

Fig. 110. Speculum Ani.

PRURITUS ANI is often an extremely troublesome affection, the itching and general irritation about the anus being almost unbearable. In many instances it appears to be a true prurigo of this part; in other cases it appears to be connected with the irritation of external piles, worms, or some similar affection. The *Treatment* must in a great measure have reference to the cause. If there be an external pile, the removal of it, or if worms, their expulsion, will probably cure the disease. If it arise from prurigo, it will require some special treatment. In some cases the arsenical preparations will be found useful, together with the local application of chlorinated lotions, or those containing hydrocyanic acid.

PROLAPSUS ANI.

Prolapsus Ani consists in a protrusion of the mucous membrane of the rectum through the anal orifice; the cellular tissue that lies underneath it being also in the majority of instances much thickened and elongated. In the ordinary prolapsus, the muscular structures of the gut are not protruded; yet it has occasionally happened that the muscular coat has descended with the mucous membrane, an invagination of the bowel taking place, which constitutes a different and far more serious condition than the ordinary prolapsus.

CAUSES.—Prolapsus not unfrequently occurs in children, especially those who are feeble, or who suffer from much irritation of the digestive or urinary organs. In weakly persons generally there is a natural tendency to prolapsus; the slight protrusion of the mucous membrane which takes place during defecation being increased by any constitutional condition that gives rise to atony of the muscular system, especially if irritation of the intestinal mucous membrane be conjoined with this, as in dysentery, chronic diarrhoea, &c. So again, the habitual constipation often occurring in persons

of a relaxed habit of body, apparently proceeding from want of power in the rectum to expel its contents, and requiring constant straining at stool, predisposes to this affection. It is especially common in those who labour under stricture, stone, or any other disease about the urinary organs that requires a considerable effort to be made in expelling the contents of the bladder. In persons whose constitution has been relaxed by a long residence in India, this disease also frequently occurs. In other cases, and indeed usually, the prolapsus is associated with piles, the weight and dragging of the hemorrhoid drawing down the mucous membrane with it. This is especially apt to happen, when there is general hemorrhoidal tendency about the anus. In fact, the causes of prolapsus may be summed up under the heads: 1. Simple relaxation of tissue, such as is met with in children and weakly persons; 2. Sympathetic irritation, as in chronic tenesmus, stone in the bladder, &c.; 3. A hemorrhoidal condition of the vessels of the part.

DIAGNOSIS.—Prolapsus is readily recognised. It consists in the protrusion of a ring of mucous membrane of a red or purplish colour, and having a somewhat lobulated look, rather lobulated in shape, and varying in size from half a walnut to a small orange (Fig. 411). The mucous membrane covering the ring will be found to be continuous with that inside the sphincter, and thus constitutes the mark of distinction between the ordinary prolapsus and the invagination.

Fig. 411.—Prolapsus Ani.

has occasionally been met with of the whole thickness of the gut, for this affection, which is extremely rare, there is a deep and distinct cleft between the protrusion and the margin of the sphincter. In prolapsus there is, when the protrusion is down, a dragging and smarting sensation, often attended with a good deal of spasm about the neck of the bladder, and not unfrequently with symptoms of stricture. In chronic cases, the anal aperture will appear to be permanently relaxed; and on introducing the finger into it, it will be found to be widened and weakened. The folds of skin in its neighbourhood will be seen to be relaxed and elongated, radiating from it as from a centre: they are commonly bluish soft, somewhat swollen, and pendulous, and often the seat of a good deal of irritation. The protrusion at first occurs only after defecation, and then readily goes back of itself, or is reduced by the exercise of steady pressure upon it; after a time, however, it will come down at other periods, and may protrude after riding, walking, or even standing, and is returned with much difficulty.

Strangulation of the prolapsus may occasionally occur, if it be allowed to protrude for a considerable length of time without a proper attempt being made to push it back. It then becomes swollen and livid, with great pain and tenesmus, discharges a fetid ill-conditioned pus, and may eventually sink into a sloughy state, and, thus separating, undergo a spontaneous cure.

TREATMENT.—The treatment of prolapsus may be said to be palliative and curative. The Palliative Treatment consists in the first place reducing the tumour when protruded. Thus, under ordinary circumstances the patient does for himself; but, if it becomes congested, it requires

help of the surgeon to put it back. This may occasionally be readily done by laying the patient on his side, or making him lean over the back of a chair; and then greasing the mass with some oil, seizing it with a soft towel, and, gradually compressing it, working it back. It may be kept up by the patient wearing a belt with a pad and elastic support. Olive-shaped powder pessaries are occasionally employed, with the view of preventing the protrusion; but I have never seen them of any service, the sphincter being usually too relaxed to keep them up, and their pressure appearing to excite irritation.

The regulation of the bowels is as important in cases of prolapsus as in piles. It is usually best done by the administration of those laxatives that have been recommended for the latter disease. It is a good plan in prolapsus to get the patient to have his daily motion at bed-time instead of at the usual hour in the morning; the recumbent position and the uniform temperature of the bed preventing the irritation of the sphincter and spasm of the anal muscles that commonly continues for some time after the reduction of the prolapsus, and which is a source of great discomfort when occurring in the early part of the day.

Curative Treatment.—The relaxation of the mucous membrane of the rectum that essentially constitutes prolapsus may often be obviated by astringent injections or suppositories. The best injections are those of the sulphate of iron, in the strength of from one to three grains in an ounce of water, thrown up in small quantities sufficient for the bowel to retain. In children, injections of this kind, conjoined with regulation of the bowels by mild aperients, the administration of a moderate quantity of unstimulating food, and afterwards the employment of tonics, will commonly remove the disease, unless it arise from stone in the bladder, or some other affection inducing much and continued straining. In mild cases of prolapsus in adults, conjoined with a relaxed state of the mucous membrane of the rectum and relaxation of the sphincter, the use of the iron injections will be found particularly beneficial, at the same time that the action of the bowels is regulated by means of an electuary taken in the morning or at night. By thus giving tone to the bowel, at the same time that constipation is prevented, the disease will occasionally undergo a cure, provided it be not associated with any affection in other organs.

In those cases in which the prolapsus is hemorrhoidal, the protrusion being dragged down by the weight and strain of the pile, the same treatment must be adopted as has been recommended for the latter disease; and usually, after the ligature and removal of the pile, the prolapsus will be cured. In slight cases of prolapsus, in which the disease appears rather to be owing to the relaxation of the sphincter and of the tissues external to it, the mucocutaneous integument hanging in loose and pendulous folds around the anus, considerable benefit will commonly result from snipping off these pendulous flaps of skin; the cut surface that is left cicatrising, and by its contraction tracing up the part, and thus preventing its further protrusion. These pendulous flaps are best removed in a radiating manner from the anal orifice, with curved knife-edged scissors.

When the prolapsus is considerable, and if the ordinary palliative treatment have, after a proper trial being given it, failed in effecting a cure, it will be necessary to remove the protruded mucous membrane by operation. This should always be done by the application of the ligature; excision, though easy, being objectionable in this as in the case of piles, on account of the danger from hemorrhage.

Application of Ligature.—The patient having had the bowels freely opened

on the preceding day, and an enema of tepid water on the morning of operation, should be directed to sit over a pan of hot water, in order to make the prolapsus descend; it may then be seized with a pair of broad-ended forceps such as are represented in Fig. 408, and drawn well forwards. The base must next be firmly tied with a strong piece of whipcord, and a similar process repeated on the opposite side of the anus. Should there be any difficulty on account of the shape of the protrusion in ligaturing the base firmly, this may be obviated by transfixing it with a hemorrhoidal needle and tying it on each side. I think, however, that it is better, if possible, to avoid doing this. The ends of the ligature must then be cut short, the whole protrusion returned into the bowel, the external flaps of skin cut off, and an opiate pill administered, so as to arrest all peristaltic action for a few days. Should the ulcerated surface show any difficulty in healing, it must be touched with the nitrate of silver. This operation always leaves a permanent cure.

The ligature of prolapsus, like that of *internal piles*, is not very painful, and for it chloroform need not be administered; indeed, it is, perhaps, better that it should not be given in these cases, as the protrusion is apt to slip under its influence, the patient not being able to exercise the proper expulsive efforts. But, as the excision of the external flaps and piles is attended by very sharp suffering, it is as well to administer the anæsthetic at the time when they are being removed.

Should a prolapsus become strangulated, it would be necessary to try to reduce it through the sphincter by the employment of the taxis; if it cannot readily be accomplished, free incisions may be made into it; if it be not reduced, it will slough away, and thus undergo permanent cure. In some rare cases, a portion of invaginated intestine descending through the anus has become strangulated; in such cases as these, reduction must be effected; if possible without, but if necessary with, division of the sphincter.

DISEASES OF THE GENITO-URINARY ORGANS

CHAPTER LXVI.

URINARY CALCULUS.

CALCULOUS DIATHESSES AND DEPOSITS.

The urine is liable to the deposit of various solid matters, which, when amorphous and impalpable, are termed *Sediments*; when crystalline, they constitute *Gravel*; and when concrete, *Calculus* or *Stone*. These deposits, whatever form they assume, are the result of constitutional causes, and these constitutional conditions giving rise to them are commonly called *Diatheses*. Of these surgeons usually recognise three: the *Lithic*, the *Uric*, and the *Phosphatic*; besides these, however, others doubtless exist, the precise characters of which have yet to be determined.

LITHIC ACID DIATHESIS.—This diathesis chiefly occurs in individuals of robust habit of body and florid appearance, who have lived high and suffered from irritable gastric dyspepsia. It is often associated with a granular

neumatic tendency, or with some of the more chronic forms of skin disease, especially psoriasis. It is characterised by scanty and acid high coloured urine, which deposits on cooling two kinds of sediment, a yellow and a red. According to Lehmann, these sediments consist of urate of soda; but holding Bird, and, I believe, most of the chemists in this country, regard them as lithate or urate of ammonium. The yellow sediment, containing an admixture of the colouring matter of the urine, is usually dependent on slight disorder of the digestive organs and skin, coming and going under the influence of very trivial causes. The red sediment, owing its colour, according to Bird, to an admixture of purpurine, a highly carbonaceous ingredient, and indicative of imperfect assimilation, is met with in persons of full habit, who live too freely. A variety, or rather an admixture, of these sediments, constitutes the *lateritious deposit*, so common in gout and rheumatism. The red sand or gravel is a crystallised variety of the lithic acid sediment. It may be compared, in general appearance, to cayenne pepper, and under the microscope presents the characters seen in Fig. 413. It is not unfre-

Fig. 412.—Lithic Acid.

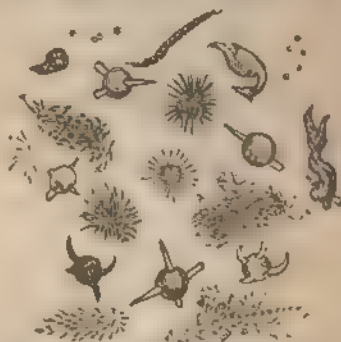

Fig. 413.—Lithate of Ammonia.

quently met with in children of a strumous habit, who are allowed more animal food than they can well assimilate. Occasionally crystals of lithic acid are found intermixed with these deposits, presenting the characters figured in Fig. 412.

Calculi.—The calculi that occur in this diathesis are of two kinds; the lithic acid, and the lithate of ammonia. The lithic acid calculus (Fig. 414) is usually of small or moderate size, varying from a pin's head to a pigeon's egg; it is oval, somewhat compressed and flattened, smooth on the surface, and of a fawn colour. On section it is seen to be laminated, and to present various shades of a light brown or fawn tint. The lithate of ammonia calculus is of very rare occurrence; when met with, it is chiefly in children, and is composed of concentric rings, having a fine earthy appearance, and being clay-coloured.

Treatment.—The treatment of the lithic acid diathesis must be directed to the removal of the prime causes of this condition, viz., mal-assimilation, defective oxygenation of the blood, and the ingestion of too large a quantity of stimulating food. All these may be remedied by attention to ordinary hygienic measures; the patient must live sparingly, should avoid fermented liquors, especially red and effervescent wines, and abstain from sweets, pastry, &c. He should take plenty of out-door exercise, and keep the skin

Fig. 414.—Lithic Acid Calculus.

in healthy action by warm dry air or vapour bathing, and the use of horse-hair gloves. The bowels must also be carefully regulated by means of saline and other aperients, with occasional alterative doses of Plummer's or blue pill; to which, if the constitution be peculiarly rheumatic or gouty, some colchicum may advantageously be added. A very good aperient for general use in these cases, is a drachm of Rochelle salt in an ounce and a half of the compound decoction of aloes, taken at night or early in the morning; or a dessert-spoonful of the following powder every morning;—*R Pulv. Rhe. ʒss., Potassæ tartratis, ʒi., Magnesiæ ustæ, ʒij., Pulv. Zingiberis, ʒj.;* *ft. pulvis.* The patient may also be directed to drink some of the natural alkaline waters, as those of Vichy or Fachingen. The Vichy waters, containing a large quantity of carbonate of soda, with free carbonic acid, are extremely serviceable for the correction of this diathesis. If they cannot be procured, a very good alkaline drink consists of a scruple of bicarbonate of potash and 5 grains of nitre dissolved in a tumbler of cold or tepid water, to which about 5 grains of citric acid, or a table-spoonful of lemon-juice may be added, and taken early in the morning or in the middle of the day.

When lithic acid calculus has actually formed, it is well not to give the alkaline remedies too long, or in too large quantity; lest the stone rapidly increase in size by becoming encrusted with phosphates.

OXALIC DIATHESIS.—This is characterised by the formation of oxalate of lime in the urine. It generally occurs in individuals in whom there is defective assimilation, dependent upon exhausted nervous energy, arising

from over-work, mental anxiety, or venereal excesses. The patient is usually pale and hypochondriacal, suffers from dyspepsia, acidity of stomach, and disturbed sleep. In these cases there is often loss of sexual power; a state of debility of the generative organs connected either with the want of erectile vigour, or too speedy emissions. The urine is usually very pale, abundant, and acid, and there is heat and smarting during its passage along the urethra. In this diathesis there is no sediment or gravel, properly speaking, but the crystals float in the

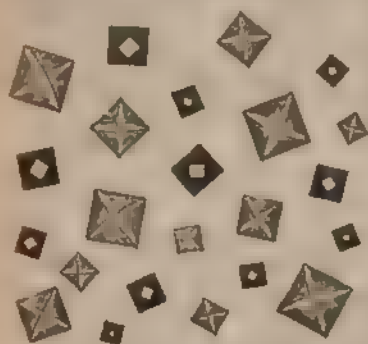

Fig. 414.—Oxalate of Lime.

urine; subsiding, however, when it stands, but not occurring in sufficient quantity to constitute a true sediment (Fig. 415).

Calculus.—The oxalate of lime or mulberry calculus is usually of a dark brown or almost black colour, moderate in size, being seldom larger than a walnut, and round; it is always rough, tuberculated, and sometimes almost spiculated on the surface (Fig. 416).

Fig. 416.—Oxalate of Lime Calculus.

Treatment.—When there is no calculus, it is necessary to put the patient upon a light and nourishing diet, especially fish, as recommended by Dr. Lind, cautioning him to avoid sweets and all fermenting liquors, with the exception of a moderate quantity of brandy. Tonics, particularly the mineral acids, iron, zinc, and quinine may be given, and the residence, if possible, be changed for a time to a warm climate. When calculus is formed, there is, owing to its roughness, and the irritable state of the patient's nervous system, usually a great deal of pain.

experienced in the region of the bladder, requiring the free administration of opiates.

PHOSPHATIC DIATHESIS.—This chiefly occurs in old persons, or in those who are prematurely aged, with a broken constitution and an anæmic condition of the system. In this diathesis, the sediment and calculi may occur in three distinct forms: 1. Triple or Ammoniac-Magnesian Phosphate; 2. Phosphate of Lime; and 3. Mixed Phosphates, consisting of a mixture of the preceding varieties.

1. The *Triple Phosphate* (Fig. 417) usually occurs in urine that is copious, pale, and barely acid, sickly to the smell, and soon decomposing and becoming very offensive. In other cases it is dark, alkaline, and mucous. This condition especially occurs in old people, and is associated with much debility, irritability of mind, pallor, and anæmia.

2. The *Phosphate of Lime* sediment is not of such common occurrence; it usually occurs in pale, and offensive, readily putrescent urine, mixed with much mucus, and in some cases apparently produced by the mucous membrane of the bladder.

3. *Mixed Phosphates* commonly occur after injuries of the spine, as the result of general impairment of the health, or in advanced cases of prostatic disease. They are occasionally met with in large quantity, forming a kind of mortar-like sediment in the bladder.

Calculi.—The phosphatic calculi are very common. The most frequent is the mixed, or fusible calculus, as it is termed, on account of the ready way in which it melts when exposed to heat. This calculus is friable, laminated, and has a chalky or earthy look. The calculus composed of phosphate of ammonia and magnesia is not so common; it resembles the preceding rather closely in its general characters, but is whiter and has a more chalky look. The phosphate of lime calculus is extremely rare; it is laminated, and harder than the other varieties.

Treatment.—The treatment of the phosphatic diathesis consists principally in improving the digestive powers, and in restoring the general strength of the patient by the administration of good food, wine, or beer. The exhibition of tonics, especially of nitric acid, should be attended to, and exercise in the open air enjoined. As there are usually much pain and irritability of system in this diathesis, opium may advantageously be administered.

Besides the calculi mentioned, various other kinds of concretions form in the urine, each of which doubtless represents a diathesis; the characters of which, however, are not so distinctly marked or so well recognised as those that have just been described.

XANTHINE, or XANTHIC OXIDE, was first noticed by Dr. Marcet, and has since been observed by Langier, Langenbeck, and others. It is of extremely rare occurrence, and has only been found in three recorded instances in the form of calculous concretions. These have generally been of small size, with the exception of the one removed by Langenbeck, which weighed 388 grains. For a detailed account of the chemical characters and constituents of this substance, as well as of the other materials of which

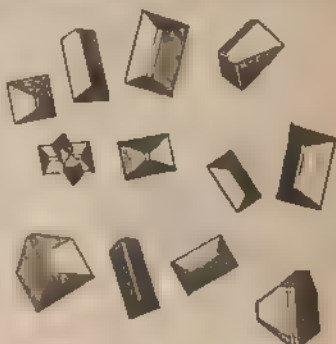

Fig. 417.—Ammoniac-Magnesian Phosphate.

calculi are formed, I must refer to the works of Drs. G. Bird, Beale Thudichum, &c.

CARBONATE OF LIME has occasionally been met with as an amorphous powder in alkaline or very faintly acid urine. I am not aware of any urinary calculus of this composition having ever been found; but Dr. Bird states that he has detected carbonate of lime as forming a distinct stratum in some phosphatic calculi; and Dr. Thudichum has examined prostatic concretions consisting almost entirely of this substance—the urinary origin of which, however, he doubts.

CYSTINE is one of the rarer forms of morbid product occasionally met

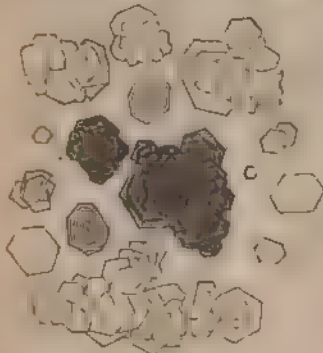

Fig. 418.—Cystine.

with in the bladder. It differs from all other ingredients in containing a large quantity—about 26 per cent.—of sulphur. It is very rarely seen as a sediment in the urine; but when it occurs in this form it presents the microscopic characters seen in Fig. 418, being composed of hexagonal laminæ. Calculi containing cystine have occasionally been met with. Dr. Golding Bird states that in Guy's Hospital Museum there are eleven composed of this peculiar animal matter, and in the Museum of University College we have some good specimens. Cystine in calculus has a peculiar yellowish or greenish and waxy look, very different

from any other ingredient met with in urinary concretions.

STONE IN THE BLADDER.

STRUCTURE OF CALCULI.—Calculi, though sometimes composed throughout of the same deposit, are not unfrequently made up of layers or strata differing in chemical composition from one another, and these usually go by the name of *alternating calculi* (Fig. 419). Most frequently the nucleus consists of lithic acid; next in the order of frequency comes the oxalate of lime; and then the concretions of a phosphatic character throughout. It is very seldom that the nucleus is absent; but concretions have occasionally been met with in which none could be detected, or in which it was even replaced by a cavity. The nucleus is usually as nearly as possible in the centre of the calculus and is generally pretty regular in shape; occasionally, however, it is branched or curiously radiated, and then the concretion generally affects a corresponding outline. Calculi containing two or three nuclei have sometimes been found

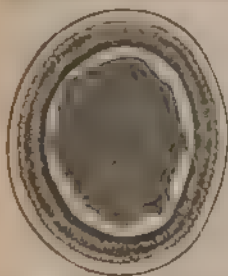

Fig. 419.—Section of an Alternating Calculus.

consisting probably of an equal number of concretions agglomerated together.

The body of a calculus having the uric acid nucleus is usually composed of some of the lithates; but not unfrequently these are overruled by a deposit of phosphates. In other instances, the body may be wholly composed of some of the earthy phosphates, which more rarely alternate with the oxalate of lime or the triple phosphates.

An oxalate of lime nucleus usually has a body of the same composition.

but in some cases it is incrustated by phosphates or urates (Fig. 420). When the interior is phosphatic, the concretion is always of the same constitution.

The alternations in the composition of a calculus are due to varying conditions of the general health, and consequently of the character and constituents of the urine, and of the state of the lining membrane of the bladder. The uric acid and oxalate of lime nuclei and layers are undoubtedly due to constitutional causes. The phosphatic laminae, whether interposed between the uric acid or incrustating the calculus, are probably chiefly dependent on vesical irritation consequent on the presence in the bladder of the previously formed uric acid or oxalate of lime nucleus.

Fig. 420.—Section of Oxalate of Lime Calculus incrustated with Phosphates.

ORIGIN.—Calculi may be formed either in the kidneys or in the bladder. Those that contain nuclei of the urates or oxalates are probably renal in their origin; whilst those that have a phosphatic nucleus are usually vesical from the first; renal nuclei of this composition being rarely met with.

All renal calculi—all those vesical calculi that have a renal origin, and some of those even that appear to be primarily formed in the bladder—have a constitutional source, arising from a morbid state of the urine, which probably in its turn depends upon mal-assimilation, the peculiar form of which determines the chemical composition of the stone. Those calculi that are formed by deposit from the urine upon and around some foreign body, as a pin or straw accidentally introduced into the bladder, and some soft phosphatic concretions that appear to be the result of an unhealthy state of its mucous membrane, may be looked upon as being local in their origin.

CALCULI OF RENAL ORIGIN.—When a stone forms in the pelvis of the kidney, it usually gives rise to pain in the loin. When of small size, it may descend into the bladder with but little suffering to the patient; but, if large enough to irritate the ureter and to pass with some difficulty, it then gives rise to a peculiar train of symptoms, which will immediately be described. In some cases the calculus attains a very large size, occupying the whole of the pelvis of the kidney, extending into the calices and ureter, and being moulded, as it were, to the shape of the parts amongst which it lies; it then gives rise, by its pressure, to absorption of the substance of the kidney, and occasions, by the magnitude that it attains, excessive pain and irritation in this region, the patient usually dying, worn out by constant suffering and by the irritation of incurable kidney-disease. In some instances, stone in this situation has given rise to abscess in and around the kidney, and has even been discharged through an aperture in the lumbar region.

Descent of a Renal Calculus.—In cases in which a renal calculus descends into the bladder, the patient is seized with pain in the loin that has been the seat of previous irritation. This pain is usually of the most agonising character, extending into the cord and testis, and down the inside of the thigh of the affected side. There is retraction of the testicle, with constipation and vomiting; frequently accompanied by the passage of scanty, high-coloured, and bloody urine, and great constitutional disturbance. This pain usually continues of a somewhat remittent character, until the calculus enters the bladder, when, unless expelled, it gives rise to the train of symptoms peculiar to its presence in that organ.

Treatment.—During the descent of a renal calculus, which always occupies many hours, and perhaps some days, the patient should have full doses of opium administered, be put into a warm hip-bath, and have mustard

poultices applied to the loin, or be cupped in this situation, if necessary the bowels should also be thoroughly emptied by enemata. It is well to bear in mind, that a somewhat similar train of symptoms to that caused by the descent of the calculus, may be excited by some forms of irritant or flatulent distension of the cecum and descending colon, which will require appropriate treatment.

CALCULI OF VESICAL ORIGIN.—Though vesical calculi often owe their origin to the descent of a stone from the kidney, yet it frequently happens that there is no evidence of their coming from such a source, but their appearance of their being deposited in the bladder; a nucleus being originally formed in this viscus by the aggregation of some substance matter, around and upon which fresh deposits take place, until a true calculus is formed. In some instances, vesical calculi have been found deposited upon and incrusting foreign bodies, accidentally introduced into the bladder, such as a piece of straw, a pin, a bit of bougie, &c.

NUMBER.—The number of calculi in the bladder varies considerably; most commonly only one is encountered; but in about one fifth of the cases operated upon, several will be found; from two to six or eight are by no means uncommonly met with. Occasionally several dozens have been detected; and there are even instances on record in which several hundreds of distinct and separate calculi have been found in one bladder. The most remarkable case of this kind is one in which Dr. Physick removed from a judge in the United States upwards of a thousand calculi, varying in size from a partridge-shot to a bean, and each marked with a number. Several calculi may become matted together in one large concretion, as in the annexed representation of a calculus (Fig. 421) that I removed from a

Fig. 421—Calculus matted together.

child four years old; it was formed of eleven distinct acid calculi soldered together in this way; besides which, three others were lodged in the bladder. When several more calculi occur, it is remarkable how uniform they are in shape, size, and weight, one being the exact counterpart of the other.

When there are several calculi in the bladder, the attrition of one against the other usually causes the opposing surfaces to become smooth, thus constituting "facets" (Fig. 422). In some cases, however, when the calculi are numerous, there are no signs of attrition. In

Fig. 422—Calculi with Facets.

a patient of mine who had fifteen calculi in his bladder, all the stones were round, about the size and shape of marbles, without any facets. In other cases, again, there may be more facets on one calculus than companion-calculi in the bladder. A second stone may occasion two or three facets on the first, having rubbed first to one and then to the other side of it.

Spontaneous Fracture of a calculus will sometimes occur within the bladder. This curious phenomenon may happen to a stone that is adherent, or to one among several calculi. When it occurs, great irritability of the bladder is set up. There are several ways of explaining this fracture, or rather disintegration, of a calculus. Civiale supposes it to occur by the contraction of the hypertrophied coats of the bladder upon the stone. It is possible that, when there are several calculi in the bladder, the concussion of one against another may give rise to it, and for the breaking

up of a calculus to happen, it would by no means be necessary that this pressure of the bladder or concussion should be sufficiently strong to resolve the stone at once into fragments. If a crack or fissure merely be formed in it, the infiltration of the urine into this may so soften and loosen its cohesion, that it becomes resolved without further violence into a number of pieces. In some instances these become agglomerated together, by the deposit of a quantity of phosphatic matter upon and around them. In other cases, the different fragments may each form the nucleus of a fresh calculus, so that the bladder may afterwards contain numerous concretions.

PHYSICAL CHARACTERS.—The *Size* of calculi varies from that of a hemp-seed or pin's head to a concretion of immense magnitude. One of the largest with which I am acquainted, is a calculus removed by the high operation by Dr. Uytterhoeven of Brussels, which I saw some time ago in his possession, and of which he has been obliging enough to give me a cast; it is of pyriform shape, and measures $16\frac{1}{2}$ inches in its longest circumference, and $12\frac{1}{2}$ inches round at its broadest part, being $6\frac{1}{2}$ inches long, and about 4 wide. In the celebrated case of Sir W. Ogilvie, Cline attempted, but failed, to extract a calculus measuring 16 inches round one axis and 14 round the other. It weighed 44 ounces, and must have been of about the size of Dr. Uytterhoeven's. These enormous concretions are happily rarely met with at the present day; the usual size of stones removed by operation being from about one to two inches in the longest diameter, somewhat narrow, and perhaps flattened.

The *Weight* of calculi commonly varies from a few grains to several ounces; the commonest size is from three drachms to about an ounce or two in weight, occasionally from three to six; from this they may range upwards until several pounds are reached. Thus, in Cline's case the stone weighed 44 ounces, Deschamps saw one of 51 ounces, and Morand one weighing 6 lbs.: none of these admitted of removal. The largest calculi are usually composed of phosphates, in greater part if not in whole. Large and heavy calculi are certainly less frequently met with now than formerly, owing to operations for stone being simpler and less dreaded since the introduction of anaesthetics, and hence practised in an earlier stage of the disease.

The *Hardness* of calculi varies considerably; the oxalate of lime is the hardest; the lithates come next in consistence, and are often very hard, though brittle; the phosphatic calculi are always comparatively soft and friable.

The *Shape* of calculi presents great variety; most commonly, however, they have an ovoid figure. Concretions of urate of ammonia and uric acid are generally pretty regularly ovoidal, smooth, and disc-like. Those composed of oxalate of lime are usually somewhat globular or square-shaped, and generally rough, nodulated, or spiculated upon the surface. The phosphatic calculi present usually the most irregular outline; most commonly, it is true, they are ovoid or globular, but are not unfrequently branched, as if moulded to the interior of the kidney, constricted, or of an hour-glass shape. The cystine calculi are generally tolerably oval and regular in outline.

Position.—Most frequently calculi lie loose in the bladder; but occasionally they may be fixed, either by being encysted, and then lying in one of the sacculi that have already been described within the walls of the bladder (Figs. 423 and 424); or by being fixed in and embraced by one of the ureters; and in other cases by being deposited upon, and partly included in, fungous growths.

CAUSES.—Whenever a foreign body of any kind, as a piece of broken catheter, &c., is introduced into the bladder, it will form the nucleus of a calculus, speedily becoming incrustated by calculeous, probably phosphatic matter. But the causes of calculi occurring spontaneously are very obscure. There can be little doubt, it is true, that the different forms of concretion are connected with the varieties of diathesis that have already been described, and we may look upon the formation of a calculus as an indication of the

Fig 143.—Exterior of Bladder, containing an Encysted Calculus at x

Fig 144.—Interior of the same Bladder, showing a small Orifice leading into Cyst at a

existence, in a greater degree of intensity than usual, of the causes which ordinarily give rise to sediments or gravel; but why, in particular cases, aggregation into a calculeous mass takes place, it is impossible to say.

Age exercises considerable influence upon the production of calculi. Stone may occur in the bladder at all periods of life, and even, according to Stahl, may be congenital. The greatest number of cases occur during the first two decennial periods; thus Thompson, as the result of his statistical enquiries, states that one-third of the entire number of cases occur before seven years of age, and one-half of the entire number before the thirteenth year is completed. Coulson has collected 2972 recorded cases of lithotomy from various sources; of these, 1466 occurred under the age of ten, 731 from eleven to twenty, 205 from twenty-one to thirty; 264 from thirty-one to fifty, and 306 from fifty-one and upwards. In many of these cases, although the patient was cut towards the middle period of life, the stone probably began to be formed during childhood.

Sex influences materially the occurrence of stone, which is far more frequent in the male than in the female, in the proportion of about twenty to one of cases requiring operation. This, however, does not represent the exact ratio; as, owing to the shortness and large size of the urethra in females, many small calculi are voided by them that would be retained in the male.

It would appear that in some parts of the world calculi is a far more common disease than in others. It is generally more frequently met with in cold than in warm climates. The Negro race is remarkably exempt from this affection. It is a singular fact that in some parts of the same country calculous disorders are of far more frequent occurrence than in others. Thus it is well known that the inhabitants of the east coast of England and Scotland are peculiarly liable to these disorders; and that in Norfolk it occurs with especial frequency, this district furnishing, in all probability, as many cases as the half of the rest of England. In America also, it would appear that the inhabitants of certain States are peculiarly liable to the

affection; and I understand that in some districts of Germany the disease may be said to be almost unknown, whilst in others it is of common occurrence. The relative frequency of the kinds of calculus also varies in different countries. Dr. H. V. Carter, who has analysed and described upwards of a hundred specimens contained in the Museum of the Grant Medical College at Bombay, shows that the percentage of calculi with an uric acid or urate of ammonia nucleus is in India, 56·30; in England, 71·79; while that of calculi with a nucleus of oxalate of lime is in India 38·65, in England 16·87. The calculi composed purely of oxalate of lime also greatly exceed in number those which consist entirely of uric acid or urate of ammonia. To what these differences are owing, it is impossible to say. Peculiarity of race, of constitution, and of diet, with exposure to prevalent easterly winds, have all been assigned as reasons for them; but probably not on very sufficient grounds.

SYMPTOMS.—The symptoms of stone in the bladder vary according as the calculus lies loose in the cavity of the viscus or is encysted. Their intensity will depend on the size and shape of the stone, the condition of the bladder, and the constitution of the patient. Most commonly, the severity of the symptoms is in proportion to the magnitude of the calculus. This, however, is not always the case. In a patient whom I once cut, the most intense suffering and repeated attacks of cystitis had been occasioned by a small but sharp-pointed calculus, not weighing more than a drachm; and some years ago I saw a patient in whose bladder five calculi were found after death, nearly as large as chestnuts, though their presence had never been suspected during life by the different surgeons under whose care he had been for stricture, so little distress had they occasioned. In some cases, the symptoms of stone very suddenly declare themselves; and then the surgeon finds on examination that the patient has a large calculus, which must have been a long time forming without attracting attention. Rough and angular calculi necessarily give rise to more severe symptoms than smooth ones, owing to their inducing a chronic form of cystitis; and, as the constitution is usually a good deal shattered and the nervous system very irritable in those conditions of the system in which the phosphates are deposited, phosphatic calculi are usually attended by more local suffering and constitutional disturbance than other forms of the disease.

The symptoms induced by stone are the result of the mechanical irritation produced by the presence of a foreign body in the bladder; they consist of Pain, Increased Frequency in Micturition, occasional Stoppage of the Urine, and Various Morbid Conditions of that Fluid.

The Pain in calculus is often the first symptom that attracts attention; it varies greatly in character and degree. It may not only be experienced in the region of the bladder and the perineum, but may radiate widely in the course of the sacro-lumbar nerves, the patient complaining of a heavy and dragging sensation in the groins, extending down the outside or back of the thighs, and not uncommonly experienced even in the soles of the feet. The penis is the seat of a good deal of uneasiness; frequently of a sharp and cutting pain at the end of the glans. This is especially noticed in children, in whom attention is often attracted to the complaint by their constantly squeezing and pulling the organ to relieve the distress they suffer in it. The pain is much increased by any movement by which the stone is jolted about in the bladder, as in driving, riding, or jumping; and is especially severe in those cases in which cystitis occurs. It is always most severe towards the termination of, or immediately after micturition, as there is then a tendency for the calculus to roll forwards towards the neck of the

bladder, where it comes into contact with and is grasped by the most sensitive part of that organ. Hence it is not unfrequent, in cases of calculus in children, to find that the little patient instinctively lies upon its back or on its side whilst passing urine, and thus escapes much of the agony that it would otherwise suffer. In adults in whom the prostate happens to be enlarged the calculus usually lies in a depression behind this gland; and hence, being prevented from coming into contact with the neck of the bladder, occasions less suffering than in other cases.

In consequence of the irritation set up in the bladder occasioning chronic inflammatory action of the mucous membrane, there is an *Increased Frequency of Micturition*. The urine is passed frequently, in small quantities at a time, and usually contains some mucus or pus, and is occasionally tinged with blood or loaded with thick vesical mucus. But in many cases the urine remains remarkably clear, transparent, and free from marked admixtures throughout. If the kidneys be irritated, the urine is commonly albuminous. The presence of blood in the urine is often one of the earliest signs of stone in the bladder, and in children especially should lead to the suspicion of the existence of calculus. It may be in large quantities, and may continue for many weeks, especially in the earlier stages. The urine may then clear as the bladder becomes accustomed to the presence of the stone, and only reappear upon the influence of active movement, or of any cause of increased irritation of the organ. It very rarely happens that a stone has existed for any time, without the urine becoming occasionally streaked or tinged by blood.

An occasional *Stoppage in the Flow of Urine* before the bladder is empty commonly occurs, owing to the stone being impelled against its neck, and thus blocking up the urethra; but, on the patient lying on his back or on his side, the stream flows again, the situation of the calculus being changed.

As a result of the straining and general irritation about the genito-urinary organs, *Prolapsus of the Anus*, accompanied by *Tenesmus*, is by no means uncommon, especially in children; and in some cases there is very troublesome *Priapism*.

When a stone is *encysted*, those symptoms that depend upon its being loose and rolling about in the bladder, are necessarily absent; thus there is no stoppage of the urine, this fluid is seldom bloody, and the pain is materially increased by jolts and rough movements, though there are seldom any pain in the usual situations, and increased frequency of micturition from the pressure and irritation of the calculus.

PHYSICAL DIAGNOSIS OF STONE.—The existence of stone is finally determined by *Sounding the Bladder*.

A *Sound* is a solid steel instrument shaped like a catheter, but shorter, and with a more pronounced curve (Fig. 425), so that it may explore thoroughly all parts of the bladder,

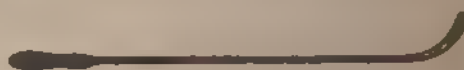

Fig. 425.—Sound for examining Bladder

especially those behind the prostate. It should have a wide and smooth handle and be slightly bulbous. The operation of sounding is conducted as follows. The patient lies upon his back on a hard mattress, a full bladder is sound well oiled and warmed is then passed into the bladder, which should, if the patient can retain it, be allowed to contain three or four ounces of urine. The surgeon then using his left hand, or crossing over to the patient's right side, whichever he finds most convenient, carefully directs the head

the instrument towards the back of the bladder, turning it from right to left over the whole of that region, as shown in the following cut (Fig. 426); he next draws it forwards on one side as far as the neck, tapping as it were gently with its beak; he repeats the same manoeuvre on the other side; and, lastly, directs the end of the instrument by raising its handle into the lower fundus, which he carefully explores. Usually the stone is readily detected by these manoeuvres, and its position in the bladder will often be dependent upon, and may to a certain extent be taken as an approximative indication, of its size.

Thus, when moderately large it will usually be found lying to one side, most generally the right, of the neck of the bladder; when small, it will be placed towards the fundus, near the orifice of one or other ureter. These then are the situations in which the surgeon should first seek for a stone, and in which

he will generally find it when present. Should it not be met with here, the chances are, more especially if the patient be elderly, that it will be found in a pouch behind the prostate, where it may be detected by raising the handle and so depressing the beak of the sound. Should the surgeon not detect the calculus in any of these situations, he depresses the handle between the thighs, and tilts up the beak so as to examine the pubic portion of the organ (Fig. 427). In the event of his not meeting with a stone, he may direct the patient to stand up, and then explore the bladder, first upon one side, then on the other. Should the rational symptoms of stone be well marked, though no calculus be struck, the surgeon must not give a decided opinion in the negative after the first exploration, but should examine the patient again a few days later,

with the bladder in different states as to its contents. In making this second examination, I have found it of great service to use a hollow steel sound, by which the organ can be injected or emptied at pleasure (Fig. 428). The patient

Fig 426.—Sounding for Stone behind Prostate

Fig 427.—Sounding for Stone above Pubes.

Fig 428.—Hollow Sound

should on this occasion have his bladder injected through such an instrument as this, with four or six ounces of tepid water, so as to distend the organ.

slightly, and prevent the folds of mucous concretion that may exist in it. Its interior way already described, and, if the stone can of the bladder are gradually allowed to exit, the patient is desired to stand up whilst the examination is made. In this way, by examining a patient in different conditions of the bladder as to capacity, and position, the existence of a stone may be ascertained. A lithotrite may occasionally be used for the detection of small calculi lying behind the bladder, more readily reached by its short beak than by the lithotome. These examinations must not, however, be continued for more than five minutes, lest the bladder should be injured. If the stone is struck by the sound, there is not only a click communicated to the instrument, but there is a vibration which can be detected by the by-standers, as well as by the surgeon.

By conducting the sounding properly, the surgeon can not only determine the existence of a stone, but its position, whether single, if it be encysted, and the general character of the stone, which it is of importance that he should be able to determine before any operation. A good deal of this information can be obtained by ordinary sounding, but some of the points can be ascertained by sounding with the lithotrite.

The hardness of the stone may usually be ascertained by the clear ringing character of the click; a lithic stone giving a sharper sound than a phosphatic one.

A calculus may generally be known to be present by the times, but not at others (Fig. 429); if the

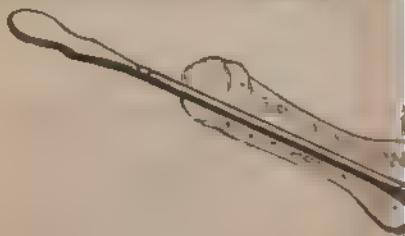

Fig. 429.—Sounding for Stones.

stone is in one situation; and if the beak of the instrument is applied to it, so as to isolate it, but feel a kind of tumour in the bladder, around or on one side of the prostate.

The fasciculated, roughened, and sacculated stones are generally detected by the way in which the instrument is moved and rubs over the organ.

The size of the calculus is best determined by the way in which the instrument is moved. A surgeon may sometimes come to a decision as to the size of the stone, by observing the extent of surface along which the instrument is being withdrawn. It can be arrived at in this way; and I have known surgeons deceived in their estimate of the size of the stone, when several small ones lying together for

lithotrite and seizing the calculus gently between its blades, a correct estimate of its size may always be arrived at.

In order to determine that several *calculi* exist in the bladder, it is sometimes sufficient for the surgeon to feel that the beak of the sound comes into contact with a stone on each side of the organ, or that it can be distinctly insinuated between two concretions. In some cases, however, these points cannot clearly be made out; and then the surgeon, introducing a lithotrite and seizing the first calculus with which he meets, should hold this between the blades of the instrument, and whilst it is so fixed move it and the lithotrite from side to side; when, if a click be heard and felt, he may be sure of the existence of another stone.

Mistake in Soundings occasionally occur. The surgeon may mistake a hardened and fasciculated bladder, having its ridges perhaps incrustated with sabulous matter, for a calculus; this is especially apt to happen in children. In these cases, however, the mistake may usually be guarded against by the absence of a distinct click, though a rough grating sensation be experienced, and by the surgeon being unable to isolate a stone. Yet the difficulty in some cases is great; Velpeau states that he is acquainted with four instances, and S. Cooper with seven, in which patients have been cut and no calculus found; and when we reflect that these accidents have happened to such men as Cheselden, who on three occasions cut a patient and found no stone; to Crosse, to Roux, and to Dupuytren, it is easy to understand that in some cases the difficulty of coming to a correct decision must be very great.

In women the symptoms of stone closely resemble those met with in men, and the detection of the calculus is usually very easy, owing to the shortness of the canal and the facility with which the stone may be tilted up by introducing the fingers of the left hand into the vagina. The sound used in these cases should be shorter and less curved than that employed for the detection of calculus in the male bladder.

PATHOLOGICAL CHANGES INDUCED BY CALCULUS.—After a stone has existed for some time in the bladder, it induces serious pathological changes in the whole of the urinary apparatus. The *urethra* usually becomes slightly dilated; and the *prostate* not unfrequently somewhat enlarged and irritable, in consequence of which a kind of pouch is formed behind it, in which the calculus is apt to lodge. The most important changes, however, take place in the bladder and kidneys. The bladder becomes extremely sensitive, especially about its neck, and is consequently unable to contain as much urine as usual; hence it becomes contracted. In some rare instances, however, as will be more especially noticed when we come to speak of lithotrity, it falls into an atonic condition, and then is apt to become rather largely dilated. The mucous membrane is commonly a good deal inflamed and irritated by the presence of the calculus; and the muscular coat becomes thickened and hypertrophied, so as to give it a very fasciculated or columnated appearance. Cysts occasionally form, containing sabulous matter and fetid pus or urine, and in some cases lodging a concretion, which then constitutes an encysted calculus lying altogether outside the cavity of the bladder, with which it merely communicates by a very narrow aperture, as in Figs. 423 and 424, representing a case that was under my care some years ago, and which is fully described in the Journals for March, 1853. The *kidneys* are usually irritated, often congested, frequently in a state of granular degeneration, and ultimately become the seat of such structural changes as are incompatible with life. When death occurs as the consequence of stone, the patient usually sinks, worn out by protracted suffering and kidney-disease.

LITHOTOMY

It is not my intention to enter into the operation that has been practised from the of the gradual modifications that have ad from the rude attempts of the Greek and and unscientific procedures adopted by the revival of letters. For all this, I would refer of Deschamps and of John Bell. The operation this country, is essentially that introduced or less according to the views of particular generally are agreed upon the great principles carrying these out ; as in the direction and instruments employed, which have been in views of particular operators. But, although tion, as modified and practised by Liston, and safest mode of cutting for the stone, no doubt that recourse may occasionally be taken by other methods instead of it. Indeed, there is no question as to the size, shape, and position of the stone ; the object of all is to render it desirable, and indeed necessary in every case. Hence, a surgeon should not be too rigid but should adopt one or other of the methods according to the exigencies of the particular case.

INSTRUMENTS.—The table for operating should be at such a height, so that when the surgeon sits on a stool he will be on a level with his breast ; a few towels should be upon the table, and covered by a piece of oil-cloth, and a tray of sand placed under it on the floor. The instruments are the following :—a pair of lithotomy forceps, a scalpel, a staff, forceps, and scoops of various sizes. There may be added a searcher, and a brass injector.

The *tapes* should be of coarse flannel, and about 12 inches broad.

The *scalpel* for the adult may be of the straight kind (Fig. 430) ; for children, it may be made of the curved kind (Fig. 431).

Fig. 430.—Lithotomy
pointed lithotomy-knife of the size and shape of the hand (Fig. 431).

Fig. 431.—Probe pointed

The *staff* should have a deep groove on the back, so that the third of the instrument, it should be well rounded, so that the urethra will admit, and have a roughened surface to prevent it from slipping.

The *forceps* must not be too heavy, but strong enough to hold the handles, and have the joint well set back so that the blades may be brought

recommended by Liston, should be lined with linen to prevent the stone from slipping (Fig. 433). Mr. Coxeter has made them with open blades, but lined with linen as heretofore (Fig. 432); in this way, as there is less

Fig. 432 — Open bladed Lithotomy Forceps.

metal, the weight is diminished, and the diameter of the instrument with a stone in its grasp is materially lessened. The ordinary forceps are straight, but it is advantageous to be provided with some that are curved (Fig. 434). The handles should be made with a loop on one side and a ring on the other; the ring for the reception of the thumb should be placed somewhat obliquely. The *scoops* of different sizes, and curved, can most conveniently be used when fixed in a roughened handle (Figs. 435 and 436). The *tube* should be of gum-elastic, well rounded at the end, and provided with silver rings. The *searcher* is a slightly curved sound, having a bulbous extremity (Fig. 438). The *syringe* presents nothing peculiar.

Searcher.

In describing the operation of lithotomy, we shall first of all consider *seriatim* the different steps of an operation that presents no unusual complication or difficulty; we shall then consider the difficulties that may be met with, and the accidents that may occur during the operation, and the principal sources of danger and the causes of death after its performance.

PREPARATION OF THE PATIENT.—Before subjecting a patient to operation, his general health must be properly attended to; and, indeed, if we find the constitution much broken by prolonged suffering, the bladder or kidneys seriously diseased, as indicated by the existence of pus or albumen in large quantity in his urine, it will be wise to postpone the operation for a time, or perhaps even to defer it altogether. There are few conditions in which a surgeon is placed, that test his moral courage more severely than the refusal to operate on a patient for stone, and thus allowing him to die unrelieved.

For a surgeon to do this, unmoved by the his friends, requires no little self reliance. emaciated, his constitution broken down, organised extensively, lithotomy would be rapidly fatal result, and the performance of act of cruelty. Supposing, however, that the urine is either healthy or contains but albumen, that there is no visceral complication of the operation, and that the patient's health will only be necessary to subject him to pre short time, so as to allay or remove irritability proceeding with it. With this view he should for about a week or ten days preceding the properly regulated, but not be of too low a level by the administration of opiates or henbane. On the day preceding the operation, a di aperient should be administered; and on the rectum must be emptied by means of an enema.

LATERAL OPERATION.—All the urine has been drawn off, that organ should be filled with eight ounces of tepid water, in order to steam and extraction of the stone. After chloroform the surgeon should introduce a full-sized staff, in order to feel for the calculus. If he detects it; if he cannot detect it, it is usually recommended to draw the staff and introduce a sound, with and, in the event of his still failing to detect the operation must be deferred, for it is that lithotomy should never be performed at the time when the patient is actually on the not to proceed with the operation unless the staff; lest the point of this, though appar

Fig. 459.—Position of Patient and Line of Incision for Lateral Lithotomy

stiffened by chronic rheumatic arthritis; but particular difficulty in the operation, though in position of the limb. The surgeon then, se

shaves the perineum—if this have not already been done—and introduces his finger into the rectum to ascertain that the gut is empty. He then gives the staff into the charge of a trusty assistant, who stands on the patient's left, and who raises and draws aside the scrotum with the left hand whilst he holds the staff in the right (Fig. 439). The surgeon then sees that the staff is held in the way in which he prefers it. There are two ways in which it may be held; it may either be drawn well up into the arch of the pubes, or it may be pushed somewhat down, and slightly turned towards the left of the perineum. Liston always employed the first method, which I certainly think is the best, as it tends to increase the space between the urethra and the rectum, and consequently lessens the danger of wounding that gut, which more than counterbalances the advantage of the other method—that of approaching the membranous portion of the urethra to the surface.

The external incision is made by entering the knife in the raphe of the perineum one inch and a half above the anus, and carrying it downwards and outwards, until it reaches a point that is just below the anus, but about one-third nearer to the tuberosity of the ischium than to the margin of the anal aperture (Fig. 439). It is useless to prolong the incision beyond this, as any freer division of the structures of the scrotum and on the nates cannot facilitate the extraction of the stone; but it must occupy the extent indicated, otherwise considerable difficulty may be experienced in the later steps of the operation. The depth to which this incision should be carried must vary according to the obesity of the subject; usually from about three-quarters of an inch to an inch, but not so deeply above as below. By this incision

the skin, superficial fascia, and subcutaneous fat are divided. After it is completed, the knife is again introduced a little below the upper part of the wound, and the blade is run lightly downwards over any resisting structures; the left fore-finger being placed at the middle of the wound, so as to protect the rectum. In this way the transversalis perinei muscle is divided, together with some cellular tissue and small vessels, and the triangular space is opened between the accelerator urine and erector penis muscles; the knife is then withdrawn, and the left index finger is pushed

Fig. 440—Lateral Lithotomy: Finger in Groove of Staff

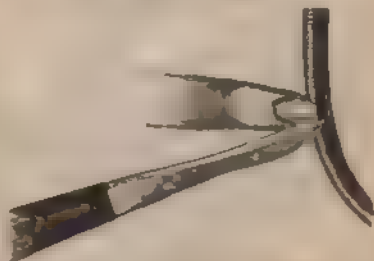

Fig. 441—Knife in Groove of Staff

deeply into this space until the edge of the nail is lodged in the groove of the staff (Fig. 440), which can be felt just anterior to the prostate, then covered by the membranous portion of the urethra. The point of the knife is then pushed through the urethra at its membranous part into the groove of the staff, above the index finger, which protects and presses to the right the rectum lying beneath it (Figs. 441 and 442).

Fig. 442.—Second Stage of Lithotomy.

When the knife is felt to be well lodged in the groove, its handle is slightly depressed, so that the point may be raised; at the same time the blade should be somewhat lateralised, so that its side lies parallel to the ramus of the ischium. The edge be turned too directed downwards towards the mesial line the rectum may be wounded, if it be directed too much outward the internal pudic artery will be endangered (Fig. 443), hence the course is the proper one.

Fig. 443.—Arteries of Perineum and Deep Fascia. The surgeon, keeping the knife steadily in this position, and pressing the point firmly against the side of the groove of the staff, which he must never for a moment let go, pushes it forwards through the deep perineal fascia, a few fibres of the levator ani, and the prostate, and thus makes an entry into the bladder.

(Fig. 442); he then withdraws the knife by keeping its back against the staff, so as not to enlarge the extent of the incision in the prostate. Through this, and along the staff, he then pushes his left index finger until it reaches the bladder, when he endeavours to feel the calculus with its tip. Should his finger be short, the perineum deep, or the prostate enlarged, he may be unable to reach the bladder in this way; and must then introduce a blunt gorget, as recommended by Cheselden and Martineau, in order to dilate the aperture in the prostate. If he use his finger for this purpose, he gives it a twist or two after passing it through the prostate, so as to expand and dilate the aperture through which it is entered. Having made sure that it is in the bladder, and having, if possible, felt the stone, he directs the assistant to withdraw the staff from the urethra.

Here let us pause, and examine the principal points in these the first and second stages of the operation. It will be observed that, in accordance with the best authorities upon this subject, and with my own experience, I have recommended the external incision to be free, the rectum to be protected by the left index-finger, the knife to be somewhat lateralised during and after the opening of the urethra, and the deep incision to be limited.

1 The *position of the knife* must be carefully attended to, especially during the deep or second incision. At this stage of the operation the edge should be *lateralised*; that is, directed about midway between the horizontal and perpendicular positions, so that the surface of the blade lies nearly parallel to the ramus of the ischium. The manner of holding the knife has been much discussed, and necessarily and naturally varies with different surgeons. I believe it signifies little how the handle of the instrument is held between the surgeon's fingers, provided the edge is never turned upwards, but is always kept well lateralised, and the point steadily pressed into the groove of the staff.

Provided a surgeon knows what he is about, he may safely hold his knife as best suits his own convenience. In the first incision, most operators, I believe, hold the knife *under* the hand, as represented in Fig. 444; a position which that excellent lithotomist and accomplished surgeon, Ferguson, preserves throughout the operation. Liston, in the early part of his career, appears to have held the knife, in the second stage of the operation, *above* the hand; and in all the representations, published as well as unpublished, that he has left of his operation, he has depicted the knife and hands in the position shown in Fig. 445; which in the last edition of

Fig. 444.—Position of Hand and Knife
(Ferguson).

Fig. 445.—Position of Hand and Knife
(Liston).

his *Practical Surgery*, he describes as a correct sketch of "the position of the hands and knife" at the commencement of the second stage of the operation. There can be no doubt, however, as Ferguson has pointed out, that in actual practice, at least after his first few years as an operator,

he held the knife under the hand, with the index-finger upon the outer back of the blade.

For my own part, I believe that every surgeon will hold the knife in a way which he finds most convenient, and, as it were, natural to him. If any rules can be laid down on this point, I should say that, in operating on a child, or on an adult with a shallow perineum, the knife is most conveniently held as represented in Fig. 444. But if the patient be fat, and the perineum deep, then I think that it is a question whether greater success may not sometimes be secured by holding the knife somewhat in the manner of a gorget, with the index-finger, perhaps, a little more upon the side of the handle (Figs. 442 and 446); in this way the point is firmly pressed into

Fig. 444 - Position of Hand and Knife (Author)

downwards. No danger can result in the deep incision from pushing the point of the knife up into the groove of the staff; but there is great danger of missing the bladder, and entering the recto-vesical space, if it be at all depressed and the handle raised, though this cannot always be avoided if the staff be pushed deeply into the bladder.

2. The incision into the prostate in the adult should be of very limited extent: on this point, I believe, all surgeons of the present day are agreed. Scarpa advises that the incision into it should not exceed five lines in adults, and two in children. It is difficult to measure the extent of the incision; it is sufficient to say, that it should be as limited as possible, and if care be taken to push the knife in, with the point well pressed against the prostate, and the blade forming but a limited angle with the shaft of the staff, and especially in withdrawing it that it be brought carefully back over the finger and still in contact with the instrument, there will be no danger in cutting too widely, or in doing more than merely notching the apex of the prostate (Fig. 447, a). The danger, however, it must be borne in mind, does not

Fig. 447 - Incision in Prostate

consist in the section of the prostate itself—which is a reality a structure of but little importance—but a cutting beyond it into the reflections of the prostatic fasciae, which will be opened up if the base of the prostate be cut, and the wound of which will, almost to a certainty, be followed by urinary extravasation and diffuse inflammation.

In the section of the prostate, then, two points have specially to be attended to: one is, that the knife in entering be not pushed forwards at too great an angle with the staff, so as to cut widely; and the other is, that

in its withdrawal the blade be kept steadily in contact with the staff. Indeed, I believe that there is more danger of doing mischief in the withdrawal than in the entry of the knife; for, if it leave the staff for a moment, all guide is lost, and the edge may sweep downwards through the base of the prostate and its investing capsule. As the knife is withdrawn, the left index-finger is pushed forwards into the aperture in the prostate, which is then dilated by its pressure to a sufficient extent for the introduction of the forceps, which are slipped in as the finger is withdrawn, and for the extraction of the stone. This part of the operation may very conveniently be performed, as was usually done by Liston, at the moment when the surgeon is stooping down, engaged in selecting his forceps. The dilatation of the prostate is readily effected; for this structure, though dense, is friable, and breaks down easily under somewhat forcible pressure by the finger. In this way, by a mere notching of the prostate,—by a slight section of its apex or urethral surface, followed by simple dilatation with the finger,—sufficient space will be obtained for the extraction of all moderate-sized calculi, without the employment of any violence, or the infliction of any bruising upon the tissues.

But another obstacle exists which will prevent the dilatation of the neck of the bladder to any very material extent, without an amount of bruising, or laceration, or even rupture that would probably prove fatal to the patient. This obstacle consists of a firm resisting tissue, which has been described by Tyrrell as “an elastic ring,” surrounding the neck of the bladder; by Liston, as “a fibrous or ligamentous band surrounding the orifice of the bladder, into which the muscular fibres of the organ are inserted.” If this ring or band be ruptured, either by the finger or by the expansion of the forceps, fatal consequences will ensue; but if it be divided, the other tissues, as Liston observes, will yield to an inconceivable extent, without injury to the tho-vesical fascia. The division of this ring must only be practised to a very limited extent. I believe that it is always effected in the act of pushing the scalpel inwards into the bladder; a mere notching of the fibres of the ring, indeed, is sufficient to allow the requisite expansion to take place when pressure is applied.

In thus describing the mode of incising the prostate and neck of the bladder, I have, generally, used the term “dilatation;” and I believe that, by a simple process of dilatation or expansion of these parts, and without any violence whatever, small calculi of or under an inch in diameter may be extracted. In fact, for the removal of such stones, no force whatever is required, either in opening up the prostate or in withdrawing the calculus. But, in removing stones of greater magnitude than this, I believe that the process of expansion of the prostate and neck of the bladder, whether effected by the finger, by a blunt gorget, or by the opening up of the blades of the forceps, is a process of laceration rather than of dilatation, as I have frequently had occasion to observe in experiments on this point made on the dead subject. This laceration is, however, confined to the substance of the prostate, and does not extend through its capsule, and into the fasciæ of the pelvis. Indeed, it is extremely difficult, nay, almost impossible, with any ordinary force, to lacerate the dense fasciæ reflected over the prostate, which, like other aponeurotic structures, scarcely admit of being torn. This structure, therefore, remains as a firm unbroken barrier between the pelvic fasciæ and the external wound, preventing the possibility of the infiltration of urine into the internal subperitoneal cellular tissue, and lessening materially the chance of the extension of diffuse inflammation into the pelvic fasciæ.

Extraction of the Stone.—A pair of forceps of size proportioned to that of the calculus, and in tepid water, must be slid along the incision, and by which the neck of the bladder is fixed by the point of the finger, and it is moved. The forceps having been introduced, when a gush of urine will usually take place, and fluid have not already escaped at the time of the prostate. By this gush the calculus is sometimes be carried into the grasp of the instrument. The stone requires to be felt for with the index finger, as has been ascertained, usually at the inferior opening are opened; and, by pushing one again, giving it a slight shake, the calculus generally

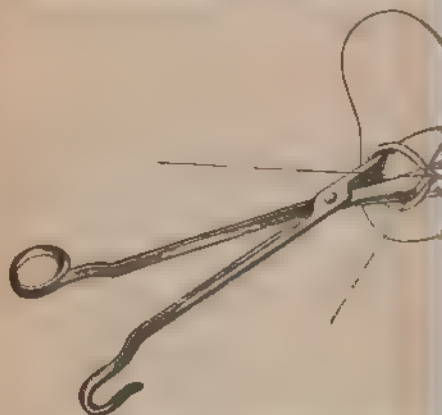

Fig. 448.—Direction of Forceps in Extraction of

stone. The forceps should be introduced along the blades, in the position for extraction. If its long axis be

Fig. 449.—Position of Finger and Scoop in Extracting Stone

in the event of fracture occurring, it will be necessary to irrigate freely and repeatedly with tepid water, injected through a tube introduced by the wound.

It is of the first importance to extract the stone, or even chipping fragments from it. No effort consistent with the safety of the patient should be made in obtaining this desirable result; not for the sake of the patient, but from a regard to the well-being of the bladder. If broken by the attempt at extraction, what is the result? obliged to introduce repeatedly the forceps to clear the bladder; the mucous membrane

ing the fragments, is liable to be pricked, bruised, and excoriated in the endeavour to seize them. The bladder requires to be frequently washed out with copious injections of tepid water, and the operation thus becomes greatly and dangerously prolonged. Even after much time and labour have been spent in these efforts, fragments are apt to be left behind which may occasion great present irritation, and, if retained, will form the nuclei of future recurrent calculi.

In children, and indeed in most cases in which the perineum is not very deep, so that after the introduction of the finger the stone can be felt and hooked forwards, the scoop is a most convenient instrument for its extraction; and in these cases I often employ it in preference to the forceps.

After the calculus has been removed, it must be examined for facets, or the interior of the bladder explored by means of a *searcher*, and, if other stones be found, they must be dealt with in the same way as the first.

The *gun-elastic tube* may then be introduced, and secured with tapes to a band round the patient's abdomen. This tube must be kept free from coagula, by the introduction into it, from time to time, of the feather of a pen. The tube is of great service by preventing the wound from becoming blocked up by coagula, and the free escape of the urine consequently interfered with. By means of this tube a ready outlet is given to the urine, the chance of infiltration is lessened, and if there be hemorrhage the wound may readily be plugged round it.

After-treatment.—The patient must then be removed to a bed, which should be properly arranged by having a large square of Macintosh cloth put across it. On this a folded sheet should be laid, which must be rolled up on the further side, so that, as it becomes wetted by the escape of urine, it may be drawn across from under the patient. This must be changed frequently, in order to keep him clean and dry. A full dose of tincture of opium in barley-water should then be given; a warm flannel laid across the abdomen; plenty of barley or gum-water allowed for drink, and nothing but rice milk or light pudding for diet during the first three or four days. After this some broth may be allowed, and the quality of the food gradually improved. Occasionally, however, it may be necessary to depart from this routine system of dieting the patient after lithotomy; and I have with great advantage allowed wine, and even brandy, a day or two after the operation. In an old man, on whom I some time ago operated at the Hospital, there was so great a tendency to depression, that it became necessary to administer the brandy-and egg mixture freely from the first; and to this, I believe, he owed his good recovery.

At the end of thirty-six or forty-eight hours the tube may be removed, the sides of the incision by that time having become glazed over, and little danger of infiltration existing. The urine continues to flow entirely through the wound for the first four or five days. About this time it frequently suddenly ceases to do so, escaping by the urethra. This is owing to the prostate becoming turgid by inflammatory action, and thus blocking up the aperture in it; but as this swelling goes down, in the course of a day or two, the urine usually escapes by the wound again, and continues to do so in gradually decreasing quantities until the aperture is finally closed, which usually happens at about the end of fourteen or eighteen days; though in patients who have suffered from phosphatic calculus it sometimes takes a longer period, owing to the broken state of the general health. Should the wound fall into a sloughy state, the patient must be put on a very generous diet, even a free allowance of stimulants; and the tincture of benzoin may

be daily applied. When slow of healing, of silver applied to the bottom; and, should may be touched with the electric cauter. constitutional treatment should be continued to prevent a recurrence of the disease.

LATERAL LITHOTOMY IN CHILDREN under the most successful of all the great operations, much in the same way as in the male; a few points of modification or of difference in young subjects. The following are worth remembering by the surgeon in proceeding to operate.

1. The urethra in children will communicate with the bladder perhaps at first be expected from their age and staff.

2. The perineum is usually proportionally smaller in consequence of the straining produced by the disease.

3. There is often from the same cause a protrusion of the rectum.

4. As the prostate is a rudimentary organ in children, necessarily passes, in most cases, beyond the neck of the bladder.

5. In children the tissues are more easily lacerable under the finger.

6. The most important point, however, is the position of the point of the knife in making the deep incision, and to be careful not to enter the recto-vesical space, which may happen under the hand of an inexperienced surgeon. I have known this to occur in several instances, and experience, the forceps being passed into the rectum, the position of its being the bladder; and in every case the finger is introduced. This accident is the more likely to happen, in children, as the tissues are very yielding, and readily admit of being pushed in; and the finger may thus pass between the bladder and the rectum, or into the loose cellular tissue of the rectum, and the bladder is opened, urine escapes; and the surgeon in the mean time, supposing the cavity, which he believes to be the interior of the bladder, so, but the recto-vesical space. The laceration of the bladder, a distressing and fatal accident is materially lessened by the use of tepid water, by which it is steadily kept open. In young children lithotomy is from this cause more dangerous. It falls to the lot of but few surgeons of the present day to pass through an active professional life without operating on children; and when it occurs, those will be the most charitable who have themselves had the most experience of the difficulties which it encounters.

DIFFICULTIES DURING LITHOTOMY.—There are two-fold; 1, in Entering the Bladder; 2, in the Extraction of the Calculus.

1. *Difficulty in Entering the Bladder*—This may, however, arise in consequence of the point of the knife well lodged in the groove of the urethra, and pushed into the recto-vesical space; the tissue

a kind of cavity that he mistakes for the interior of the bladder. If the perineum be very deep and the prostate enlarged, he may also experience some difficulty in reaching the bladder; but he can scarcely fail to do so if he push the knife well on in the groove of the staff, and dilate the incision in the prostate with a blunt gorget, if his finger fail to reach the cavity beyond it.

In children, however, great and sometimes insuperable difficulty has been experienced in opening the bladder. This difficulty arises in consequence of the small size of the urethra, the mobility of the bladder, and the ready lacerability of the tissues. If, after the groove in the staff has been exposed, care be not taken to insinuate, as it were, the nail into the opening in the urethra thus made, the membranous portion may be torn across; and the neck of the bladder, receding before the finger, may easily be pushed away from the surface, so that the surgeon may fail in reaching the cavity of the organ. When the road is once lost in this way, there is the very greatest difficulty in finding it again. The course that should be pursued is, I think, as follows. If the staff have not been withdrawn, the surgeon must again place the knife in its groove, and carefully push it on towards the neck of the bladder, notching that structure and passing the finger cautiously along the groove, and hooking down the parts with his nail until he reach the inside of the bladder. Should the staff have been withdrawn, the surgeon must endeavour to pass it again; if he succeed in this, he may act as just stated; but if he cannot succeed in introducing the staff fairly into the bladder, he must on no account whatever endeavour to open that viscus, or continue his attempts at the extraction of the calculus, but must at once abandon the operation until the parts have healed, when he can repeat it. The great danger in these cases arises from the surgeon losing his presence of mind, and endeavouring to enter the bladder without a guide—a procedure which must be unsuccessful, and can only end in the destruction of the patient.

In adults, the difficulty is to get out the stone; in children, to get into the bladder.

2. *Difficulty in Seizing and Extracting the Stone* is far more frequently met with than in reaching the bladder. This may be owing to a variety of causes. It is likely to happen in all those cases in which, either from the depth at which the bladder lies from the surface, or from the peculiar position of the calculus, the stone cannot be felt with the finger after the incisions have been made into the neck of the bladder.

Difficulty from the Position of the Stone.—The calculus may be lodged in the lower fundus. This is especially apt to happen if the patient be old and fat, and have a deep perineum, perhaps with enlarged prostate, behind which the stone may be lodged. This constitutes the greatest difficulty. Here the best plan is to use a much-curved pair of forceps, and to tilt the bladder up by introducing the finger into the rectum, so as to bring the stone within reach.

When the stone is situated in the upper fundus of the bladder, above the pubes, it is altogether out of the axis of the incision, and in such a case can only be extracted with great difficulty. Aston Key recommends that in such cases the abdomen should be compressed, and the calculus thus pushed down into reach. This suggestion is a very useful one; and it was only by employing this manoeuvre and using a very curved scoop, that I could remove a calculus lodged above the pubes, in the first patient whom I cut at the Hospital, many years ago.

Difficulty in consequence of the Stone being Fixed to or Retained in the

Bladder.—A small calculus may be encased in a membrane, and in this way elude the surgeon. In such circumstances, there is nothing for the surgeon to do but to disentangle and remove the calculus by means of a probe, if it can be so reached; if not, by expanding the bladder, and pushing aside the mucous membrane that surrounds it.

In consequence of *spasm of the bladder*, it has happened that a calculus has been so fixed, that, on application of the forceps, the blades closed between the walls of the viscus without touching the stone, and giving rise to the danger of rupture. I have been disposed to think that this "spasm of the bladder" is not so much a spasm, and that the real difficulty has arisen from a contracted and rickety pelvis. But, whatever the cause, the difficulty that has undoubtedly been encountered by the surgeon to desist from the operation, and for weeks endeavour to complete the extraction "*à deux temps*" of Deschamps.

The stone may be so fixed between the neck and the bladder, as to be detached with the forceps, the scoop will be found to be the best instrument for removal.

When the calculus is *encysted*, its extraction is attended with most dangerous consequences. In such cases, to operate is to operate in cases of encysted calculus the surgeon has been unfortunate. In such cases, containing an encysted calculus, he must be guided by the condition in which he finds the bladder. If the cyst be very small, as in Fig. 424, he must go no further with the operation, as it will not be worth the trouble. If, on the other hand, the cyst be large, he might feel disposed to make an effort to remove it. In such a view he might adopt the plan pursued by Deschamps, to endeavour to enlarge the orifice of the cyst by the bistoury cautiously applied, and then find the scoop. Such a proceeding, however, is in such cases, in account of the readiness with which the stone will escape the tonal cavity; as well as difficult in execution, as the parts are lying.

I believe that a calculus may occasionally be encapsuled, in another way,—by being enclosed in a membrane whilst lying on the floor of the bladder. In a child on whom I operated for stone some years ago, of about the size of a pea, I felt, with the finger, a body, covered apparently by mucous membrane, on the floor of the bladder. On scraping through the membrane with the point of my nail and a curved scoop, I extracted it, with a cyst attached to it. This cyst, which was of about the thickness of a pin, had a reddish colour, and resembling a piece of parchment. It was found to be a false membrane, composed of a single layer. The patient made a good recovery, without any of secondary hæmorrhage, which occurs after such an operation.

Rickets of the Pelvic Bones may constitute a serious or even an insuperable obstacle to the extraction of a calculus. This condition may act in two ways. It may narrow the brim of the pelvis in its antero-posterior diameter, to so great an extent as to prevent the passage of the stone downwards after it has been seized by the forceps. This condition is more to be feared in children, in whom the bladder, being an abdominal organ and lying high, is altogether above the brim of the pelvis in these cases. Or there may be difficulty in the extraction of the stone through the inferior outlet, owing to the approximation of the rami on each side. The first cause of difficulty once occurred to me, in operating on a very rickety boy four years and a half old. Of the second I have had no experience. The rickety condition of the pelvis may be suspected in cases in which the lower limbs are much distorted. Its existence may be ascertained by digital exploration of the rectum, and by external measurements. If it be found to exist to an extreme degree, it would probably be safer to perform the suprapubic operation.

Difficulty depending upon the Shape and Size of the Stone.—If the stone be very round, it is usually more difficult to seize than when flat or elongated. Flat, disc-shaped calculi, however, occasionally fall into the fundus of the bladder behind the prostate, and then cannot be readily reached by the forceps, which passes over them. Under these circumstances, they are best extracted by the curved scoop. Very flat broad calculi, and those that are round, egg-shaped, or branched, are the most difficult to remove, even though their size be not very great. As a general rule, however, it may be stated that, the larger the calculus, the more difficult is its extraction. This arises not so much from the outlet of the pelvis being too narrow, as from the necessity of making the internal incisions through the prostate to a very limited extent. There will always be considerable difficulty experienced in extracting calculi weighing six or eight ounces and upwards; though cases are recorded by Cheselden, Klein, and others, in which calculi from twelve to fifteen ounces in weight have been extracted by the lateral operation. Any calculus above one inch and a half in its shorter diameter will present considerable difficulties in being extracted through an incision in the prostate of the ordinary size; viz., not exceeding eight lines in length, even though this be considerably dilated by the pressure of the fingers; and I think it may be safely said, that a calculus two inches and upwards in diameter can scarcely be removed by the ordinary lateral operation with any degree of force which it is safe to employ. In the facility with which the calculus is extracted, however, much will depend upon the make of the forceps. As Liston most truly observes, "There can be no more fatal error than to attempt the extraction of a large stone with short and shabby forceps." In these cases I think the open-bladed forceps (Fig. 432) will be found useful, the absence of metal in the most convex part of the blade lessening materially the bulk of the instrument when grasping a stone.

In the event of the calculus being too large to be extracted by the ordinary lateral operation, what course should the surgeon pursue? Three are open to him: 1. Division of the Right Side of the Prostate from the interior of the wound; 2. Crushing the Calculus in the Bladder, and then removing it; and 3. The performance of the Recto-vesical Operation.

The Incision of the Right Side of the Prostate gives considerable additional space, and is sufficient for most ordinary purposes; very large calculi being fortunately very rarely met with. This section may be made in introducing into the wound a probe-pointed scalpel (Fig. 431), guided by the index-finger, and cautiously dividing the right side of the prostate downwards

and outwards, in the same way that the section of the left has been made. This procedure must be carefully done, with due regard to the important parts in the neighbourhood of the gland. In two cases I have seen Liston do this. In one the patient recovered, in the other he died of diffuse cellular inflammation of the pelvis; and I have had occasion to practise it once on a patient whom I cut at the Hospital, and who made an excellent recovery.

The second plan, that of *Crushing the Calculus in the Bladder through the wound in the perineum*, would certainly be a hazardous procedure. The

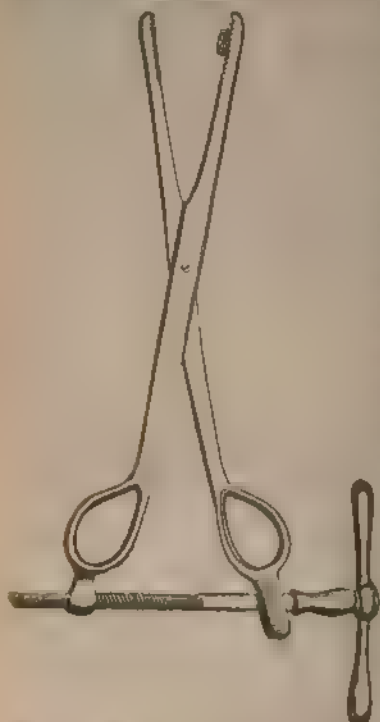

Fig. 450.—Lithotomy Crusher for Large Stone.

irritation that would necessarily be set up by the large incision, or crusher (Fig. 450) that has been devised for this purpose, by the presence of the fragments of stone, and by the necessary difficulty and delay of clearing them out of the wound, would probably be fatal to the patient. In the event of its being impossible to extract the calculus through the perineum, I think it would be safer to adopt the third course, and to perform the medical operation, which will presently be described. Should, however, the unusually large size of the stone have been recognised at the commencement of the operation, it might be thought more advisable to practise the high or the recto-vesical than the lateral operation.

Difficulty from Fracture of the Calculus.—The difficulty of extracting is greatly increased if the stone is broken. Fracture of a calculus is of two kinds. In the one case the stone is simply broken into small fragments, or splinters, so to speak, are detached from it. This accident may happen to hard as well as to soft calculi, and is generally owing to the surgeon employing too much pressure on the blades of the forceps, fearing that the stone may slip from between them; or it may arise from the large size of the calculus requiring some force to be exercised in its extraction, when the surgeon is very apt to compress the forceps as he draws the stone down. When this accident is found to have occurred, the surgeon must remove with care the fragments that have been detached. He should then wash out the bladder by copious injections of tepid water, and very carefully examine its interior for any loose pieces. It is seldom that any ill consequences result from this occurrence, except delay in the completion of the operation.

The second mode of fracture consists in the crumbling down of the calculus, so soon as it is seized by the forceps, into a soft mortary mass. The stone is not broken into large pieces, but, having naturally little cohesion, disintegrates into a mass of softish fragments, none of which pieces exceed a cherry-stone in size, and which indeed resemble a wet mortar.

aggregation, rather than distinct pieces of calculus. This crumbling down can only occur in phosphatic calculi, and is more likely to happen with the triple phosphate. It is in no way the fault of the surgeon, but arises from want of cohesion in the calculus, so that the blades of the forceps bite, as it were, through it. It is an unpleasant accident to occur, as it becomes extremely difficult, if not impossible, to clear away the whole of the soft mortary detritus from the interior of the bladder, to the lining membrane of which it tenaciously adheres, small masses lying under the folds into which the contracted organ is thrown. As much as possible should be removed by the scoop, and the remainder washed away, as far as practicable, by copious injections; with all care, however, some will be left behind, and may be discharged through the wound some days, or even two or three weeks, after the operation. When this happens, the bladder should be thoroughly washed out every day, or every second day, by warm water injections thrown in through a catheter passed down the urethra and allowed to regurgitate through the wound; and this plan must be persevered in so long as any foreign body escapes. Should the wound have healed, the detritus must be treated as in a case of lithotrity; and, by means of a large-eyed catheter, the bladder must be washed out every second or third day until all is removed.

ACCIDENTS DURING LITHOTOMY—The principal accidents that may occur during the performance of the lateral operation of lithotomy are Hemorrhage; Cutting the Bulb; Missing the Membranous Portion of the Urethra; Wound of the Rectum; or Wound of the Posterior Part of the Bladder.

Hemorrhage during lithotomy may occur from three sources:—1. The Superficial Arteries of the Perineum; 2. The Deep Arteries of this region; and, 3. The Prostatic and other Veins. When excessive, from whatever source it proceeds, it is always a very serious complication; for even if it do not prove fatal by the induction of syncope, &c., which I believe to be very rarely the case, it is apt to lead to a fatal termination indirectly, and at a later period, by favouring or predisposing to the occurrence of low inflammatory diseases, local or constitutional. I believe that patients who lose a large quantity of blood at the operation seldom recover.

1. Hemorrhage from the *Division of the Superficial or the Transverse Artery of the Perineum* is seldom of a very dangerous character, though occasionally, if these vessels be of larger size than usual, they may furnish a serious quantity of blood; in such circumstances their ligature would be required, and might be practised either before or after the extraction of the calculus. It is better, if possible, to wait until the completion of the operation, lest the ligature be pulled off during the extraction of the stone.

2. The *Division of the Deep Arteries* of the perineum, that of the bulb and the internal pudic, would be attended by far more serious, perhaps even by fatal consequences; as, from the depth at which the vessels are seated, it would almost be impossible to apply a ligature to them, unless the patient were very thin, and the perineum proportionately shallow. In the event of a ligature not being applicable, the surgeon would have to trust to plugging the wound around the tube, or to the pressure of an assistant's fingers continued for a considerable time. The pressure of the fingers of relays of assistants, kept up for a considerable length of time, is perhaps the surest mode of arresting the hemorrhage. The pressure must be kept up for many hours, thus South relates a case in which it was maintained for fourteen hours; and Brodie one in which, after twenty-four hours, it succeeded. The assistants should not be changed more frequently than necessary, each keeping up pressure for two or three hours, and removing his fingers as

cautiously as possible. It is, doubtless, very rare for these arteries to be wounded when they follow their usual course; though such accidents have happened in the hands of some of the most skilful lithotomists, such as Home, Bell, Roux, and Desault. It was the opinion of Aston Key that the artery of the bulb was generally cut during lithotomy; but in this I believe he was mistaken, so far as its trunk is concerned, though doubtless in many cases the bulb itself may be wounded, and the mesh of twigs, in which the vessel terminates, divided; this, however, would not yield an alarming hemorrhage. The trunk of the artery of the bulb would, however, be endangered by opening the urethra too high up, and lateralising the knife too early, and might bleed very freely.

The internal pudic artery, bound down by a strong fascia and under cover of the ramus of the ischium, runs but little risk unless the knife be lateralised too much, and the incision be carried too far outwards. It is in some of the anomalous distributions of these vessels that the greatest danger would be occasioned. The artery of the bulb, the inferior hemorrhoidal, the dorsal artery of the penis, or the internal pudic, may take such an anomalous course that their division must be inevitable; and, as the surgeon has no possible means of knowing beforehand whether the distribution of the arteries is regular or not, and as his incisions are all planned on the supposition that they are, he is not to blame in the event of a vessel being accidentally divided, when it takes an abnormal direction, with which it is impossible to be acquainted until after the accident has occurred.

If the incision be commenced too high up, and especially if the upper part of the first incision be made by pushing the knife in too deeply, the corpus cavernosum and its vessels may be wounded.

It may, I think, be stated as a general rule, that serious hemorrhage is usually best avoided by making the incisions low; and indeed, I believe that the great secret of success in the lateral operation of lithotomy consists in making all the deep incisions as low as practicable; the knife entering the groove of the staff from below upwards, rather than from above downwards.

3. *Venous Hemorrhage* may occur from two sources—the superficial or the prostatic veins. It is very seldom that any trouble arises from superficial veins; but in one case I have seen very considerable loss of blood occur from a large vein running transversely to and near the upper angle of the wound, lying almost immediately under the skin, which had been incompletely divided. From the prostatic plexus hemorrhage is most likely to occur in old people, in whom the veins in this situation are often enlarged—almost hemorrhoidal.

Whether the venous bleeding takes place from a superficial or a deep source, it is very apt to find its way back into the bladder, to mix with the urine, and thus to escape through the tube rather than from the wound itself; or the blood may probably coagulate in the interior of the bladder, distending that organ and producing a feeling of dysuria. Should it proceed from a superficial source, it may be necessary, as was done in the case just alluded to, to pass a ligature under the vessel, and thus arrest it. If it occur from the prostatic veins, the better plan will be to plug the wound. This is done by passing long strips of lint, either dry or soaked in a solution of perchloride of iron or of alum, along the tube, which must be left to the wound and kept pervious, or the lithotomy tube may have a "petticoat" of thick muslin tied round it, into which the strips of lint are stuffed. The advantage of this arrangement is, that the whole apparatus may very easily be removed together at the end of forty-eight hours.

Hæmorrhage from any of the above named sources, but more especially from the deep arteries and veins, may take place into the bladder; when this occurs, the urine that escapes will be seen to be deeply mixed with blood, and coagula will form in the interior of the viscus, which becomes distended and rises above the pubes, with dulness on percussion in the hypogastric region. The patient will become pale, faint, and cold. Under such circumstances, the coagula must be washed out of the bladder with cold water, the source of hæmorrhage ascertained by an examination of the wound, the further flow of blood arrested by plugging the ligature or the actual cautery, restoratives administered, the pelvis placed high, and the patient kept cool.

Wound of the Bulb is not of very uncommon occurrence in lithotomy; and I believe is of no consequence beyond furnishing a small additional quantity of blood. Indeed, the bulb is so situated, in many cases overlapping the membranous portion of the urethra, that this can scarcely be opened without wounding it.

Missing the Urethra altogether, and opening up the bladder through or even altogether beyond the prostate, is an accident that may happen if the surgeon miscalculate the depth of the perineum, and, keeping the incisions too low, thrust the knife too deeply. It is, I believe, an inevitably fatal accident, as in it the base of the bladder and the recto-vesical fascia are opened, and the patient is thus exposed to the occurrence of diffuse inflammation of, and infiltration into, the pelvic fascia. I was present many years ago at the *post mortem* examination of a fatal case of lithotomy, in which perhaps the most skilful operator of that day had opened the bladder beyond the prostate, leaving the urethra altogether untouched, and in which the patient had died from the cause just stated.

Wound of the Rectum occurs, I believe, more frequently than is generally supposed. It may happen either in consequence of the staff being too much depressed, the edge of the knife turned too directly downwards, or the rectum being distended and overlapping the sides of the prostate. I have also known the lower part of the rectum perforated by the surgeon's finger, whilst depressing the gut so as to keep it out of the way of the knife. The *Treatment* of this accident will vary according to the size and situation of the aperture. If it be of but moderate extent and low down, just above the anus, it will probably close as the wound granulates and the urine resumes its passage through the urethra. If the incision be more extensive and higher up, the patient will incur the risk of the miserable infirmity of recto-vesical fistula being induced. In such circumstances the proper treatment is to divide the sphincter and from the opening downwards, and thus to lay the gut and wound into one cavity, which will probably fill by granulation, and thus close the urinary passages.

Wound of the Posterior Part of the Bladder is, I believe, of very rare occurrence; yet it has happened in consequence of the knife being thrust too deeply along the groove of the staff, more particularly in operations on children, and would be specially apt to happen in such cases if the bladder did not contain much urine at the time. This is an additional reason for injecting the bladder before operating.

In *children*, the lateral operation of lithotomy presents certain special difficulties which have already been adverted to. These are; 1, the surgeon missing the bladder and opening up the recto-vesical space (p. 1088), 2, not opening the urethra and neck of the bladder sufficiently with the knife, but pushing these parts before the finger, and so tearing across the urethra, and thus necessarily being unable to complete the operation (p. 1089); and 3,

running the knife too far along the groove of the staff into the bladder, and thus wounding the posterior part of that organ.

SOURCES OF DANGER AND CAUSES OF DEATH AFTER LITHOTOMY.—Lithotomy, even in healthy subjects, is always a dangerous operation; and though the rate of mortality doubtless depends greatly upon the dexterity and skill of the operator, more is, I believe, due to the constitution and age of the patient, and especially to the state of his kidneys. Sir B. Brodie most justly says, "Success in lithotomy most undoubtedly depends in great degree on the manual skill of the surgeon, and on the mode in which the operation is performed; but it depends still more on the condition of the patient with respect to his general health, especially on the existence or non-existence of organic disease." That the mere cutting into the bladder is not a very dangerous proceeding, provided that viscus and the kidney be healthy, is evident from the fact that in those cases in which surgeons have had to extract bullets, bits of catheter, &c., from this organ, bad consequences have rarely occurred, though the operations have often been tedious. In lithotomy the case is different; for here the bladder is not usually in a state of chronic irritation, but the kidneys are frequently diseased, and these conditions influence the result of the operation materially than any other circumstances. Hence an operator may have run of unsuccessful cases; or by a fortunate concurrence of favourable causes more particularly in children, it has occasionally happened that a surgeon has cut 20 or 30 patients in succession without losing a single one, but several deaths then occurring, though the operation was performed in the same way and with the same care as before, his average had fallen to above the usual level. Green, at St. Thomas's, cut 40 patients in succession and only lost one. Lynn cut 25 patients for stone without losing one, and he said that he thought he had at last discovered the secret of performing lithotomy with success; but, he added, the Almighty punished him for his presumption, for he lost the next 4 cases that he cut. Brand Cooper, of Guy's, cut 30 patients in succession without a death, but he lost several, thus reducing the rate of mortality to the usual standard. Liston, during a period of six years, in which he operated 24 times, lost a patient from lithotomy at University College Hospital; but out of the whole 37 cases which he cut during the period of his connection with that institution, there were 5 deaths; reducing the average to 1 in 7.2. This success was, however, very great when it is taken into consideration that most of these cases occurred in adults, and that many of them were of a very serious character. I find on reference to the Hospital Records, that only 7 of the patients were under 10 years of age, whilst 14 were above 50; of these, 10 were 80 years of age, of whom one died and the other recovered. I believe that Liston lost only one patient under 60 years of age, and that was that of 18, in whom he found it necessary to divide the right side of the prostate as well as the left, and who died of infiltration of urine. Thirty-eight patients, successively operated on at the Norwich Infirmary, recovered, but the average rate of mortality in that Institution, calculated from 76 cases, has been 1 in 7½. Cheselden only lost 1 in every 10½, and, according to South, at St. Thomas's the mortality has not amounted to more than 1 in 9½; but a good many of these patients were probably children. Sir B. Brodie states, that of the 59 cases operated on in all the London Hospitals in the year 1854, 10 died; making the mortality as nearly as possible 1 in 6. But the more recent and extended statistics collected by Thompson, shows that the average mortality in the London Hospitals is 1 in 7½. According to Coulson the average mortality in England, during

from 1743 cases of the lateral operation, is 1 in 6·93 cases; whilst in France it is 1 in 5·7; and for Europe generally 1 in 5·14. The more recent statistics of Thompson show a more favourable result for lateral lithotomy in England. He finds that out of 1827 cases there were 220 deaths, or as nearly as possible 1 in 8.

Age exercises a more marked influence on the result of lithotomy than any other condition. Lithotomy may be looked upon as one of the most successful operations in surgery at early periods of life, a hazardous one in middle age, and an extremely dangerous one at advanced age. At the Norwich Hospital, lithotomy has been found to be four times as fatal in adults as in children. Coulson finds, on analysing 2972 cases of lithotomy, that the mortality at each successive decennial period is as follows. Below 10 years it is 1 in 13, and thence gradually augments from 10 to 80 years to 1 in 9, 1 in 6, 1 in 5, 1 in 4, 1 in 3·65, 1 in 3·23, 1 in 2·71.

The reason of the small mortality after lithotomy in children, as compared with adults, is twofold. In the first place, the urinary organs are less developed, and possess far less irritability than in the adult; and secondly and chiefly, the urine is less acrid, less irritating, less loaded with effete materials of an unhealthy character, and is consequently less apt to excite inflammation in those tissues over which it filtrates in its passage through the wound.

When children die after lithotomy, they do not usually perish from the same causes that prove fatal in the adult, viz. kidney-disease and diffuse pelvic inflammations and infiltrations; but they usually die in consequence of some accidental violence having been inflicted during the operation, such as the mistaking the recto-vesical space for the interior of the bladder, tearing across of the urethra and non-extraction of the stone, wounding of the recto-vesical fold of peritoneum, or perforation of the bladder by the point of the scalpel. It is by these accidents usually that death happens in children that are cut for stone, and not from circumstances that may follow the most skilfully performed operation.

The *Shock of the Operation* occasionally proves fatal, though probably much less frequently since the introduction of chloroform than was formerly the case. Yet, even now, patients occasionally die from this cause, induced either by a very much prolonged operation, or by the system being weakened, and having lost its resisting power in consequence of disease of the kidneys, perhaps of a latent character.

The *State of the Kidneys* influences the result of lithotomy in the adult more directly than any other condition. If these organs be sound, the patient will usually recover; hence in children, in whom the complication of renal disease rarely exists, lithotomy is very successful, even though the operation is proportionately far more severe in them than in adults. If, on the other hand, the kidneys be extensively and chronically diseased, the patient will commonly die, even though he have been operated upon with the utmost care and skill. The condition of the kidneys that is especially fatal is chronic pyelitis, and a granular state of the organs. This morbid condition is chiefly evidenced by the presence of albumen in considerable quantities in the urine, with muco-pus. If the albumen, in subsiding to the bottom of a test tube, after being coagulated by heat and acid, form a precipitate that does not amount to more than one-tenth of the bulk of the urine, the case may, I think, be looked upon as tolerably favourable; but, if it amount to one-sixth, the case is decidedly unfavourable, though even under these circumstances I have often seen recovery take place. Yet, with kidney-disease that will furnish such a quantity of albumen as this, the patient

will be very liable to the occurrence of low and diffuse cellular inflammation.

A *Prolonged Operation*, even under chloroform, is dangerous, and, although it is certainly not well to operate against time, yet it is undoubtedly advantageous to finish the operation with as little delay as is consistent with the safety of the patient, even though he be anesthetized.

Hemorrhage does not so often prove fatal, either shortly after the operation, or at a later period, as might be expected from the great vascularity of the parts incised. Secondary hemorrhage, of a dangerous or even fatal character, may, however, come on six, eight, or ten days after the operation. I have known it as late as the fourteenth day. It must be borne in mind that, when hemorrhage takes place after the operation, the blood may find its way into the bladder rather than escape externally, detained by the wound with coagula, but not giving any external evidence of the mischief that has occurred. Secondary hemorrhage will usually cease on plugging the wound with sponge or lint soaked in alum solutions. Should it prove serious, however, the actual cautery may be advantageously employed. In a case that occurred to me on the ninth day, the bleeding was stopped by wiping on the wound with the actual cautery, a practice which, I have been assured by Mr. A. Dalrymple, was occasionally successfully practised by that distinguished lithotomist, his father.

Cystitis is, in my experience, a rare sequence of lithotomy. I have, however, seen it occur, attended by the secretion of large quantities of ropy mucous from the bladder, coming away two or three days after the operation, with tenderness in the suprapubic region. It may arise before the operation, or occur either from long continued or rough manipulations with the forceps in searching for the stone, or from the irritation of the tube. The symptoms are apt to simulate those of pelvic peritonitis. The Treatment consists of leeches above the pubes, abundant demulents, and washing out the bladder with tepid water injected through the wound.

Diffuse Inflammation of the Cellular Tissue of the Pelvis, especially of the layers around the neck of the bladder, between it and the rectum, and that extend from thence under the peritoneum, is the most frequent cause of death after lithotomy. This inflammation, which is always of the erysipelatous kind, followed by rapid sloughing of the textures that it invades, may arise from two causes. 1. From the urine being introduced into the cellular tissue, in consequence of the incision extending beyond the limits of the prostate, into the loose layers of tissue that surround that gland; 2. In consequence of the bruising and laceration to which the neck of the bladder, the prostate, and the textures between it and the rectum, are subjected, in prolonged attempts to extract a large calculus from the bladder.

1. The danger of *Cutting beyond the Limits of the Prostate* in the actual has already been adverted to. In the extraction of calculi of ordinary size there can be no necessity to extend the internal incision, but when the calculus is of considerable magnitude, the surgeon, wishing to get as much space as possible, may inadvertently carry his knife beyond the prostate, or, if he make a cut into the right side of this gland, he may perhaps go a little too far, and thus open the loose cellular tissue or fascia which surrounds it, and which is continuous with the pelvic and subperitoneal space of cellular membrane. By dilating the incision in the prostate downwards and outwards, either with the finger or with a blunt gorget, the dense tissue surrounding the gland is not divided, and injury to this tissue is prevented.

If the incision extend beyond the prostate, the urine, as it escapes through

the wound, sinks into the meshes of the loose cellular tissue over which it flows, and thus gives rise to infiltration, followed by rapidly extending inflammation and sloughing, which speedily involve the whole of the neighbouring textures. This mischief generally occurs within the first forty-eight hours; indeed, I have never seen it come on after the third day. It is indicated by the patient being seized with rigors, followed by dry heat of skin, a quick pulse, which, after a time, may become intermittent, and a dry and brown tongue. At the same time he will complain of some tenderness about the lower part of the abdomen, and in the groins; the belly becomes tympanitic, the body covered with a profuse sweat; hiccup comes on, the pulse becomes more weak and fluttering, and death usually occurs about the fourth or fifth day after the operation. In some cases, there are more decided signs of peritoneal inflammation; but, as Brodie very truly remarks, this is not the primary disease, but is only induced secondarily by the inflammation and sloughing of the cellular tissue of the pelvis spreading to the contiguous serous membrane.

The *Treatment* of such cases must be conducted on the ordinary principles that guide us in the management of diffuse inflammations. It is only by administering ammonia, with such a quantity of wine or brandy as the state of the system may indicate, together with such nourishment as the patient can take, that life can be preserved. The disease is a depressing one, and requires a stimulating plan of treatment. Brodie has recommended that in these cases a free incision should be made through the sloughy tissues about the wound into the rectum, in accordance with the general principles that guide us in the management of similar affections elsewhere. In one case of the kind that occurred under his care, he saved the patient by passing a curved probe pointed bistoury into the wound to its furthest extremity, to the left side of the neck of the bladder; he then pushed it through the tunics of the rectum, and, drawing it downwards, divided the lower part of the gut together with the sphincter; thus laying the wound and the rectum into one. The relief was immediate, and the patient recovered. This plan of treatment certainly seems rational, and worthy of trial in similar cases.

2. Diffuse inflammation of the cellular tissue around the neck of the bladder and prostate arising from *Bruising and Over-distension* of the parts during the extraction of a large calculus is, I believe, a more frequent occurrence than infiltration of urine, and fully as fatal. This sequence of lithotomy is especially apt to occur in those cases in which, in consequence of diseased kidneys, or the existence of other organic mischief, the patient is more than usually liable to the supervention of diffuse or erysipelatous inflammation; indeed it is in this indirect way, I believe, that diseased kidneys constitute such a formidable obstacle to the safe performance of lithotomy.

In the extraction of large calculi, considerable traction is required, and force must be exerted; hence undue bruising and pressure are very apt to be inflicted upon the parts that constitute the line of incision. It is in this way that the danger of lithotomy increases almost in exact proportion to the size of the calculus: for here the surgeon is often placed between the horns of a dilemma. He must either cut beyond the limits of the prostate, and thus incur the risk of inducing urinary infiltration into, or diffuse inflammation of, the pelvic fasciæ: or else, by limiting his incision to the margin of the gland, and thus having, perhaps, an aperture of insufficient size, he may inflict severe injury by the bruising and laceration of parts during forcible and possibly prolonged efforts at extraction. It must, however, be borne in mind that, the larger the stone, the more probability is there of the existence of old standing disease of the bladder or kidneys, and of an unfavourable result

from this cause. Crosse, of Norwich, has drawn up a table that shows the influence of the weight, or in other words, of the size of a calculus on the results of lithotomy. He found that when the stone was one ounce and under in weight, the deaths were in the proportion of 1 in 11.25 cases. When it was from 1 to 2 ounces in weight, there was 1 death in 6.61 cases: when from 2 to 3 ounces, 1 death in 2.18 cases: when from 3 to 4 ounces, 1 death in 1.57 cases: when from 4 to 5 ounces, 1 death in 1.66 cases. The table, which has been constructed on the results of 703 cases, illustrates very clearly the fact, that the operation for the removal of a large calculus is more dangerous than that for the extraction of a small one.

The symptoms of diffuse inflammation of the cellular tissue arising from the cause now under discussion, very closely resemble those from infiltration of urine, and the treatment must be conducted on precisely similar principles.

Peritonitis does not frequently occur after lithotomy, except as a consequence of the extension of inflammation from the bladder or the pelvic fasciæ to the serous membrane, or from wound of the posterior part of the bladder. To one or other of these conditions, more especially inflammation of the pelvic fasciæ, it will always be found to be secondary.

Sloughing.—In persons of a feeble and cachectic habit, especially in the who are the subjects of phosphatic calculi, the wound will often assume a sloughy condition, and heal slowly. In such cases a liberal allowance of stimulants will be required, together with the local application of compound tincture of benzoin; and, in order to facilitate contraction at a more remote period, a solution of nitrate of silver, or the tincture of cantharides.

Having finished the consideration of the ordinary lateral operation, we shall now proceed to that of other methods for extracting the stone by cutting procedures. These are the *Median*, the *Bilateral*, the *Medio-lateral*, and the *Suprapubic* operations; each of which has its advocates, to the exclusion of the others, and each of which undoubtedly possesses certain special advantages. In addition to these, there are various modifications of these different operations which the ingenuity of surgeons has devised, but which are usually little to recommend them in the eyes of any except their originators.

MEDIAN LITHOTOMY.—The *median* operation of lithotomy is that procedure by which a stone is extracted through an incision in the raphe of the perineum, extending into the urethra behind the bulb.

History.—The history of the median operation affords an illustration of the mutability of professional opinion, and makes it appear as if there were a cycle of opinion in surgery, as in fashion, politics, and philosophy. The median operation was introduced three or four hundred years ago, and continued to be practised up to the middle of the last century, when, on account of its tediousness, its painful character, and the excessive mortality following, it caused it to fall into disuse as soon as the safer and simpler method of Celsus was introduced. Of late years, however, it has been revived under a somewhat modified form; and it is this modern median operation, and supposed advantages over the lateral, that we must here consider.

The old median operation—called also the "*Marian*," from one Sanson Marianus, who wrote on it, though it did not originate with him, and "*operation of the apparatus major*," from the number of instruments used in it—was performed in the following manner, according to John Hall: a grooved staff was introduced into the bladder, and the patient tied up in the usual way; the lithotomist then, kneeling or sitting before him, made an incision in the perineum, not exactly in the raphe, which was thought to be dangerous, but very slightly to the left side, and terminating just above the anus. The knife was then carried on to the membranous part of the urethra.

which was opened on the groove of the staff; and, the knife being kept firmly pressed against the staff, a long probe was introduced into the bladder by its side. The knife and the staff were now withdrawn, nothing but the probe being left in the bladder, to serve as a guide into this cavity. Along this probe, two iron rods, called "conductors," were now passed, and with these the operator dilated the prostate and neck of the bladder, by separating the handles—at least, it was said that he dilated them, but, as John Bell pathily observes, "he dilated, or, in plain language, tore open, the prostate gland." These conductors being held aside, "dilators" were introduced so as to enlarge the opening, the forceps were then pushed into the bladder, and the stone extracted as it best could.

The principles of this operation were—a limited incision in the membranous part of the urethra above the anus; dilatation, and not incision, of the prostate and neck of the bladder; or, to use the words of Le Cat, "small incision; much dilatation."

Its results were, however, so unsuccessful, that it fell into entire disuse here, and almost so on the continent, merely appearing from time to time under various modifications at one or other of the continental schools. This condition of things prevailed till ten years ago, when a new form of median operation was devised by Mr. Allarton, who with great perseverance and equal ability has urged it upon the attention of surgeons in this country, by whom it has now been extensively practised.

Operation.—This operation, for the introduction of which into modern surgery the greatest credit is due to Mr. Allarton, is performed as follows. A staff, grooved along its convexity, having been inserted into the bladder, the patient is tied up in the usual manner; the surgeon then, sitting in front, introduces his left index finger into the rectum, and feels for the apex of the prostate, against which he keeps it lodged, in order to judge of the distance of the prostate from the surface, to act as a guide to the knife, and prevent the rectum from being wounded. A straight-backed bistoury is now entered half an inch above the anal aperture, and pushed straight forwards to a depth of about an inch and a half in the mesial line, so as to enter, if possible, the groove of the staff at the apex of the prostate. A small incision upwards is then made in the groove of the staff, and, as the knife is withdrawn, the incision in the skin is also extended upwards; the knife is then laid aside, and a long ball-pointed probe is introduced into the bladder along the groove of the staff, which is then withdrawn. The probe is now the only guide to the bladder; and up to this point, therefore, there is but little, if any, difference between the modern median and the old Marian operations, except that the incision is exactly in, instead of a little to one side of, the middle line. The forefinger is now introduced along the probe, and by working it forwards the prostate is dilated, and the finger enters the bladder, when, the probe being removed, the forceps is introduced, and the stone extracted. Thus it will be seen that the only real point of difference between this and the old Marian operation, is that in the modern median the finger is used as the dilator, whilst in the Marian the prostate and neck of the bladder were forcibly expanded or torn open by the use of instruments; a difference, however, of no slight moment.

I have found it advantageous to modify this operation in one or two points. The first, which I think of some utility, is to use, instead of the ordinary curved staff, a rectangular one grooved from about one inch above the elbow nearly to the point, resembling the staff introduced by Dr. Buchanan of Glasgow (Fig. 451). Its use and advantages are that, when in the bladder, the angle rests against the apex of the prostate and can be felt in

the perineum, and the surgeon can judge of the exact point where to enter his knife (directing it so as to open the groove just below the angle), which he cannot do with the curved staff; the incision upwards also is limited, and the

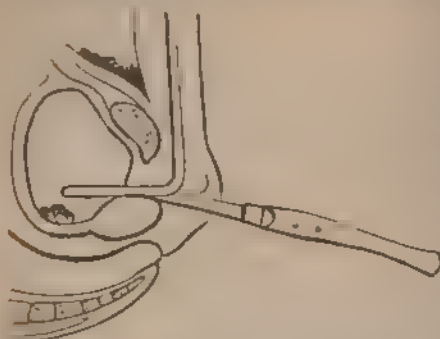

Fig. 451.—Median Operation with Rectangular Staff

is, besides, less dangerous, wounding the rectum, the urethra being drawn upwards away from it, and not pushed down against it, as with the ordinary staff. The knife should be straight, each having the blade not more than two inches long; so that the surgeon can tell to a depth he has entered it. I have found it advantageous in practice to carry a bone director, shaped like a hernia-director, along the groove, after the incision has been made in the urethra, so as to open up the canal and thus to clear the passage for the finger. After having opened the urethra, I think it is best to dilate the prostate before withdrawing the staff; by pushing the finger slowly, with a rotatory movement, along its side, the bladder is entered with more ease and certainty; whereas, if only the probe be used, it is not so stiff enough, and the surgeon is apt to push the bladder before him. It has been proposed to employ mechanical means of dilatation, instead of the finger, to open up the prostate and neck of the bladder, and I have seen some dilators for this purpose constructed by Mr. Coxeter on the principle of the two-bladed dilator of the female urethra. I have used them on a dead subject; but I have not ventured to use them on the living, lest, by the employment of screw-power, the same deep lacerations of the neck of the bladder should result that were so fatal in the old Marian operation. Indeed, I believe that their use would be fraught with danger from the liability to occasion rupture of the neck of the bladder; and if permitted I cannot but fear that they will bring discredit on the operation, reducing it to the condition of the old Marian, and repeating the dangers of that procedure. No safe dilatation can be effected except by the finger, with which no harm can be done, whilst it appears to me that the greatest possible mischief may be done with screw-dilators.

COMPARISON BETWEEN THE MEDIAN AND THE LATERAL OPERATIONS.—The two operations, the lateral and the median, cannot with propriety be compared as a whole, as we have as yet no sufficient statistics to enable us to determine whether the mortality after the median has been less than that which followed the lateral. We may, however, compare the modern median operation with the lateral, and endeavour to determine in what respects the median is superior, in what inferior, to the lateral, and in what cases it might be employed instead of the latter. For in this, as in lithotomy, the surgeon should not be too exclusive; it is his duty to learn and to practise different methods of attaining the same end, and to make use of one or other according to the requirements of the actual case before him, and to endeavour to select what is good and to reject what is doubtful in each method brought before him. It would be in the highest degree unwise to lithotomise only, or to cut only, every patient with stone coming under his care; and I believe that there is a choice as to the cutting operation in

or extensively torn and bruised to allow of the passage of a large stone. No amount of simple dilatation of which these tissues are susceptible can make a passage through them that will allow of the extraction of a stone $1\frac{1}{2}$ or 2 inches in diameter; such a stone must either be cut or torn out. Now what space have we in the median operation for the introduction of the forceps and the extraction of a large stone? Here, I think, is the weak point of the modern operation. In it the incision is made, and all the manipulation is practised, towards the apex of the narrow triangle formed by the rami of the pubic bones. The base of this triangle is represented by a horizontal line corresponding to the level of the membranous portion of the urethra, and consequently does not occupy the widest part of the perineum; it is formed by the transverse muscles of the perineum, and the lower portion of the deep fascia, supported and filled up by the rectum and the tissues which are attached to and support the gut on each side. These parts form a rigid wall or barrier stretching across the perineum, which cannot be depressed, and requires to be divided laterally into the ischio-rectal fossa before a stone of any considerable magnitude can be removed. It was in consequence of the extensive bruising and laceration of these structures, and the difficulty experienced in bringing the stone through them, that the old Marian operation fell into disuse.

In performing the median operation there are three points, or rather planes, of obstruction, between the surface and the interior of the bladder. The first is occasioned by the transverse muscles of the perineum, and, perhaps, also by the under portion of the deep perineal fascia. In the lateral operation we cut across this plane, and lay open the ischio-rectal fossa, giving abundance of room for the manipulation of the forceps and the extraction of the stone, along the base of the triangle formed by the rami of the ischiatic and pubic bones. But in the median we have to extract towards the summit of this space, at the apex of a narrow triangle, having the transverse muscles forming a tense bar along its base, and offering a material obstacle to the introduction of the forceps and the extraction of the stone.

The second obstacle lies in the prostate; but, as it is easily removable by dilatation, it cannot be considered a serious one.

The third, the deepest and most important, is situated at the neck of the bladder. We find here a narrow tense ring beyond the prostate; and this bar remains intact in spite of the dilatation and laceration to which the prostate has been subjected. On introducing the finger, we shall feel it grasped tightly by this ring. This inner ring of the neck of the bladder cannot be dilated beyond a certain point. I have found, by experiments on the dead subject, that it cannot be expanded to a size more than sufficient to extract a calculus of one inch in diameter without laceration or incision. The existence of this ring is the greatest barrier to the extraction of the stone, and its laceration or rupture is well known as one of the most dangerous and fatal accidents in lithotomy. It is in consequence of the obstacle offered by this that the median operation is not available for the extraction of large calculi. A calculus, for instance, two inches in diameter, cannot be extracted by the median operation without the employment of great violence. But though much force is usually required in order to extract a calculus of even moderate size through this tense ring at the neck of the bladder, it is an undeniable fact that serious consequences seldom follow the violence so used, and that a degree of force, which would be fatal in lateral lithotomy, may be employed without danger in the extraction of a calculus by the median operation. In this respect the extraction of a calculus

4. *Wound of the Rectum.*—This gut is not in much danger in the operation, unless it be distended. In the median, on the other hand, rectum is in considerable danger. If this operation be performed on a dead body, it will be found that the back of the bistoury comes very, I say uncomfortably, close to the finger in the rectum; and if another finger be placed in the wound, they will come into very close apposition anterior to the prostate. In the old Marian operation, the rectum was very frequently cut, air and feces issuing from the wound.

5. *Treatment of the Prostate.*—As to any difference in this respect—dilatation in the median, section in the lateral operation—I believe it is more imaginary than real. I think that it is very nearly the same in both operations when properly performed. All are agreed that in the lateral operation but a limited incision should be made in the prostate and near the bladder, these structures being merely notched, and the opening is then dilated with the finger, so as to avoid wounding the capsule of the prostate and opening up the pelvic fascia. The difference between an incision that opens the capsule of the prostate, and dilating this structure by the finger, is very great. The great object in lateral lithotomy is not to open up the pelvic fascia with the knife; and it is difficult, if not impossible, to tear this with the finger. If we take an aponeurosis out of the body, it will be found to be very difficult to tear; but if touched ever so lightly with the knife, it separates at once. So, in the median operation, the prostate is dilated to a considerable extent without opening its capsule. I have used the word "dilate;" but dilatation appears to me to be an erroneous term. I believe that the prostate is not simply dilated, but partially lacerated; that there is an actual laceration of the substance of the prostate, but not extending into or through its capsule. I have often examined the prostate in the dead subject, after it has been subjected to this process of "dilatation," and have always found its substance more or less torn. A laceration of the substance of the prostate, however, is of no consequence, and only becomes dangerous when it amounts to rupture of the capsule, when it exposes the patient to the fatal accident of extravasation of urine and diffuse inflammation of the pelvic fascia. Now, in the lateral operation, in running the bistoury down the groove of the staff, the surgeon may readily, unless care be taken, and very often, I believe, does actually and almost unavoidably go beyond the limits of the prostate, and thus exposes the patient to these dangers. In the median this cannot be done, if the knife be not withdrawn after the urethra is opened, the prostate being dilated solely with the finger. So far as this point, then, is concerned, I think that the median may be regarded as safer than the lateral operation, it being impossible to open up the pelvic fascia with the finger in the median, whilst they may be opened by the knife in the lateral.

In fact, the neck of the bladder and the prostatic portion of the urethra are in the median operation placed very much in the position of the female urethra when that is dilated for the extraction of a calculus: being dilated to a great extent, somewhat lacerated perhaps, but not torn through so as to admit urine into the fascia of the pelvis, and in that I believe the great essential superiority of the median over the lateral operation to consist.

6. *Manipulation of the Forceps and Extraction of the Stone.*—In the adult, the main difficulty of lithotomy does not lie in entering the bladder, but in the completion of the operation, that for which the operation has been undertaken—the removal of the stone. And the difficulty and danger increase in proportion to the size of the calculus; the distance between the neck of the bladder and the perineal integuments must either be widely

or extensively torn and bruised to allow of the passage of a large stone. No amount of simple dilatation of which these tissues are susceptible can make a passage through them that will allow of the extraction of a stone $1\frac{1}{2}$ or 2 inches in diameter; such a stone must either be cut or torn out. Now what space have we in the median operation for the introduction of the forceps and the extraction of a large stone? Here, I think, is the weak point of the modern operation. In it the incision is made, and all the manipulation is practised, towards the apex of the narrow triangle formed by the rami of the pubic bones. The base of this triangle is represented by a horizontal line corresponding to the level of the membranous portion of the urethra, and consequently does not occupy the widest part of the perineum; it is formed by the transverse muscles of the perineum, and the lower portion of the deep fascia, supported and filled up by the rectum and the tissues which are attached to and support the gut on each side. These parts form a rigid wall or barrier stretching across the perineum, which cannot be depressed, and requires to be divided laterally into the ischio-rectal fossa before a stone of any considerable magnitude can be removed. It was in consequence of the extensive bruising and laceration of these structures, and the difficulty experienced in bringing the stone through them, that the old Marian operation fell into disuse.

In performing the median operation there are three points, or rather planes, of obstruction, between the surface and the interior of the bladder. The first is occasioned by the transverse muscles of the perineum, and, perhaps, also by the under portion of the deep perineal fascia. In the lateral operation we cut across this plane, and lay open the ischio-rectal fossa, giving abundance of room for the manipulation of the forceps and the extraction of the stone, along the base of the triangle formed by the rami of the ischiatic and pubic bones. But in the median we have to extract towards the summit of this space, at the apex of a narrow triangle, having the transverse muscles forming a tense bar along its base, and offering a material obstacle to the introduction of the forceps and the extraction of the stone.

The second obstacle lies in the prostate; but, as it is easily removable by dilatation, it cannot be considered a serious one.

The third, the deepest and most important, is situated at the neck of the bladder. We find here a narrow tense ring beyond the prostate; and this bar remains intact in spite of the dilatation and laceration to which the prostate has been subjected. On introducing the finger, we shall feel it grasped tightly by this ring. This inner ring of the neck of the bladder cannot be dilated beyond a certain point. I have found, by experiments on the dead subject, that it cannot be expanded to a size more than sufficient to extract a calculus of one inch in diameter without laceration or incision. The existence of this ring is the greatest barrier to the extraction of the stone, and its laceration or rupture is well known as one of the most dangerous and fatal accidents in lithotomy. It is in consequence of the obstacle offered by this that the median operation is not available for the extraction of large calculi. A calculus, for instance, two inches in diameter, cannot be extracted by the median operation without the employment of great violence. But though much force is usually required in order to extract a calculus of even moderate size through this tense ring at the neck of the bladder, it is an undeniable fact that serious consequences seldom follow the violence so used, and that a degree of force, which would be fatal in lateral lithotomy, may be employed without danger in the extraction of a calculus by the median operation. In this respect the extraction of a calculus

by the median operation resembles the removal of one through the urethra of the female; the great point in favour of the median over lateral procedure, and the cause of comparative safety, being, that the fasciæ are not incised, nor otherwise opened. But, it may be said, is it easier, when the finger is in the bladder, than to push a probe-pointed toury along it, and cut downwards and outwards through these structures into the ischio-rectal fossa, if the stone be large, and thus get plenty of space? Nothing could be easier or more simple; but what would be the consequence? We at once reduce the median to the conditions of the lateral operation. A free incision in the neck of the bladder and prostate increases the tendency to hemorrhage, opens up the fascia, and exposes the patient, in fact, to all the dangers of an ill-contrived lateral operation, destroying once and altogether the principle of the median operation—viz., dilatation and not incision; and if we do not gain space by incision, but attempt to extract a moderately large stone by dilatation of the parts, we shall certainly not succeed, but our dilatation will end in a laceration, not only of the substance of the prostate, which is safe, but of the neck and perhaps the base of the bladder, which will be fatal. Urinary fistula was common in the old Marian operation. It remains to be seen whether it will be so in the modern median.

In conclusion, then, it appears to me that the median operation, when performed in suitable cases, has the advantages over the lateral of being attended by less risk of arterial hemorrhage, and with less danger of injury to the pelvic fasciæ: but, that in consequence of the very small size of the opening that can be made in the bladder by it, *provided these advantages be maintained*, it is only applicable to stones of at most a medium size, so that it cannot in all cases be substituted for lateral lithotomy, as the general operation for stone, where lithotripsy is not admissible.

Indications for the Median Operation.—The median operation may properly be performed in the following classes of cases. 1. In cases where foreign bodies, such as pieces of bougie, of tobacco-pipe, &c., are lodged in the bladder, the median is preferable, the body being small, elongated, and easily extracted. 2. It may be employed to remove stones not exceeding one inch in their smallest diameter. But then, it may be said, could stones of this size can generally be safely subjected to lithotripsy. That is true, in certain of these cases, lithotripsy is not admissible; so that the median operation is indicated in cases of small calculi in which lithotripsy cannot be practised in consequence of irritability of the bladder, or of the patient being too weak to bear repeated sittings. If a small calculus be lodged behind the prostate, in a pouch which occasionally forms at a lower part of the bladder, we may come down on it at once by the median method. 3. When there are numerous small calculi, lithotripsy is not desirable, and the median operation appears to be preferable. 4. In cases in which lithotripsy has been performed, and the patient is unable to expel the fragments, we may perform the median operation, and readily extract the detritus by a scoop, as it lies behind the prostate. 5. In the case also of calculi which are too large to be successfully subjected to lithotripsy, but which, if removed by the lateral operation, are attended by a frightful rate of mortality, it seems to me that the median operation might possibly be advantageously combined with lithotripsy. The stone having been broken up at one sitting, the fragments might at once be extracted through a limited incision in the median line of the perineum. 6. In cases in which the patient is so anxious to avoid the loss of an additional ounce or two of blood might turn the scale against him, median is preferable to lateral lithotomy. For, although it is by

means almost a bloodless operation, as is supposed by some, yet there is less hemorrhage during the performance, or rather, perhaps, less continuous oozing after its completion, than in the lateral, and there is certainly not the danger of the profuse bleeding that is sometimes seen in that operation. Where we have to do with a stone of large size, the median is not, in my opinion, safe; such an amount of traction must be used as will infallibly bruise and lacerate the neck and base of the bladder, and expose the patient to infiltration of urine and deep pelvic inflammation—to all the dangers, in fact, of the old Marian operation; dangers which were so great that more than half the patients subjected to it perished, and which caused it to be abandoned for the lateral.

I have said nothing special about the performance of the median operation in children. Under the age of puberty, lateral lithotomy is a very successful operation; certainly the most successful of all the *great* operations in surgery. The median can scarcely prove to be superior to it in this respect; and unless it can be shown to possess decided advantages over the lateral in ease of execution—and in this particular respect, in my opinion, it falls far short of the lateral—it does not appear to me to be desirable to abandon an operation of proved safety for one that is still on its trial.

BILATERAL LITHOTOMY.—The bilateral operation of Dupuytren is a modification of the median.

In it a transverse incision is made across the perineum half an inch above the anus, the horns of the incision extending to two-thirds of the distance between the anus and the tuber ischii on each side (Fig. 452). The dissection is carefully carried down to the central point of the perineum, and the membranous portion of

Fig. 452.—Lines of Incision in Bilateral Lithotomy (Dupuytren).

the urethra is opened on a grooved staff previously introduced; along this the double lithotome *caché* (Fig. 453) is passed, the blades expanded to a

Fig. 453.—Lithotome Caché

proper distance previously regulated, and both lateral lobes of the prostate divided to a corresponding extent downwards and outwards in withdrawing the instrument. The extraction of the stone is then effected in the usual way. This operation appears to me not to have received the attention from surgeons in this country that it deserves. By it the prostate is divided equally on both sides in its greatest diameter; if the expansion of the lithotome be carefully guarded, there is no danger of going beyond the limits of that organ or of wounding the internal pudic arteries; and the interior of the bladder is reached by the most direct and the readiest passage. In with-

drawing the lithotome, its concavity should be turned downwards and handle well depressed.

COMBINATION OF THE MEDIAN AND BILATERAL OPERATIONS.—Cruikshank recommended a combination of the median and the bilateral operations in lithotomy, by which the chief objections to both are got rid of. This mode of operation I have often practised on the dead subject, and once on a living, and it appears to me to be one well deserving a trial on the living for the extraction of very large calculi from the bladder; for those cases in fact, which cannot be removed by the ordinary median operation with too great an amount of force, and consequent bruising or laceration of parts. It is easy of execution, seems likely to be attended by little risk of hemorrhage, of urinary extravasation, or of pelvic inflammation, and of the bladder at the part which is nearest the perineal surface.

The operation may be performed in the following manner. The patient having been tied up, and a deeply grooved rectangular staff passed into the bladder, the urethra is opened at the membranous part with the edge of a knife turned upwards, as described in the median operation; the distal end of the lithotome is then slid along the staff into the bladder, its concavity turned downwards, the blades expanded to but a limited extent, and the prostate and the soft structures between it and the surface incised as it is withdrawn. If the stone be not very large, the incision may be confined to one side only, and made with a probe-pointed bistoury. It will be found that a great space is obtained by the perpendicular incision in the skin. The limited transverse cut removes that tension and resistance of the deep structures, which in the ordinary median operation interfere seriously with the manipulation of the forceps and the extraction of the stone, and, by division of both sides of the prostate to a limited extent, abundance of space is obtained.

HIGH OR SUPRAPUBIC OPERATION.—Although the median and lateral operations for lithotomy are perhaps the safest for the extraction of stones of moderate size, yet there can be no doubt that their results are extremely unfavourable, when the calculus exceeds a certain magnitude, and in these circumstances it may be deemed expedient to perform the "high operation" in preference to them. It is fortunate, however, that large calculi comparatively rarely met with, and will doubtless become more rare, as the diagnosis of stone can now be made at a very early period of the existence of the calculus, and as the treatment is now generally preventive. Of the 703 Norwich cases, that form the basis of Cruikshank's tables, indeed of our chief information on these points, 529 were under 1 ounce weight; 119 weighed from 1 to 2 ounces; 35 from 2 to 3, 11 from 3 to 4; 5 from 4 to 5; and only 4 were above this size. Hence, if we confine the high operation to those instances in which the calculus is above this size as will readily admit of extraction through the perineum, we shall not have occasion to perform it; yet instances occasionally occur in which the other method of extracting the calculus presents itself. Thus, by the method, M. Uytterhoeven succeeded in extracting a calculus, of which I have kindly given me a cast, which measured $16\frac{1}{2}$ inches in one circumference, and $12\frac{1}{2}$ in the other. It was perfectly moulded to the shape of the inside of the bladder, and clearly could not have been removed by any incisions through the perineum, as the outlet would have been insufficient for its extraction. The patient survived the operation 6 days.

But not only may the high operation be required on account of the size of the calculus; it may be rendered necessary by other conditions.

such as the existence of so much rigidity about the hips in consequence of rheumatic disease, as would prevent the proper exposure of the perineum; or by that region being the seat of disease which would interfere with any operation being practised through it; or the pelvic outlets may be so contracted by rickets as to prevent the possibility of the extraction of a stone through them by any of the perineal operations.

Operation.—The high operation consists in making an incision through the abdominal wall, above the pubes, and opening the anterior part of the bladder underneath the reflection of the peritoneum that passes upwards from its superior fundus.

In performing this operation, it is necessary that means should be taken to raise up the fundus of the bladder, so that it may project above the pubes, and thus admit of being safely opened. With this view various contrivances have been invented, such as catheters containing sliding stylets, which can be pushed through the bladder when that viscus is exposed. These instruments, though ingenious, are not necessary; for the end of an ordinary catheter introduced through the urethra, and made to project above the pubes, will serve as a sufficient guide.

The bladder having been slowly but fully injected with tepid water, so that it may rise above the pubes, an incision, about three inches in length, is to be carried from the pubes directly upwards in the mesial line. The pyramidales are then to be cut across near their origin, the linea alba exposed, cautiously opened near the pubes, and divided upwards some little way. The peritoneum must next be pushed back, and the dissection carefully carried through the cellular tissue above the bone, until the instrument previously introduced can be felt through the bladder, when, if it contain a sliding and pointed stylet, this may be pushed through the coats of the bladder; if not, an incision must be made down upon it, and the aperture in the organ enlarged downwards towards the neck of the bladder by means of a probe-pointed bistoury, so as to admit the fingers. The forceps must then be introduced, and the calculus extracted.

After the operation, there will always be risk of the occurrence of urinary infiltration into the cellular tissue around the margins of the wound. In order to prevent this, the older surgeons kept the bladder empty by making incisions through the perineum into the membranous portion of the urethra or neck of the bladder, thus complicating seriously the operation; but this accident may best be prevented by introducing a gum elastic catheter into the urethra, and leaving it there for a few days until consolidation has taken place and the wound shows a disposition to close, pressure being at the same time kept up on the lips of the incision.

Another cause of danger in this operation, is wounding the peritoneum, which may occur in consequence of the contracted state of the bladder causing it to lie low in the pelvis, and thus preventing the proper introduction of instruments to carry it up above the pubes.

Dr Humphry, of Cambridge, has collected 104 cases in which this operation has been performed; of these 31 proved fatal, chiefly from peritonitis and urinary infiltration—the mortality amounted consequently to 1 in $3\frac{1}{2}$; and M. Souberville, one of the greatest modern advocates of this operation, lost 1 patient in 3. The general result, therefore, is not very satisfactory; though, as in many instances the operation was performed in cases in which the internal method was not applicable on account of the size of the stone, we cannot with justice compare the two procedures in regard to the mortality attending them.

LITHOTRITY.

The operation of *Lithotrixy*, by which the stone is crushed in the bladder and the pulverised fragments are expelled or extracted through the urethra, is of modern, and indeed of very recent invention; for, notwithstanding that various rude and incomplete attempts may at different times have been made with this view, it was not until about the years 1818 or 1820 that the subject began to attract serious attention. About this time Civiale followed by Amussat, Leroy, and others, began constructing instruments which, though very imperfect, yet were sufficient to break down a calculus in the bladder. From this period the system made rapid progress; and successive improvements made by the surgeons whose names have just been mentioned, together with the ingenious mechanical adaptations introduced by Weiss, Heurteloup, Costello, and Charrière, enabled surgeons to attack the stone with certainty and effect. It is, perhaps, principally due to the labours of Civiale and Amussat in France, and of Brodie in this country, that the system has been brought to its present state of perfection. For the safe and proper performance of the operation of lithotrixy, the surgeon is not only to be acquainted with the general principles on which it is undertaken, but he must be thoroughly conversant with the more minute details in the construction and the manipulation of the instruments employed, as well as with the state of every part of the urinary organs. It is impossible for any surgeon who wishes to practise lithotrixy successfully, to devote too much time and attention to these points.

INSTRUMENTS.—The instruments required for lithotrixy are the following.

An ordinary *sound* with a short beak is required to examine the condition of the bladder. The steel sound should be hollow, so that the bladder may, if necessary, be injected through it after or during sounding, without necessity of changing the instrument (Fig. 428). This will be found of no service in the later stages of the operation for detecting small fragments.

A *brass syringe*, with rings, and having a large piston rod, so that it may work easily, should be at hand, and admit of adaptation to the hollow sound.

The surgeon should also be provided with *silver catheters* of three different kinds: one with large lateral eyes, another with a large eye in the convexity and a third with a large eye in the concavity near the point; all having elastic gum bougie fitted to the interior, instead of a stylet, to clear out the fragments. These should also fit to the syringe.

The instrument for breaking the stone consists of Weiss's *lithotrite*, represented in the annexed cut (Fig. 454); or a similar instrument with

Fig. 454.—Lithotrite for breaking the Stone.

by a rack and pinion is employed by some surgeons. The lithotrite should be made of well tempered steel; and should always be tested by being used to crush a piece of sandstone grit, of about the size of a walnut. It should be of as full a size as the urethra will readily admit; it must have the blades well serrated, and the female or under blade open at the beak, an oval aperture, through which the detritus of the crushed stone is forced, and thus any entanglement of it between the blades is prevented (Fig. 454).

The object of this open-bladed lithotrite is to break the larger and harder stones into fragments; but it is not equally efficient with the smaller calculi, nor can it pulverise the larger fragments.

The lithotrite should be cut out of a bar of solid steel, and not, as is the case with some instruments, made of a plate of this metal, turned up at the edges; as such a one possesses too little strength to be used with safety on large and hard calculi. Those cut out of a bar of metal have an external blade, having a grooved shape, as in Fig. 457. In this, the male or internal branch, cut to fit accurately (Fig. 456), slides smoothly, the whole instrument possessing an amount of strength and power that no calculus can resist. The bent-up instruments are composed of an outer tube of metal, as represented in its transverse section (Fig. 458), in which the internal blade fits less accurately (Fig. 455), but which possesses less strength, especially at the elbow, than those cut out of the solid. The scoop may, however, be so constructed without danger.

Fig. 456

Fig. 455

Fig. 458.

Fig. 457.

The lithotrite, such as is represented in Fig. 459, invented by Civiale, has a double action, enabling the surgeon to work it either by the hand or by a screw. In this instrument, there is no fenestrum in the female blade. It is of two kinds. In one, the male blade is much narrower than the female; in the other, it is nearly as broad. The first kind is useful in crushing through moderate-sized stones; the second kind, with the broad male blade, is used

in completely crushing up and removing the detritus of small calculi and the larger fragments into which a stone has been broken by the open-bladed lithotrite.

Fig. 459.—Civiale's Lithotrite for crushing Fragments.

in completely crushing up and removing the detritus of small calculi and the larger fragments into which a stone has been broken by the open-bladed lithotrite.

Besides these instruments, a small lithotrite is occasionally used for crushing fragments in the urethra; and another instrument, shaped like that represented in Fig. 142 (p. 372), for withdrawing them from that canal.

PREPARATION OF THE PATIENT.—Before proceeding to the operation of lithotripsy, it is necessary that the patient's constitution should be carefully attended to; the bowels should be freely opened, and the condition of the digestive organs attended to, and more especially that all local irritability about the urinary organs should be subdued by ordinary medical treatment. This is even of much greater importance in lithotripsy than in lithotomy. In lithotripsy, we must always expect that any existing irritation or inflammation of the bladder will be increased by the necessary introduction of instruments, and by the presence of sharp fragments of calculus in the bladder, and their passage along the urethra; but in lithotomy all source of irritation is at once removed by the extraction of the stone. The condition of the urinary organs must be very carefully examined; and, if these be diseased, it will probably be requisite to abandon the operation.

In a subsequent part of this chapter, when we come to the comparative lithotomy and lithotripsy, we shall examine the conditions which render each more or less favorable to the performance of the latter operation. At present we will suppose a case in which the surgeon may have recourse to lithotripsy with every prospect of readily and permanently freeing the patient of his calculus; one in which the calculus is of moderate size, soft, and not too hard; the urinary organs healthy, and not over-irritable, and the patient an adult, but not too aged. In performing the operation in such a case, but little preparatory treatment is required; though it is well to keep the patient quiet for a few days, and to regulate the bowels before anything is done. Should the patient's health not be in a satisfactory state, or should his urinary organs be irritable, he must be treated on ordinary medical principles until his health be restored, and then restored for the surgeon safely to undertake an operation. Should the patient be nervous about the use of instruments, or should the bladder be irritable, a large sound may be passed every second day, so as to accustom the patient and the parts to the use and contact of instruments.

USE OF ANÆSTHETICS.—Much difference of opinion exists as to the advisability of employing chloroform in lithotripsy. It has been objected to its use that the sensations of the patient are an useful guide to the surgeon in his manipulations; and that, if these be annihilated by anæsthetics, error may be done by the lithotrite nipping or otherwise bruising the mucous membrane. But this objection is not tenable. It is the sensations of the surgeon, and not those of the patient, that constitute a valuable guide, although in the majority of cases lithotripsy, when properly performed, is almost a painless procedure. Yet cases not unfrequently occur in which the patient can with difficulty support the necessary manipulations, and which either from nervousness or from irritability of the bladder, he rejects the introduction of the lithotrite, or even does not allow his bladder to be duly distended by injection. In such cases chloroform is of inestimable service; and many patients when anæsthetised can be safely supported in lithotripsy, who could not suffer the operation under other circumstances.

OPERATION.—The operation of lithotripsy may be divided into three stages.

1. The Introduction of the Instrument. 2. The Search for and Seizure of the Stone. 3. The Crushing of the Stone.

1. *Introduction of the Lithotrite.*—Lithotripsy may most conveniently be performed with the patient either lying on his back upon a hard mattress, or on a couch or table. If the patient be very stout, or the prostate enlarged, the pelvis may be raised by a hard pillow, so as to allow the stone to rest on the posterior surface of the bladder. The surgeon, standing on the right side of the patient, carefully introduces the hollow sound, or catheter, and draws off the urine; he then slowly, and very cautiously, injects the bladder, by means of the brass syringe, with from four to six ounces of tepid water. The use of drawing off the urine is to make sure of the bladder holding the proper quantity of fluid when it is afterwards injected; and the object in injecting it, is to distend it with fluid to such an extent as to prevent the mucous membrane from being seized in the grasp of the lithotrite, or injured by the splintering of the stone. The instrument is then withdrawn, after the situation of the stone has been detected by it, and the lithotrite is introduced. Should the patient be able to hold enough urine to protect his bladder from the action of the lithotrite or the fragments, the injection may be dispensed with, and the lithotrite may at once be used. As this is straight, with a sharp elbow near the beak, some little skill is required in passing it. In doing this, the surgeon must keep his eye upon the direction

curved beak of the instrument, the direction and position of which must be constantly observed or rather judged of; and especial care must be taken, in carrying it under the pubes, not to injure the urethra by pushing the beak of the lithotrite forwards too suddenly, instead of wounding it, as it were, under the arch of that bone. The instrument should first be introduced nearly parallel to the abdomen, the penis being held between the left fore and middle fingers, and drawn over it. As the lithotrite passes down, it must be gradually raised to the perpendicular position; and as its curve passes under the pubes, the handle should be depressed between the thighs (Fig. 460). The direction of the curve is the thing to bear in mind; and the position of the handle must be varied in accordance with the course which this takes. The lithotrite should be well greased with olive oil, so that the branch and screw may work smoothly. Lard or ointment should not be used for this purpose, as it is apt to clog, and to entangle gritty bits of calculus.

2. *Seizure of the Stone.* — The next point is to seize the stone, which will generally be found in the situation where its presence was detected during the sounding of the bladder. If large, the stone will probably lie low, near the neck

Fig. 460.—Introduction of the Lithotrite.

of the bladder; if small, it is most frequently met with at the right side, or at the inferior fundus. Should it be situated in a sacculus or depression in this region, it may most readily be seized by introducing a finger into the rectum, and raising up the lower part of the bladder; or, better still, by raising the pelvis on a hard pillow, and so causing the stone to roll up on the posterior surface. Sir B. Brodie strongly advises that the lithotrite should never be used as a sound to ascertain the position of the stone; if this be done, the patient suffers pain, the bladder is irritated, the urine is expelled, and the stone not readily seized. In seizing the calculus, a good deal of tact is required. There are two ways of seizing the stone. Sir B. Brodie recommends that it should be done by pushing the female blade of the lithotrite against the inferior fundus of the bladder, pressing gently down with it so as to make a conical depression in this situation, and then inclining the beak towards the stone, drawing back the male blade with the thumb (Fig. 461); with a slight shake or jerk, the surgeon then tries to get the calculus between the blades, at the same time that the male branch is being pushed forwards to seize it. In this manœuvre the female blade should be moved as little as possible, but the stone must be seized by pressing the thumb upon the half circle of steel fixed on the male branch. In this way the stone may often be seized at the first attempt, but in other cases it is not grasped until after several efforts have been made to fix it; the calculus, especially if round, slipping away from between the blades of the instrument, and being merely scraped by them. Civiale adopts another procedure. In passing the lithotrite, he feels where the stone lies; he then very gently turns the beak of the instrument towards the opposite side of the bladder, opens the blades, and then, turning them over towards the stone, seizes it between the open blades. In these

manœuvres, all rough handling must be most carefully avoided, and the instrument should be turned about as little as possible. It is far safer to

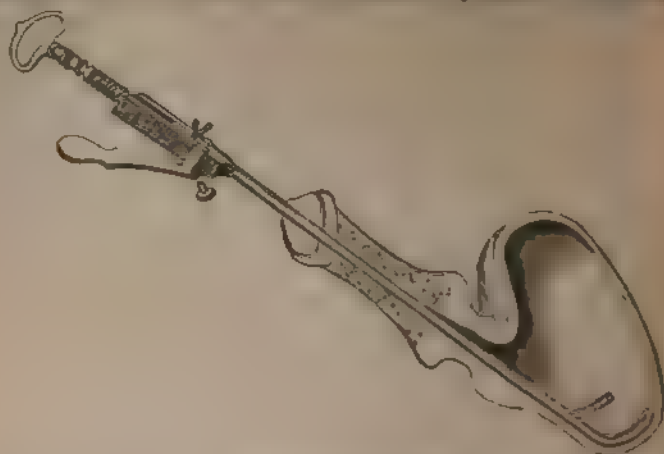

Fig. 461—Seizure of the Stone.

desist in the operation, if there be any difficulty in seizing the stone, than to persevere in repeated and fruitless attempts, by which the bladder may be severely injured and inflamed. Rather than do this, the patient should be allowed to get up and move about for a few minutes, when the position of the stone may be so far altered that it admits of being seized.

3. *Breaking the Stone.*—When the stone has been seized, it is gently raised in the grasp of the lithotrite, so as to be placed about the middle of the bladder, and it is then crushed. This important step of the operation, like all the others, requires to be deliberately and carefully done (Fig. 462).

Fig. 462.—Position of Lithotrite in crushing the Stone.

If Civiale's improved lithotrite be used, the stone, if small, may often readily be crushed by the pressure of the hand alone without the action of the screw (Fig. 463). If the ordinary lithotrite be employed, the breaking

Fig. 463—Position of Hand in using Civiale's Lithotrite.

should not be effected by suddenly and forcibly screwing up the instrument, but the screw should be gradually worked by a series of short and sharp

turns, so as to constitute almost percussive movements (Fig 464). In this way the calculus is generally made to crumble down, rather than to fly

Fig 464 —Position of Hands in using ordinary Lithotrite.

asunder; and, as it yields, the screw must be worked tightly home. The blades of the instrument may then be opened again, a fragment of the broken calculus seized and crushed in the same way as before; and thus the disintegration of the stone is in a great measure effected and sometimes completed at one sitting. It is of the greatest moment, however, that too much time be not consumed at one sitting. Nothing is more dangerous than the long-continued contact of instruments with the interior of the bladder; in this way great irritability, or an atonic condition of this organ, terminating in low cystitis and pyæmia, is apt to be produced, and death may thus result. The shorter the sittings, the more likely will the case do well. The first sitting should not exceed ten minutes, and the subsequent ones five. In the repetition of the sittings, the surgeon must be guided by the effect produced on the stone and on the bladder. The calculus may be entirely destroyed in one sitting, but most commonly from three to five or six are required, these should, if possible, be conducted at intervals of three or four days, though this must depend upon the amount of irritation induced by them.

At the first sitting, it is sufficient to break up the stone; the fragments being left to be dealt with subsequently. This sitting is by far the most important of all: it should not occupy more than about five minutes. After the stone has been broken up, the patient should be made to lie on his back for about twenty-four hours, be kept warm, and be plentifully supplied with diluents. He should pass water in a urinal, and not be allowed to stand up or to lean forward, lest the fragments fall against or become fixed on the neck of the bladder, where they may produce great irritation and distress. Much of the success of lithotripsy will depend upon the gentleness with which the proceedings are conducted during the first sitting, and the care with which the patient is managed for a day or two subsequently.

Before withdrawing the lithotrite, the surgeon must be careful to see, by the scale on the handle, that the male blade is well home. If this be not the case, and the instrument be enlarged by any fragments or detritus being entangled between the blades, laceration of the neck of the bladder or urethra might occur in attempting to withdraw it.

After the stone has been broken, little detritus will usually escape during the first twenty-four hours; but after this it is expelled, in some cases in considerable quantity, each time the urine is passed. In others, it does not escape so readily; and then the surgeon requires to introduce Civiale's instrument (Fig. 459), by which he can seize the smaller fragments, crush them, and, screwing the instrument home, extract the beak filled with detritus. In using this instrument, however, care must be taken not to get hold of too large a fragment; for, in breaking this up, whether by the hand or screw, the beak may be clogged with the detritus in such a way that

it does not readily close, and then there might be considerable difficulty in withdrawing it. Should this accident occur, the scissor may be engaged, passing its beak back into the bladder, tapping sharply upon the instrument, and moving the male branch to and fro. In crushing fragments between the prostate, Civiale turns the concave part of the beak downwards, and withdraws the fragment in this position. In doing this, however, great care must be taken not to nip the mucous membrane of the bladder.

After each sitting, except the first, the bladder may be washed out by injecting it with tepid water through a catheter. The most convenient

Fig. 405. Large Silver Catheter for emptying Bladder.

instrument I have employed for this purpose is a full-sized silver catheter, nearly straight, and having a large eye in its concavity (Fig. 405). This acts as a scoop, and will bring away large quantities of fragments that can not readily escape through the catheter with internal eyes, or that has an opening at its convexity. For bringing away the finer detritus, a double current syringe is useful. In using the latter instrument, the point of which should be directed towards the inferior fundus, a considerable quantity of water may sometimes with advantage be pumped through the bladder by adapting a flute-valve syringe or elastic bottle to it.

The interval between the sittings will vary according to the effect produced. If all go well, the second sitting may usually take place about five or six days after the first, and they may then be repeated at intervals of from three to four days; each sitting should be short—not exceeding five to eight minutes. When the surgeon believes that the bladder has been emptied of all fragments and detritus, a final exploration must be made. This last act of the operation is necessarily one of the greatest importance, as on the precision with which it is conducted depends in a great degree the future immunity of the patient from a recurrence of the disease. Any fragment, however minute, that is left behind necessarily constitutes the nucleus of a further calculus.

The exploration is best conducted by means of a small lithotrite, the bladder containing but a moderate quantity of urine. The whole of the interior, but especially the part behind the prostate, should be carefully explored; and if any fragment be found it must be crushed, and the detritus extracted. Civiale employs the "trilobe," allowing the urine slowly to trickle out through the shaft of the instrument, at the time when he is drawing and closing the blades over the floor of the bladder, by withdrawing the tubular shank over them. As a measure of additional safety, the exploration should be repeated after the lapse of a week or two, and the bladder be well washed out after each procedure.

During the whole of the treatment, it is necessary to adopt means to allay irritation. With this view the patient should be kept in bed, or on a couch, a moderate diet only should be allowed, plenty of demulcent drinks given, such as barley water, soda-water, or milk; and opiates or benizans, if necessary, should be administered.

The amount of irritation of the bladder developed after lithotomy will vary greatly in different cases. In some, where the stone, when introduced, has excited much pain and irritability of the organ, the sufferings are at once lessened by its being broken up. It is difficult to account for this, except on the supposition that the fragments, being spread over a wider surface than the unbroken calculus, press less directly on any one part, and produce less local irritation. More frequently, however, the crushed stone

produces much greater irritation than the unbroken one. In this respect, however, much will depend upon the care that is taken after the operation. If the patient be kept lying on his back, if diluents be freely given, and opiate and belladonna rectal injections used, the irritation from this source will be materially lessened. But if the patient be allowed to walk about, and to pass urine standing up or leaning forward, some of the fragments may be driven into the neck of the bladder, or even the deeper part of the urethra, producing there the most intense and painful strangury. When this unfortunate accident occurs, the patient will pass urine every half hour or oftener, squeezing out a few drops, writhing, and perhaps screaming with the agony he suffers, as the vesical neck contracts on the ragged fragments; his pulse will become quick, his skin hot and perspiring, his tongue dry, the urine scanty, high-coloured, and perhaps more irritating; and, unless relief be speedily given, nervous exhaustion will set in, and death ensue. Under such unfavourable circumstances no time is to be lost. The patient should be anaesthetised, the bladder injected with weak belladonna solution, gr. i. to ℥iv. of water, the lithotripsy scoop introduced, the fragments broken up as completely as possible, and detritus taken away, or washed out. No other means than this, or lithotomy, will save the patient; and nothing is more remarkable than to witness the immense relief that the patient derives when the large angular fragments are broken up into detritus.

ACCIDENTS IN LITHOTRITY. —In considering the accidents in lithotripsy, I put out of consideration those that may arise from the surgeon acting carelessly, or with improper force, and thus occasioning laceration of the urethra, or injury to the coats of the bladder; so also accidents occurring from the bending or breaking of the instruments will scarcely happen, if these have been properly tested on a piece of sandstone grit before being employed in the bladder.

Impaction of Angular Fragments of Stone in the Urethra.—This is a most dangerous and painful accident, and not only occasions great local irritation, ending perhaps in cystitis or abscess, but may give rise to severe rigors and nervous prostration. It most commonly arises either from the surgeon attempting to do too much at the first sitting, or from the patient moving about too much, or straining to pass urine after the stone has been broken. The fragments are especially apt to lodge in the prostatic urethra, or about the bulb, and there give rise to a very great degree of irritation, and even of fatal mischief, producing great constitutional disturbance of an irritative and asthenic type. When the pieces are impacted low down in the urethra, it is absolutely necessary to remove them from the canal as speedily as possible, lest the constitutional disturbance occasioned by them prove fatal to the patient. This may be done in various ways. Most frequently, they may be pushed back into the bladder by passing a large catheter carefully down to them. The most convenient instrument for this purpose is one that is open ended, so that the fragment may be received in the aperture at the end of the instrument, and so pushed on before it. Through such a catheter as this a stream of water may be injected, and the fragment

Fig 466 — Urethral Lithotrite

thus forced back. Should these manœuvres fail, it has been proposed to crush them in the urethra with a small lithotrite (Fig. 466), but this plan

is somewhat hazardous, as it is very difficult to avoid puncturing up the mucous membrane of the canal with the bit of stone. The safest procedure seems to be, either to extract them through the urethral orifice, or to cut them out through the perineum. Extraction through the urethra can only be effected by the forceps (Fig. 467), or by Civiale's instrument (Fig. 111).

Fig. 467.—Urethral Forceps

Should this means fail, or should the fragment be very deeply seated, as in the membranous portion of the urethra, and the local and constitutional irritation produced by it be so great as to threaten abscess or a fatal termination, the better plan would be to make an incision directly over upon it, and to remove it through the perineum by a medial operation of lithotomy. If such an operation as this be required, the surgeon might possibly feel disposed to extend the incision a little, and empty the bladder of any remaining detritus by means of a scoop.

The *Chronic Enlargement of the Prostate* of old people complicates seriously the operation of lithotomy, not only in rendering the introduction of instruments more difficult, but in offering an obstacle to the escape of the fragments. Enlarged prostate cannot, however, be considered to be in any means an insuperable bar to lithotomy; as, after the stone has been crushed, the bladder may be emptied by means of the scoop, or by Sir F. Crampton's device, which consists in exhausting the air from a properly constructed bottle, fitted with a stop-cock, and then attaching this to a catheter previously introduced, and opening the stop-cock, when the pressure of the atmosphere drives the contents of the bladder, urine and all, into the exhausted bottle. As a general rule, it is not desirable to turn the blades of the lithotrite downwards, lest the floor of the bladder be injured. But in some cases in which a small stone is lodged, or fragments have fallen into a pouch behind the prostate, or in which the prostate is enlarged as to form a bar which rises above the floor of the bladder, it will be impossible to seize the calculus or the fragment, unless this manoeuvre be adopted. In doing this, risk of injury will be materially lessened, if not altogether removed, by somewhat depressing the handle of the lithotrite, and thus preventing all downward pressure of the blades, which are gently opened and closed over the base of the bladder.

DANGERS IN LITHOTRITY.—The principal dangers in lithotomy arise from the state of the bladder and kidney. They consist in the induction of Cystitis of a low form, Atony of the Bladder, or Renal Irritation, or in the occurrence of Pyæmia, with much constitutional disturbance of a low type.

Cystitis may occur in consequence of the increased irritation to which the bladder is subjected. It sometimes occurs during the earlier period of the operation, in consequence of the irritation of the bladder by large and angular fragments, and subsides at once when these are crushed up and pulverised. Should it continue, it speedily assumes a low form, and is apt to prove fatal by the induction of typhoid symptoms, even if it does not do so, its continuance is an insuperable obstacle to the further crushing of the

stone; and in cases of this kind the best course that could be pursued will be, after getting the patient into as favourable a state as possible, to remove the fragments by lithotomy.

Atony of the Bladder is one of the most dangerous conditions that can occur in lithotomy. This state of things happens usually in old people, in whom the urinary organs may appear to be in a peculiarly quiet and favourable condition before the operation, the patient being able to hold his urine for six or eight hours, and to bear the injection of ten or twelve ounces of fluid. Under these circumstances, the surgeon should be upon his guard; for the danger of this condition is, that the bladder does not possess sufficient contractile power to expel the fragments. These consequently accumulate in the lower fundus, and irritate the mucous membrane, and thus the foundation may be laid for fatal cystitis, which in these cases always assumes a typhoid type.

The atony of the bladder appears to arise partly from that natural want of expulsive power, which is not unfrequent in old people, and partly from a kind of paralysis of the organ, induced by the contact of the instruments, especially after long sittings, and by the pressure of the fragments, by which the bladder is, as it were, overpowered. Such patients usually die with severe constitutional depression, and with pyemic symptoms.

When atony of the bladder has come on, it is essential that the surgeon should rid the patient of the fragments which he is unable to expel. This may sometimes be done by means of the scoop, assisted by washing out the bladder through the large-eyed catheter; but the safer plan would probably be, to get the patient into as good a condition as possible, and then cut him. Thus I once did in an interesting case under my care at the Hospital; the patient, an old man, had been lithotomised by a surgeon out of doors a few weeks before admission, but no fragments had passed; on sounding him, I found a moderate-sized calculus, with what appeared to be a large mass of soft concretion, of the nature of which I was not aware until after its removal, the patient having concealed the fact of his having been lithotomised. On cutting him in the usual way, I removed a lithic acid calculus about as large as a pigeon's egg, and a handful of fragments of another calculus of the same composition, which had been crusted over and matted together by phosphatic deposit. The patient made a very good recovery. In such cases I should, in future, perform the median operation, and clear out the bladder with a scoop.

Irritation of the Kidneys, giving rise to suppression of urine, occasionally occurs. In such cases, cupping the loins, and the warm hip-bath, would be the proper treatment to pursue.

Constitutional Disturbance.—Very considerable constitutional disturbance occasionally follows lithotomy. The patient is seized with severe and long-continued rigors, followed by profuse sweating, lasting for many hours. These serious symptoms are most apt to come on after the first sitting, and are analogous to those nervous phenomena that are apt to follow upon the introduction of instruments in strictures, &c. They may pass off, leaving merely a temporary debility; or a typhoid state may set in; the pulse becoming quick, feeble, and intermitting, the skin hot and dry, and the tongue brown. This condition is apt to prove fatal, either directly, or by intercurrent visceral mischief: it appears to arise in many cases from causes independent of the operation, or that are called into activity by the shock and slight constitutional disturbance induced by it. This is more especially apt to happen when there is latent disease of the kidneys. Indeed, there is no condition of system that is more directly antagonistic to the success of

lithotripsy than chronic diseases of the kidneys, as indicated by the presence of much albumen in the urine. When this occurs to any considerable extent with or without casts of tubes and blood, the increased irritation induced by the operation will almost to a certainty prove fatal. In other instances again, the fatal result is more directly dependent on the irritation induced by the operation leading to the formation of abscess in the neighbourhood of the prostate, or around the neck of the bladder; and in other instances again, on the supervention of unhealthy suppuration in some of the abscesses that are occasionally met with in this organ. From whatever cause arising this condition is usually eventually fatal by the supervention of pyæmia, and is undoubtedly often predisposed to by the previous existence of chronic renal disease.

The *Treatment* of this state of things should consist in the free administration of stimulants—brandy, ammonia and ether followed by full dose of opiate, and abundant warm diluents. Especial care must be taken not to repeat the sitting for at least a week or ten days after rigors have passed off.

COMPARISON BETWEEN LITHOTOMY AND LITHOTRIPSY

Lithotomy and lithotripsy differ so entirely from one another in principle and detail, that it is useless to attempt to establish a comparison between different steps of these two operations. It is, however, a question of very first importance and interest to ascertain by which operation a patient can most safely have a calculus removed from his bladder. In determining this point, it is not only necessary to make a comparison between the general results of cases that have been subjected to the two procedures, but especially to ascertain those circumstances that influence the result of an operation in particular cases—to determine, in fact, in what cases lithotomy and in what lithotripsy, holds out the best prospect to the patient. It is, I think, in the highest degree impractical to enter into a discussion as to which should be the general method of treatment in cases of stone. Both operations have been reduced to great simplicity and certainty; but neither should be exclusively practised. It is undoubtedly the duty of the surgeon to make himself familiar with the practice of both, and to adopt that which promises best in the particular instance with which he has to do. However, I were called upon to say which operation I consider most generally applicable, then I should unquestionably answer lithotomy. Yet there can be no doubt that there are many cases in which lithotripsy is the preferred method; and in those in which lithotomy or lithotripsy may be done with equal chance of success, the preference should be given to the crushing or the cutting operation.

STATISTICS.—The statistics that are before the profession do not represent the true state of the question, so far as a general comparison between the two operations is concerned. For it must be borne in mind that those cases which are lithotomised have invariably been picked; whilst lithotripsy has been performed on almost all patients as they have presented themselves. For lithotripsy to be successfully done, it is necessary that the stone be of moderate size, single, not too hard, and that the urinary organs be in a healthy state and free from irritation: and this is the state in which most of the cases have been, in which crushing has been done. In lithotomy cases, on the other hand, the surgeon has had to contend with all the difficulties of large multiple calculi, diseased bladders, and bad constitutions. Hence, in comparing the statistics of the results of lithotripsy with those of lithotomy, we compare the statistics of the results of operations performed under the

favourable circumstances on a series of selected cases, with those of cases taken indiscriminately and often presenting most unfavourable conditions.

Another cause of uncertainty with regard to the statistics of lithotritry is, that those we possess are chiefly from a professed lithotritist, M. Civiale, the accuracy of which has been denied in a very decided and emphatic manner by many of the leading surgeons in Paris, who have inquired fully into the matter; and the conclusions from which must necessarily be received with much hesitation in this country, where it is difficult to arrive at the real truth of the statements advanced on either side.

If we compare Civiale's statistics of lithotritry with those of lithotomy, as practised by the most skilful surgeons, Cheselden, Liston, and the Norwich operators, we should at once decide in favour of the crushing method; for Civiale states that out of 591 operations he had but 14 deaths, or 1 in 42.2; whilst, as we have seen, the most skilful lithotomists in this country, where the results of the cutting operation have been far more successful than elsewhere, can only boast of such a rate of mortality as 1 in 7.9, or at most in 10. But though the success is thus stated by Civiale to have been great in his own cases, the accuracy of this statement has been denied by other French surgeons, and it is certainly very different from what has occurred elsewhere. Thus of 162 cases operated upon by lithotritry by various surgeons in Paris, Civiale states that death resulted in 38, and a cure in 100 instances; the results of the remaining cases being unknown, or the cures incomplete. In this country it is impossible to say, even approximately, what the average mortality after lithotritry has been; for, with one exception, those surgeons who have had most experience in this operation have not published any account of their cases; but I believe there is a very general feeling that, in the different London hospitals in which it has been performed, lithotritry has not been a very successful operation. The same remark appears to hold good with regard to the Parisian hospitals; Malgaigne estimates the mortality from lithotritry in these institutions at 1 in 4, while he calculates that of private cases at 1 in 8. This difference between the results of this operation in hospital and private practice can easily be accounted for by the difference in the constitutions of the patients, and by their applying for relief in private in a less advanced form of the disease than in hospital practice. We find that the same holds good with regard to the results of lithotomy. Thus, Conlson states that Dudley lost only 1 in 36 of the private patients that he cut, Mettauer, 1 in 36½; Martineau, 1 in 42; and Mott, 1 in 50. These results are fully as favourable as Civiale's statistics of lithotritry, and show the influence that the constitution of the patient, and a proper selection of cases, may exercise upon the results of the cutting operation. The only statistics of lithotritry that we at present possess are those given by Sir B. Brodie, as the result of his practice, chiefly on private patients. That eminent surgeon states that, out of 115 cases of lithotritry—not all, however, on different individuals, the operation having been repeated more than once on several of the patients—he lost 9. Of these, death was directly attributable to the operation in 5 instances; and, in the remaining 4, it appeared to be dependent on organic disease, brought into activity by the shock of the operation.

Lithotritry, as has already been stated, cannot be applied to all cases of stone; but, in many that are unsuited to the operation, lithotomy may be done with success. In some cases, however, no operation can be practised in consequence of serious disease of the genitals, bladder, or kidneys, or of some visceral mischief that would necessarily interfere with the performance of any capital operation. The necessity of selecting cases of lithotritry is well

instanced by a statement that Civiale has given with reference to this point. This dexterous lithotritist considered that, of 838 calculous patients applied to him during a series of twenty years, only 548 were fit cases for lithotomy, and 290, or more than one-third, were not operated on by that method; of the last 332 cases included in this list, 241 were lithotomized, 36 being considered unfit for that operation. Of the 91 cases crushed, 28 were cut, and in 8 others lithotripsy and lithotomy were combined. Of these 36 cases subjected to lithotomy, Civiale lost 18, or exactly one-half. These figures show that lithotripsy cannot be considered the operation for stone; but must, even in the hands of the most delicate and successful practitioners, be in many instances replaced by the cut operation.

SELECTION OF OPERATION: LITHOTOMY OR LITHOTRIPSY.—The circumstances that must chiefly determine the surgeon in the selection of the proper operation that is to be performed are—1, the Age of the Patient; 2, Size and Character of the Stone; and 3, the Conditions of the Urinary Organs.

1. *Age.*—The age of a patient is an important element. As a general rule, it may be stated that at the middle and advanced periods of life lithotripsy is most successful; while, in early ages lithotomy is the preferred operation. In children under the age of puberty, the genito-urinary organs are undeveloped; the urethra is small, and the bladder narrow. These conditions not only necessitate the employment of instruments specially constructed of reduced size, and render great care in their manipulation requisite, but the narrowness of the urethra is especially apt to render the expulsion of the fragments of the crushed stone extremely difficult, and favour their impaction. If, in addition to this, we bear in mind the sensitiveness of the bladder in young children, and their restlessness under the repeated sittings which may be necessary, it can easily be understood that lithotripsy is neither an easy nor a safe operation in them; unless the calculus be so small—not larger than a cherry-stone—that it can be crushed and brought away at one sitting. Lithotomy, on the other hand, is so successful an operation in children, that the surgeon would gain nothing by substituting lithotripsy for it. Thus, of 35 children under 10, operated by Cheselden, only 1 died; and of 58 children cut for stone at St. Martin's, but 1 case proved fatal; and the average mortality of lithotomy in children is not more than about 1 in 14. Guersant, at the Children's Hospital in Paris, had performed lithotripsy in boys 18 times; 3 of the patients required to be afterwards subjected to lithotomy; and of the remainder there were 10 cures and 5 deaths—a lamentable mortality in operations for stone in children. Hence lithotomy, being much safer and far more applicable, should be preferred to lithotripsy in all patients under ten, and in those under twenty years of age.

At very advanced periods of life, the irritable state of the urinary organs, the tendency to the supervention of low cystitis, and the enlarged size of the prostate, are often such as to prevent the performance of lithotripsy with any prospect of success. At the same time, the success of lithotomy in advanced age has been very great in the hands of some surgeons. Thus Sequin states that, of 14 octogenarians whom he lithotomized, he did not lose one; of 27 septuagenarians, but two. Lithotomy, on the other hand, is very inapplicable in aged persons.

It is at the middle period of life, or in persons who, though advanced in years, preserve their powers unimpaired, that lithotripsy is most generally applicable and is most successful.

2. *Size and Character of the Stone.*—With regard to the size of the stone, surgeons generally recognise the fact that a small stone is more favourable to lithotripsy than a large one. All calculi below one inch in diameter may be crushed, provided other circumstances are favourable. In regard to larger calculi, it is, as a general rule, not well to attempt to crush a stone that is above one inch and a half in diameter; much, however, will depend on the composition and density of the calculus. The objections to lithotripsy in any given case are, not that a large stone cannot be broken, because in most cases this can be done; but that the fragments may be so large, angular, and sharp, as to require separate crushing to enable them to pass; that their quantity would be so great that the bladder would in all probability not be able to get rid of them; or that their presence, and the necessary operations for their disintegration and removal, would produce a dangerous amount of irritation. This is especially applicable to *lithic acid* concretions, giving a clear and ringing sound, the fragments of which do not disintegrate, but split up into sharp and angular spicula and scales. *Oxalate of lime* calculi, occurring chiefly in young people, comparatively rarely admit lithotripsy, but, when crushed, break up very readily; and, as there is usually a co-existing healthy state of the urinary organs, the cases have a favourable issue. *Phosphatic calculi*, which are soft and friable, and do not yield angular fragments requiring repeated disintegration, may, even if of larger size than that mentioned, be broken up. Some of the French lithotrisers are in the habit of breaking up friable phosphatic calculi of from fifteen to twenty lines in diameter. At the same time, the shattered state of system, and the irritable condition of the urinary organs in the phosphatic diathesis, often counterbalance the advantage that would otherwise have been derived from the character of the stone.

If there be several stones, the propriety of performing lithotripsy will depend in a great degree upon the size of the calculi. If these be small—not larger, perhaps, than small nuts, and not very numerous, the bladder being healthy—the operation may be performed with safety. I have removed successfully in a few sittings five or six calculi about half an inch in diameter. But if the calculi be larger than that, lithotripsy is not a very successful procedure; for, though each calculus may not be very large, yet the aggregate of the whole is considerable; and, besides this, the calculi will each require a separate operation, as it were, and may each contain a hard and possibly very resisting nucleus.

The case in which a calculus, after having been broken up into several fragments, has been left in the bladder, each fragment forming the nucleus for a new stone, is occasionally met with. Such cases are usually most successfully cut; but under favourable circumstances as to the condition of the urinary organs, they may be subjected to lithotripsy.

3. *The Conditions of the Urinary Organs* that influence the propriety of performing lithotripsy or lithotomy have reference to the state of the kidneys, the bladder, the urethra, and the prostate.

As a general rule, it may be stated that the greater the irritability and inflammatory tendency of the urinary organs, the less successful will lithotripsy be. The repeated introduction of instruments, however carefully and skilfully conducted; the presence of fragments of calculus, and their tendency to impaction or entanglement in the urethra, necessarily dispose to inflammation, even in the most favourable cases, and very readily excite it, if there be any tendency to such action existing in the parts. If, however, the stone be small, or of moderate size, and friable; the bladder healthy, and of good contractile power; the urethra capacious; and the patient of

sound constitution and quiet temperament, the stone may often be broken up and the fragments expelled with comparatively little suffering. In such cases, under a combination of favourable circumstances, such as these, lithotomy ought unquestionably to be preferred to lithotripsy.

If, however, the bladder be very irritable, or if the patient's constitution be an excitable one, so that he does not well bear the introduction of instruments; and more particularly if it be found that this local and constitutional sensitiveness, instead of being blunted by the methodical introduction of sounds or bougies, is rather increased thereby; and especially if the stone be of such size that several sittings would be required before the fragments could be expelled—lithotomy should be employed.

The existence of organic disease, however, about the urinary organs, constitutes the greatest obstacle to lithotripsy; and, when extensive, must constitute a complete bar to the performance of that operation. It is not easy, however, to determine the amount of local disease that should thus be held as contraindicating lithotripsy. On this point the opinions of surgeons differ much; and it is particularly in the management of these cases that the advantage of that tact and dexterity in the use of the crushing instrument, which habit can alone give, is so well exemplified.

The condition of the *kidneys* merits special attention. If these organs be diseased, as indicated by the presence of casts of tubes, or of a considerable quantity of albumen in the urine, or in any other way, the performance of a series of operations in the bladder would be likely materially to increase mischief in them, and consequently ought not to be undertaken. Organic disease of the kidneys is a more serious obstacle to lithotripsy than to lithotomy, on account of the prolonged nature of the operation, and the liability to sympathetic or propagated irritation in these organs, giving rise to purulent nephritis. It is not only by the operation increasing the mischief that harm might result, but also in consequence of the tenderness, low and diffuse inflammation of the bladder, prostate, and surrounding cellular planes, and to pyæmia, that always co-exists with kidney disease.

The conditions of the *bladder* that interfere seriously with lithotripsy are partly functional, partly organic. The functional derangements are of very opposite kinds; viz., a state of extreme irritability of the organ, or an abnormal want of sensibility of it—a state of atony. The organic consist of hypertrophied, fasciculated, sacculated, and permanently contracted states of the viscus, which is then most commonly irritable as well.

A *chronically inflamed or irritable state* of the bladder, more particularly if the organ be thickened and fasciculated, so that it will not bear the injection of a few ounces of tepid water, seriously interferes with the success of lithotripsy. A very irritable and sensitive bladder not only will be the seat of severe suffering on the introduction of instruments, but may not admit of holding sufficient water to make the operation a safe one, and readily become dangerously inflamed in consequence of the repeated introduction of instruments, and the presence of angular fragments. If, in the ordinary operation of sounding occasion much distress, if the patient cannot hold his urine long, and pass it in small quantities, if it be often or much loaded with viscid mucus, he will scarcely be able to bear the procedures necessary for the operation. In some instances, however, the irritability of the bladder may be overcome, and in all it may be much lessened, by keeping the patient in bed, and, as Sir B. Brodie recommends, daily injecting tepid water. If the bladder be *sacculated*, there will still greater risk of an unfavourable result; the sacs not only retain fragments of calculus, but also becoming the seats of unhealthy inflam-

tion, in consequence of which typhoid cystitis of a very serious character, followed by pyæmic symptoms and metastatic abscesses, may result. In such cases as these, lithotomy offers the only chance to the patient. The existence of a moderate amount of vesical catarrh, if the bladder be otherwise healthy, is no objection to lithotrixy.

In *encysted calculus*, lithotrixy is, for obvious reasons, inadmissible.

Atony of the bladder is not only a serious inconvenience, but a great source of danger in lithotrixy. It cannot in all cases be positively ascertained beforehand; though it may be suspected if the patient can hold his urine for a great many hours, and can bear without complaint the injection of a large quantity—eight or ten ounces—of fluid, the interior of the bladder feeling large and smooth to the sound. This condition chiefly occurs in old men of feeble habit of body; and, if ascertained, calls for the performance of lithotomy. As Civiale has pointed out, this condition may be a source of great danger after lithotrixy, the organ not possessing sufficient expulsive power to rid itself of the fragments with which it is encumbered, and of the presence of which it seems to be insensible, so far as the feelings of the patient are concerned; while its low vitality renders it peculiarly liable to subacute cystitis, excited by the presence of the fragments in the lower fundus. It must be borne in mind, that this atony of the bladder may, especially in feeble and aged individuals, be induced by the contact of the instrument, and especially by prolonged sittings.

If the *urethra* be the seat of stricture, or be very irritable, lithotrixy—which may require the frequent introduction of instruments of large size, and will entail the continued passage of fragments of calculus—cannot be performed. Stricture of the urethra does not, however, absolutely prevent the performance of lithotrixy, but only retards the operation until the constriction can be properly dilated. Should this, however, not be practicable to the full extent of the urethra, lithotomy on a small staff must be practised.

Moderate enlargement of the *prostate*, such as is habitually met with in elderly people, does not necessarily prevent the performance of lithotrixy; though it undoubtedly complicates the operation. The introduction of the lithotrite will be attended by considerable difficulty; and the fragments have a tendency to become lodged in a pouch of the lower fundus behind the enlarged gland. This more especially happens if the middle lobe be enlarged; and in these circumstances, though the stone may undoubtedly be crushed, yet the fragments would probably require to be removed by the scoop; the operation would consequently be very tedious and prolonged, and lithotomy would probably be found to answer best. Any inflammatory disease or abscess of the prostate, must necessarily prevent the performance of lithotrixy.

I have said nothing in this comparison between lithotrixy and lithotomy of the comparative painfulness of the two operations; for, as chloroform may be administered with equal advantage in both sets of cases, there is little difference in this respect, except that perhaps the advantage lies on the side of lithotomy, as being the shorter proceeding.

From all that precedes, then, it would appear that, useful as lithotrixy unquestionably is in many cases, it cannot be looked upon as a general means of treating stone in the bladder; being only applicable in favourable conditions of the urinary organs, to calculi of small, or, at most, but moderate size, and that a large number of cases will always be left in which lithotomy offers the sole means of relief.

CHOICE OF OPERATION OF LITHOTOMY.—The particular operation of lithotomy that should be had recourse to, will also vary according to the character of the stone. If this be of small size, and the patient an adult, the *median*

operation may advantageously be performed. If it be of moderate tolerably large size, and more particularly if the operation be practised on a child, the *lateral* appears to me to be the more applicable. If, again, calculus be of inordinate magnitude, the *suprapubic* or the *recto-vesical* operation should be the method selected. In fact, the surgeon should confine himself too exclusively to any one method of operating, but should adopt that procedure which appears to be best adapted to the special circumstances presented by the particular case before him, and should vary his method according to the state of the urinary organs, the age of the patient, the size and characters of the stone.

The *Result of Operation for Stone* will depend in a great measure upon the condition of the bladder, and the character of the stone. If the bladder be healthy, all symptoms will cease on the removal of the calculus, and the patient will be restored to perfect health. This usually happens when the calculus is of the lithic acid or oxalate of lime varieties, and of renal origin. If, however, the bladder be unsound, irritable, and disposed to the accumulation of phosphatic matters, the calculus being phosphatic, and chiefly, if not wholly, vesical in its origin, then an irritable state of bladder may be produced, or may speedily return after the operation, which will consequently be unproductive of little, or only of temporary benefit.

RECURRENT OF CALCULUS AFTER OPERATION.—This may take place from three distinct causes—1, in consequence of a continuance of the constitutional condition or diathesis, under the influence of which the calculus was originally formed; 2, from the descent of a renal calculus; and 3, from a fragment of calculus having been accidentally left in the bladder.

Relapse from the first cause is probably not very common, but its occasional occurrence shows the necessity of continuing constitutional treatment adapted to the particular diathesis, after the removal of the calculus from the bladder. It is relapse from this cause that probably occurs in cases of lithotomy; though even in this operation a fragment of calculus may be accidentally broken off during extraction, and left. Yet such an accident is not very frequent; for, if the calculus happen to be broken during extraction, the fragments, if not completely cleared out of the bladder, will usually be washed away through the wound by the flow of urine. The registers of the Norwich Hospital show 1 relapse in 38 cases; those of Lunenburg, 1 in 116 cases of lithotomy (Coulson).

After lithotripsy, on the other hand, relapse is far more common. In the practice of Civiale it has occurred about once in every tenth case. But estimate, high as it is, falls far below what happens in surgical practice generally. Civiale states that, of 36 private patients on whom he operated in 1860, 10 had previously been operated on, the stone having reappeared. This must evidently arise from some fragment of calculus having escaped detection and being left behind, thus constituting a nucleus for a fresh formation. The frequency of the occurrence of secondary calculus after lithotripsy, even in such practised hands as Civiale's, certainly constitutes an objection to that operation, and shows the necessity of the surgeon carefully examining the bladder before he pronounces the patient cured; even then watching him for some length of time, in order to meet the stone at its first formation, and to adopt means for its early removal. Lithotomy cannot always be said to be so complete a cure in all cases as lithotripsy. Not only is recurrence of calculus more common after the former than after the latter operation, but it not uncommonly happens that patients who have been lithotomised successfully, and in whom no recurrent calculus has formed, continue to suffer for a great length of time afterwards from very distressing

irritability of the bladder, which resists in the most obstinate manner all the ordinary methods of treatment. This is not the case after lithotomy: when a patient once recovers, his bladder regains its tone completely, and no trace of evil consequences is left.

Treatment.—In the event of a secondary calculus forming, whether after lithotomy or lithotripsy, most surgeons would feel disposed to extract it by the cutting operation. If lithotomy have previously been performed, this may be done again in the usual way, through the cicatrix left by the former wound; or the surgeon may adopt Liston's advice to cut through the right side of the perineum on a staff with a groove to the left of its convexity. As this procedure, however, would entail the use of the left hand for cutting and extracting, most surgeons would, I think, prefer either the operation through the site of the old wound, or else the median operation. Whatever procedure, however, is adopted, it should be borne in mind that the rectum may have become rather firmly adherent to the membranous portion of the urethra and the apex of the prostate, in consequence of the contraction of the old cicatrices, and may thus be endangered.

URETHRAL CALCULUS.

Calculi are not unfrequently met with in the urethra, especially in children, passing from the kidney, perhaps, into the bladder, and thence into the urinary canal, through which they occasionally escape, but in other instances lodge, more especially at the bulb or in the navicular fossa. These calculi are commonly of the lithic acid, lithate of ammonia, or oxalate of lime varieties; they are frequently round, but not uncommonly elongated or spindle-shaped. There is reason, however, to believe that calculi may form in the urethra. One of the most remarkable instances of this kind is represented in the annexed cut (Fig. 468), taken from a drawing in Sir R. Carswell's collection at University College. The stone here was of very large size—equal in bulk to two horse-chestnuts. In cases of tight stricture, sabulous or calculous concretions may occasionally be formed behind the constriction.

SYMPTOMS.—The presence of a calculus in the urethra may always be determined by the difficulty that is occasioned in micturition, and by the possibility of feeling the stone through the walls of the canal, or of detecting it by introducing a sound into the urethra.

TREATMENT.—The removal of these calculi may be effected either by extraction or by excision. When situated towards the anterior part of the canal, an urethral calculus may frequently be extracted by passing a long and very narrow-bladed pair of forceps down to it, by which it is seized and drawn forwards; occasionally, when it has reached the navicular fossa, it will not pass through the urethral orifice unless this be dilated by incision with a probe-pointed bistoury. If the calculus be too large to be extracted in this way, and appear to be firmly fixed, an incision may be made down upon it, through the urethra, by which it may be removed. It is a good rule not to make this incision in any part of the urethra anterior to the scrotum, for, in consequence of the coverings of the penile portion of the urethra being very thin, the aperture will probably not be closed, but a

Fig. 468.—Urethral Calculus.

fistulous opening left. When the stone is in the urethra, there would be some risk if the incision were made through the stone; it is better, if possible, to push the stone out of the portion of the canal, to cut down upon the stone. This operation may readily be done by passing an ordinary director, as far as the calculus end of it, so as to lay open the urethra, the calculus extracted by means of a pair of forceps should next be passed into, and retained in the bladder in order to lessen the tendency to the formation of a fistula.

It may happen that the calculus, impeding the urine, is several that are lodged in the bladder. The surgeon should, after removing the calculus, pass a sound into the bladder, to see if other concretions exist in that organ; if they are removed by extending the incision of the urethra into the bladder, by the lateral or perineal way I once saw Liston extract two vesical calculi that had blocked up the urethra.

PROSTATIC C

Prostatic calculus differs from all others in its composition, being formed in the ducts of the prostate principally of phosphate of lime (about 85 per cent. of the phosphate, sometimes, also, the concretion is said to be composed of carbonate of lime). It generally occurs in old persons, but I have met with in young subjects. From the history of vesical calculus, I extracted two prostatic calculi.

CHARACTERS. Prostatic calculus is somewhat triangular, smooth and polished, very hard, and seldom is it branched; though it may occasionally have been met with as I have seen, presenting a branched or irregular shape. But one or two exist, and they are not of the kind of cyst in the organ. They have been met with, the ducts of the prostate being studded with them.

Fig 460.—Prostatic Calculus.

SYMPTOMS.—Calculus in the prostate causes irritation in the perineum, sometimes, in fact, to the ordinary symptoms of calculus. It often occasions a tolerably free secretion of urine. On introducing a sound, this passes over the stone with a distinct grate or click before it is increased by the finger in the rectum, thus bringing the stone into more direct contact with the sound. In these cases the calculus is deeply imbedded in the prostate. If there be many small calculi, they may be felt by introducing the finger into the rectum. A crackling or grating sensation may be felt on the passage of the calculi, something like that produced by the passage of small stones through the urethra.

TREATMENT.—The treatment of prostatic calculus will depend upon the situation, size, and number of the concretions. When they are large, single, or at most two or three in number, readily struck with the sound, and situated on the urethral surface of the organ, the ordinary median operation may advantageously be performed, and the calculus removed with scoop or forceps. If the calculi be small and very numerous, not to be felt with a sound, but only through the rectum, it will be wiser not to have recourse to operation, which could not succeed in removing the whole of the concretions. In such circumstances, a palliative treatment directed to the subdual of the irritation of the prostate, and the use of the catheter to relieve retention, is the only course to pursue. When prostatic and vesical calculus occur together, the same operation will rid the patient of both forms of the disease.

CALCULUS IN THE FEMALE.

Stone is of rare occurrence in women; in London, certainly, I believe it is not often met with. Thus, South states that, during a period of twenty-three years, 144 males were operated on for stone at St. Thomas's Hospital, and only 2 females. In some districts, however, stone would appear to be more common in women than this. Thus, according to Crosse, at the Norwich Hospital, the proportion has been about 1 woman to 19 men. Civide states, as the result of his researches, that in the North of Italy, the proportion is as 1 to 18; and in France, as about 1 to 22. Calculus in women is most frequently deposited upon foreign bodies, accidentally or purposely introduced into the bladder, such as pins, pieces of pencil, &c.

At the University College Hospital we had not had a case of stone in the female for many years until 1855, when three came under my care in the course of a few months; and since that period several have occurred.

SYMPTOMS.—The symptoms of stone in the female closely resemble those that occur in the male, and its presence may usually be easily detected by means of a short and nearly straight sound, or a female catheter. It is often simulated very closely by the irritation occasioned by a vascular arethral tumour, or by an irritable bladder; but exploration of the viscous will always determine the diagnosis.

Calculus in the female bladder, if allowed to remain unrelieved, will not only occasion the various morbid conditions in the urinary organs that have been described as following the long-continued presence of stone in the male, but will give rise to diseased states peculiar to the female. Thus the stone may be spontaneously discharged through the urethra; if of small size, without any bad results following; but if large, by a process of ulceration, in consequence of which permanent incontinence of urine will remain: or it may slough through into the vagina: or lastly, it may offer a serious obstacle during parturition to the descent of the fetal head, when, if it cannot be pushed aside to be dealt with afterwards, it must be cut out or craniotomy be performed.

REMOVAL.—A stone may be extracted from the female bladder by one of three methods: 1, by Lithoclasty, through a dilated urethra; 2, by Lithotomy; 3, by Lithotripsy. These different operations cannot be employed indiscriminately, but each one is more especially adapted to certain kinds of calculus.

1. **LITHOLASTY** may be performed in two ways—either by simply *Dilating the Urethra* by means of a sponge-tent or dilator, or else by *Incising the Mucous Membrane* at the same time that the canal is being expanded.

a. *Simple Dilatation* of the urethra may be effected quickly by the introduction of a tent of compressed sponge, or a three-bladed dilator, which is

rapidly screwed up. In this way, in from a few minutes to two hours the canal may be easily dilated sufficiently to admit of the introduction of a pair of forceps, and the extraction of a calculus of moderate size. Some surgeons prefer a slow process of dilatation, continued through many hours; but appears to me to possess no advantage over the more rapid expansion. It has the very decided disadvantage of prolonging the patient's sufferings. The plan that I have adopted with most success is to introduce a sponge into the urethra two hours before the intended extraction; and then, when the patient is under the influence of chloroform, to dilate the urethra to the required extent, with a two- or three-bladed dilator.

b. *Incision* may be employed conjointly with dilatation, in order to prevent injurious stretching of the urethra, and consequent laceration of the mucous membrane. The incisions recommended with this view should be made after the urethra has been dilated to some extent, a probe-pointed bistoury being introduced by the side of the canal, and the mucous membrane divided. Brodie made an incision directly upwards; Liston downwards and outwards on each side—on the whole, I think, the best direction for the incisions, as more space may thus be obtained.

By dilatation, either alone or with incisions of the mucous membrane, small stones may readily be extracted; but in the removal of moderate-sized calculi, the great objection to this operation is the liability to incontinence of urine resulting from it. It is difficult to say to what extent the urethra may be dilated without incontinence resulting; this must necessarily vary in different individuals. It certainly can be expanded sufficiently to admit the introduction of the index-finger, and to allow of the extraction of a calculus eight or ten lines in diameter, without any evil resulting. The incontinence of urine that may be left after the removal of larger calculi than this is not by any means complete; but a weakened state of the sphincter of the bladder results; so that the patient cannot hold her urine for more than an hour or two at the most.

2. *Lithotomy in the female* may be performed in a variety of ways. There are, however, only two modes of practising this operation that appear to me to deserve serious attention, viz., the *Suprapubic* and the *Vaginal*.

The *Suprapubic* or *high* operation in women differs in no very material respect from the same procedure in men; except that it requires more care in consequence of the difficulty there is in causing the female bladder to retain a sufficient quantity of urine to make the viscous mucus sufficiently abundant to retain the stone at the pubes. The extraction of the stone is easy, as it can be raised into the grasp of the forceps by being pushed up from the vagina.

Vaginal Lithotomy is an operation easy of performance. It may be practised by passing a straight grooved staff into the bladder, pressing the stone well down against the anterior wall of the vagina, and fixing it there with the left index-finger. A scalpel is then pushed through the anterior wall of the vagina and inferior fundus of the bladder into the groove of the staff, which it is made to enter just behind the urethra, and is then carried backwards for about $1\frac{1}{2}$ inch; through the aperture thus made the forceps is passed, and the stone extracted. The incision into the bladder through the anterior vaginal wall should be brought together by metallic sutures, as in ordinary operations for vesico-vaginal fistula, and may thus be sufficiently closed, as has been done by J. Lane, Aveling, and others.

Both the high and the vaginal operations are easy of performance. In the high operation, there would, with care, be but little risk of injuring the peritonæum; and the chance of urinary infiltration, which is a serious danger in the male, may be prevented in the female by the introduction of a catheter

catheter into the urethra. The vaginal operation, though easier of performance, is open to the objection of possibly leaving a permanent urinary fistula. If, however, the lips of the incision have not been bruised by the forceps, or in the extraction of the stone, and be immediately brought together by metallic sutures, the risk of a fistula is, after all, not great. Vaginal lithotomy may, in some cases, be the only alternative. I extracted, by this operation, a calculus measuring eight inches by six in circumference, from the bladder of a woman twenty-three years of age, who had suffered from symptoms of stone from childhood. The stone by its size offered so serious an obstacle to the descent of the fetal head during parturition, that craniotomy had been rendered necessary; the anterior vaginal wall had been a good deal bruised, and I feared that sloughing of it might take place; hence I extracted the stone by the vaginal method.

3. LITHOTRITY in the female requires to be practised on the same principles as in the male. The details of the operation differ, however, in some important particulars. The chief difficulty in the performance of the operation in the female, consists in causing the bladder to retain urine or water that is injected into it. In consequence of this there is not only great difficulty in seizing the stone, the bladder collapsing and falling into folds around it, but also danger of injuring the mucous membrane with the lithotrite. In order to cause the bladder to retain the necessary quantity of urine, the pelvis must be well tilted up, and the urethra compressed against the lithotrite. It is well not to dilate the urethra before the introduction of the instrument, as the incontinence is thereby increased.

The ordinary male lithotrite is not a very convenient instrument to use in the female bladder, the handle being awkwardly long. This is especially the case in female children. Hence I have found it convenient to have a shorter instrument constructed, with which it is far more easy to manipulate in the female bladder. If urine or water cannot be retained, the calculus may more safely be seized and crushed by means of a small and strong-bladed pair of lithotomy-forceps; or, if the stone be larger, by a crushing instrument, made of the shape of that depicted in Fig. 449, but smaller and lighter.

After the stone has been crushed, the urethra (unless this have previously been done) may be dilated by means of the two-bladed instrument to a moderate degree, and the larger fragments removed by means of a pair of slender forceps. The whole of the fragments and detritus should be removed at one sitting. The shortness and wide capacity of the female urethra will readily allow the escape of any detritus that may unavoidably be left.

For all calculi in the female bladder, except those of the very largest size, this operation is the most applicable. I have in this way crushed and extracted at one sitting, a calculus (phosphatic) fully as large as a hen's egg. By this operation the stone may be removed piecemeal and at once, without the necessity of dilating the urethra to such a degree as to incur the risk of incontinence of urine resulting. Lithotrity may be had recourse to at all ages, in the very young as well as the old; I have crushed and successfully removed a large calculus in a child three and a half years of age. Although the urethra of a female child is not very dilatable, yet it can readily, by means of a sponge-tent, be enlarged sufficiently to admit an 11 or 12 lithotrite.

CHAPTER LXVII.

DISEASES OF THE BLADDER.

CONGENITAL MALFORMATION.

EXTROVERSION OF THE BLADDER, consisting in an absence of the anterior wall of the organ, with deficiency in the corresponding part of the abdominal parietes, is occasionally met with as a congenital malformation. The posterior wall of the bladder, being pushed forwards by the pressure of the abdominal viscera behind, forms a rounded tumour of about the size of a small child, just above the pubes. The surface of this tumour is red, vascular, papulated, evidently composed of mucous membrane; at its lower part the orifices of the ureters will be observed to open, and to discharge urine in drops or in a stream. For a full description of the mechanism of the passage of the urine in this malformation, I would refer to a case which fell under my notice, and in which I made a number of experiments to ascertain the rapidity of the passage of foreign matters through the kidney, reported in the *Medical Gazette* for 1845.

This malformation is incurable. Operations have been planned and performed, with the view of closing in the exposed bladder by various procedures, but they have rarely proved successful, and have terminated in some instances in the patient's death; they do not, therefore, afford much encouragement for repetition. The patient should, therefore, wear a properly constructed instrument to receive and collect the urine, consisting of a hollow shield strapped over the part, communicating by means of a tube with an India-rubber bottle, which may be attached along the inner side of the thigh.

CYSTITIS.

Idiopathic inflammation of the bladder is of rare occurrence. The disease most commonly originates either from traumatic causes, as from the use of instruments, the irritation of broken fragments of calculus, &c. or it may arise from irritation produced by the application of blisters, the administration of diuretics, or directly from the extension of gonorrhoea to the interior of the organ.

ACUTE CYSTITIS.—The *Symptoms* of cystitis consist not only in pain and weight about the hypogastric and iliac regions, with tenderness on pressure in these situations, and a good deal of constitutional irritation, but in the existence of extreme irritability about the bladder. So soon as a few drops of urine collect, they excite so much irritation in this viscus that it cannot be retained, and are expelled by a kind of spasmodic or convulsive effort, constituting stranguary, often accompanied by a good deal of tenderness and great suffering. The urine will be found to be high coloured, and mixed with more or less mucus or pus, and often tinged with blood.

Termination.—An acute attack of cystitis usually terminates in the chronic form of the disease, and thus gradually undergoes resolution. Occasionally, however, it terminates fatally; and when this is the case the patient's symptoms commonly assume an ataxic character, the tongue becoming brown and dry, the pulse rapid and weak, and the urine becoming offensive. On examination after death, it will commonly be found that the inflammation of the bladder has gone on to gangrene of the mucous

brane, to diffuse peritonitis, or to the formation of abscess, either in the substance of the wall of the bladder or between the bladder and the rectum, with perhaps infiltration of urine in the deep cellular tissue of the pelvis or the perineum.

Treatment.—The treatment of cystitis is very simple, the disease admitting of little being done in the way of medicines. The free application of leeches to the neighbourhood of the inflamed organ, long-continued soaking in warm hip-baths, the application of poppy fomentations or of laudanum and linseed-meal poultices, the injection of emollient enemata, and the copious administration of barley-water or mucilaginous drinks, will subdue the inflammation and afford the patient great comfort; to these means may be added the administration of antimonials with henbane or opiates. The only salines that are of much use are the citrate and nitrate of potass; and these must be given largely diluted.

CHRONIC CYSTITIS.—Acute cystitis commonly degenerates into the chronic form of the disease, the symptoms of which closely resemble, though in a modified degree, those that have just been described as characterising acute cystitis, and constitute one of the varieties of the “irritable bladder.”

The *Treatment* of chronic cystitis must be of a moderately antiphlogistic character, so long as inflammatory action keeps up; when once this subsides, and the disease falls into an asthenic condition, the management of the disease must, to a considerable extent, be modified. In the early stages, whilst there is tenderness and inflammatory action, leeches, warm hip-baths, poppy fomentations, mucilaginous drinks, with henbane, and some alkaline remedies, especially the liquor potassæ largely diluted, will be found most useful, the bowels at the same time being kept open by castor-oil and enemata. If there be much strangury of a spasmodic character, it will best be relieved by cupping or leeching the perineum, the internal administration of chloric ether and opiates, or the cannabis indica, and the use of opium suppositories.

IRRITABILITY OF THE BLADDER is a condition of very frequent occurrence. It is met with at all ages, complicates many of the diseases to which the urinary organs are liable, and arises from a great variety of causes.

Symptoms.—The patient has a frequent desire to pass urine, the fluid is generally ejected forcibly, or even spasmodically, and in small quantities at a time. Its passage is attended by pain of a burning, aching, spasmodic character, then constituting *Strangury*, sometimes confined to the body, sometimes to the neck of the bladder, not unfrequently extending to the point of the penis, or radiating round the pelvis and down the thighs. The urine may in the earlier stages, and in some cases throughout, continue to be healthy; but more commonly, after the disease has lasted some little time, it becomes loaded with mucus, muco-pus, or pus. When the mucoid secretion is abundant, viscid, and glutinous, the affection becomes *Vesical Catarrh*. In this stage its duration may be indefinite, more particularly in individuals advanced in years.

Symptoms of Vesical Catarrh.—In vesical catarrh the symptoms are made up of local irritation and constitutional debility. There is frequent desire to pass urine, which is usually ammoniacal and fetid, and is mixed with a large quantity of glutinous stringy mucus, which gives it a turbid appearance. The urine, on standing, separates into two parts, the upper being clear, but the lower consisting of a thick, viscid, slimy or gummy mucus, often semi-opaque and purulent in appearance; it sticks tenaciously to the bottom of the pot, and when poured out hangs from the edge in long

stringy masses. It is often mixed with a phosphatic kind. Its microscopic appearance is as follows.

This chronic form of inflammation of the bladder, when it terminates in death, results eventually with symptoms of

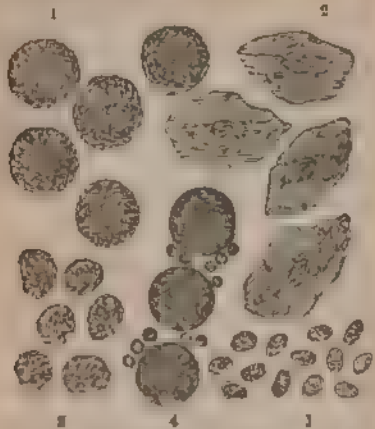

Fig. 470.—Microscopical Appearances in Mucous of Vesical Catarrh.—1. Mucous. 2. Epithelium. 3. Pus. 4. Organic Globules, met with in the urine.

folds and ridges, which become thickened by the pressure between them, so as to cause the somewhat the inside of one of the cavities of the columnar carinae. This farciculated compartment of long-continued chronic inflammation. As the organ becomes hypertrophied, in the disease, it usually becomes sacculated

Fig. 471.—Cyst in the Wall of the Bladder.

or lateral parts, of which are formed the foci of the wall, the least common kind of cyst, the mucous coat is pushed out of the cyst, the mucous protrusion (the accumulation of mucus, pus, and concretions, not

these situations. It is the retention of these cysts, where it undergoes decomposition, the great fetor of the urine in such cases.

Causes.—Irritability of the bladder may arise from a great variety of causes. These may be in men, women, or in children. The disease in men may be arranged under the following

1. **Morbid Conditions of the Urine.**—When the urine is acid and acrid, and loaded with lithates, it is especially apt to occasion inflammation, by pain and a frequent desire to expel the phosphates and oxalates in large quantities. Rarely, a source of irritability of the bladder

increased by the morbidly sensitive state of the nervous system usually co-existing with these conditions of the urine.

In *gout*, irritability of the bladder is not unfrequently met with. This appears in some cases to be owing to the acid and acrid character of the urine in that disease; in other cases, to the excitation of a distinct *gouty* inflammation of the bladder and prostate, co-existing or alternating with the articular form of the disease.

2 *Renal Disease*, more particularly the lodgment of a stone in the kidney, will often occasion sympathetic pains in the bladder, with much irritability of that organ, so as closely to simulate vesical irritability, or even to lead to a suspicion of the existence of stone in the bladder.

3 *Disease of the Bladder itself*, as a chronically inflamed state of its mucous membrane, will give rise to pain and irritation on the accumulation of a small quantity of urine in the organ, with a frequent desire for its expulsion. So also, when the interior of the organ is fasciculated, or contains cysts, and more especially if there be a tumour in a state of ulceration, a degree of morbid irritability will be induced, often of the most severe and intractable kind.

4. The *Lodgment of a Stone in the Bladder* will always, by its mechanical action, by its weight and pressure, by rolling about when the body is in motion, irritate the interior of the organ; and, in fact, the "rational symptoms" of stone in the bladder are simply those of irritability of that organ.

5. *Inflammation, Ulceration, Abscess, or other Diseases of the Prostate*, and inflammation, gonorrheal or simple, and abscess or stricture of the deeper portions of the urethra, may also not unfrequently be referred to as the occasioning causes of irritability of the bladder.

6. *Various Diseases in Neighbouring Organs* will occasion this condition. Amongst the most frequent are fissure and ulcer of the rectum and anus, piles, prolapsus, intestinal worms, gall-stones, and varicocele.

Diagnosis.—The diagnosis of irritability of the bladder is easily made; but it is often a matter of no little difficulty, though of the very first importance, to diagnose the precise cause of that irritability. This can of course only be done by a careful *surgical* exploration of the whole of the urinary organs, and often of the neighbouring parts; no mere inquiry into the nature of the symptoms, no chemical examination of the urine, can do more than establish the fact of the existence of "irritability of the bladder," and afford some evidence of a negative kind as to the absence of certain causes. But nothing short of a careful surgical exploration by means of the catheter, finger, and sound, of the urethra, prostate, and bladder, can enable the practitioner to state with absolute certainty on what this condition of irritability depends. I have repeatedly seen cases of stone in the bladder, and of prostatic disease, vainly treated by medical means for months as cases of simple "irritability of the bladder," the existence of the real cause of the symptoms having been overlooked altogether, until a proper surgical examination of the urinary organs was instituted. So closely, in fact, do the symptoms of vesical irritation, arising from gout or sympathetic with kidney-disease, simulate those that are occasioned by stone in the bladder, that it is impossible for the most experienced medical practitioner to refer them with certainty to the right cause without exploring this cavity. And, indeed, I have known several patients who had been successfully operated on for stone, and who, some years afterwards, suffered from gouty or other irritability of the bladder, imagine, but erroneously, that they were labouring under a recurrence of the calculus; so closely do the two classes of symptoms coincide in character.

Treatment.—The treatment of irritability of the bladder must reference to the removal of its cause, and the subduing of the local irritation by the use of demulcents and soothing means. It must be borne in mind that this condition is not a substantive disease, but is an accidental symptom resulting from the influence of a great number of very various causes, which must first be removed before the bladder can recover its normal sensibility and tone. When once the occasioning cause has been removed, whether that be a calculus, or gout, or prostatic disease, or a stricture, the remaining local vesical irritation may usually be removed by the use of weak alkaline and mucilaginous drinks, with henbane, cannabis indica, or opiates, a carefully regulated diet, warm hip-baths, and opiate suppositories in the rectum.

Treatment of Vesical Catarrh.—When vesical catarrh has come on, the disease has lost its active inflammatory character, appearing rather to consist of atomic exudation from the mucous membrane, a different plan of treatment will require to be adopted. In such cases as these, the greatest benefit will be derived from warm stimulating and balsamic drinks. Amongst the best are infusion of buchu or matice in large doses, either alone or conjoined with the balsams of Peru or copaiba. Turpentine, oil of turpentine, and tincture of the sesquichloride of iron, will all be found useful, and is often difficult to say beforehand which diuretic will suit best, and I lay down no precise rules to guide the practitioner in this respect, they may often be tried or alternated with advantage. In many cases temporary relief is obtained from each new remedy, which fails to be permanent. In the more advanced forms of the disease, when typhoid symptoms come on, bark and ammonia will be found most useful, together with the administration of the brandy-and-egg mixture. In these cases also of great importance to empty the bladder, by means of the catheter, of viscid mucus that accumulates in it, and the putrefaction of which, together with that of the residual urine, tends to engender the depressed state which the patient sinks. In some cases, this may advantageously be done by washing it out with warm water injections through a double catheter. In this stage of the disease, benefit may occasionally be derived from the employment of very slightly astringent injections. Amongst the most useful of these will be found the nitrate of silver, in the proportion of one grain to four or six ounces of tepid distilled water. Sir B. Brodie has advantageously employed water very slightly acidulated with nitric acid.

IRRITABILITY OF THE BLADDER IN CHILDREN appears to be an affection closely allied to the congestive and subacute inflammatory conditions of the different mucous membranes, as of the eyes, nose, and throat, that commonly occur in strumous subjects. In this disease the child passes urine with great frequency and with much pain; the urine is offensive, and usually phlegmatic; not unfrequently there is much uneasiness complained of about the groins and along the penis; in fact, many of the ordinary symptoms of gonorrhoea are present. On scouring the bladder, it will be found rough, inflamed, fasciculated, and often containing scabulous matters mixed with mucus. Occasionally there is a good deal of gastro-intestinal irritation, and unfrequently worms are present.

The *Treatment* should consist in attention to the general improvement of the health of the patient, in the removal of intestinal irritation, in the regulation of the digestive functions, and in the administration of opium in small doses, either alone or conjoined with a few minims of belladonna, at the same time that general antistrumous treatment must properly be carried out.

IRRITABILITY OF THE BLADDER IN WOMEN not unfrequently occurs, and often simulates stone so closely, that it is only after very careful sounding that the surgeon is satisfied that no calculus exists. This condition appears to be dependent on a morbidly sensitive state of the mucous membrane of the urethra and bladder that may arise from a variety of causes. In some cases it is a truly neurotic or hysterical condition. In other instances it is sympathetic; being connected with some local disease of the genito-urinary organs, with a vascular tumour at the meatus of the urethra, or with some congestive affection of the uterus, which will require to be cured before the bladder can be brought into a sound state. Prolapsus of the anterior wall of the vagina, drawing down the corresponding portion of the bladder, will keep up this condition; if so, the prolapsus must be cured by some plastic operative procedure. Under all circumstances, however, when this state has once been set up, it is very difficult to remove. In many cases it is undoubtedly due to the irritation produced by a morbid state of the urine, dependent on mal-assimilation, and usually connected with an excess of lithates.

Treatment.—In cases of this kind, careful regulation of diet, and the administration of potass with henbane or copaiba, will afford much relief; but the complaint is of a very chronic and intractable nature, and under the most careful treatment will often continue for years.

TUMOURS OF THE BLADDER, AND HEMATURIA.

POLYPI and **FUNGIOUS GROWTHS** are occasionally met with in the bladder, flat, pedunculated, or pyriform in shape. *Polypi* of the bladder may be composed of various elements; sometimes, but rarely, fibrous, at others villous; they may occur at all ages, and usually give rise to a certain degree of irritation in this organ, which is especially marked when they occur in the vicinity of its neck, where they may even cause retention of urine, and some of the symptoms of stone. *Fungous Growths* most commonly are of a malignant character, fibro-plastic, epithelial, or encephaloid; they then give rise to bloody urine, in which cancer-cells and debris may be found on microscopic examination, thus serving as a diagnostic mark of the nature of the disease.

Malignant fungus or cancer of the bladder is usually associated with similar diseases of the prostate or neighbouring structures, and in women may be secondary to cancer of the uterus. According to Walshe, it does not appear before the fortieth year.

These tumours, whether simple or malignant, occasionally become encrusted with phosphatic matter, deposited upon them by the urine; and then they will resemble still more closely a calculus when the bladder is sounded; from it, however, they may be distinguished by their fixed character, and by the impossibility of passing a sound around them. Some difficulty is often experienced in examining the bladder in these cases; for, as the fungous mass pushes back the posterior wall of the viscus, it has a tendency to elongate the prostatic portion of the urethra and the neck of the bladder, so that a very long instrument may be required to reach it.

Little can in general be done in the way of *Treatment* in this disease; though the example of Civiale might, in some cases, be advantageously followed, who removed a small growth seated at the neck of the bladder by seizing and twisting it off with a lithotrite. Warner has recorded a case in which a tumour of this kind, of the size of an egg, was tied in the bladder of a woman after dilating her urethra.

HEMATURIA.—The admixture of blood with the urine may usually be recognised by the colour that it communicates to this fluid. If the blood be in large quantities the urine will be dark brown, chocolate, or mahogany coloured, and will stain red the bottom of the utensil or a piece of blotting-paper. If it be in smaller quantities, the urine will be brown; in other cases it will be little discoloured, but will deposit a red or brown sediment on standing. Heat coagulates the blood into a brownish deposit, leaving a clear supernatant fluid; and, under the microscope, blood discs may be detected in large quantities.

Hematuria is a symptom of disease existing in some part of the urinary apparatus; but it often assumes so great an importance from the loss of blood induced, that it must be looked upon as a substantive disease.

Sources.—Hematuria may arise from 1, the Kidneys; 2, the Bladder; 3, the Prostate; or, 4, the Urethra; and from each source several different causes will produce it. The recognition of the precise morbid condition that gives rise to hematuria is of the first importance in its treatment.

1. *Hemorrhage from the Kidneys.*—When occurring from the kidneys, the bleeding may be the result of congestion of those organs, of the presence of a calculus in them, or of its descent down the ureter, or of malignant disease. The renal congestion may be inflammatory or passive; in either case the urine will present, after the discharge of blood has ceased, evidence of chronic renal disease in the form of albumen, pus, or casts of tubules. If the hemorrhage arises from renal calculus, either stationary or descending, the symptoms of that morbid condition, described in p. 1069, will be well marked.

2. *Hemorrhage from the Bladder.*—If the blood proceed from the bladder, it may be the result of congestion of the mucous membrane, of the presence of a calculus, or of the ulceration of malignant disease. When it depends on vesical congestion, there will be a sensation of weight in the region of the bladder, with frequent desire to pass urine; when on calculus, the symptoms of the existence of stone will be present; and when on malignant disease, the discharge of pus, and of the debris of the ulcerating tumor, will afford unequivocal evidences of the true source of the hemorrhage.

3. *Hemorrhage from the Prostate.*—If the prostate be the source of the hemorrhage, the discharge may be occasioned by congestion of that organ, by its ulceration, simple or malignant. In these cases, exploration of the rectum and urethra will indicate the true cause of the bleeding.

In general, when the hematuria is renal, the urine will be undecanted, mixed with the blood; when it is prostatic or vesical, the first urine passes, or that is drawn off by the catheter, will be pale and free from blood; the last; and at the termination of the flow nothing but blood may be obtained.

4. *Hemorrhage from the Urethra.*—The bleeding may arise from congestion of the mucous membrane, from inflammatory irritation of the canal, or may follow rupture of the walls of the canal, consequent on injury from the introduction of instruments.

Treatment.—The treatment of hematuria must necessarily have reference to its cause. If it arise from inflammatory congestion of the bladder, or prostate, cupping, or the application of leeches over the affected part, demulcents, and saline drinks, will be most efficacious; if from passive congestion, it will usually be found that the hepatic portal system is affected, and a few doses of mercurials, followed by the use of astringents, speedily induce a cessation of the hemorrhage. The astringent that exerts the most marked influence in arresting hematuria, when that disease is purely passive, is undoubtedly gallic acid. This may be given in ten grain doses, frequently repeated in infusion of buckthorn or uva ursi.

As a general rule, it is better not to use the catheter in these cases ; but sometimes the bladder becomes distended by a large soft coagulum, filling up its interior, and causing it to reach to the umbilicus, forming a rounded solid tumour, like a gravid uterus. Under such circumstances, the more fluid contents may be drawn off by a large catheter, and the more solid portions broken down and washed away by the injection of tepid water through a large-eyed or double-current catheter. If decomposition occur in the coagulum, giving rise to the formation of flatus in the bladder, a weak tepid saline solution, to which a little creasote has been added, may advantageously be used. I have known abundant hematuria to continue for many years—for twelve or fourteen—without any very evident cause, and without deranging the general health to so great an extent as might be expected from so continuous and copious a loss of blood.

ATONY OF THE BLADDER.

Atony of the Bladder may occur with the opposite conditions of retention and incontinence of urine, according to the part of the organ that has lost its contractile power. When the body of the bladder is paralysed, whilst the neck preserves its contractility, retention of urine will ensue in consequence of simple inability on the part of the organ to expel its contents, and not from the existence of any mechanical obstacle to the outward flow of the urine. When, on the other hand, the neck of the bladder is paralysed, whilst the body of the viscus retains its contractility, the urine cannot be retained, but dribbles away involuntarily, thus constituting incontinence.

RETENTION OF URINE.—Loss of tone in the body of the bladder, leading eventually to its paralysis, not unfrequently occurs in old age as the result of simple diminution of muscular power ; or it may happen as a consequence of fever ; or as one of the symptoms of paraplegia, from whatever cause arising. It may occur suddenly in cases of injury, in which the lower part of the spinal cord is paralysed.

Symptoms.—When this condition comes on slowly as the result of disease, the patient usually finds that the urine escapes in a dribbling manner ; that there is some difficulty, and at last an impossibility, in emptying the bladder completely ; and that there is not that forcible ejection of the last drops of urine that is characteristic of a healthy tone in the organ ; at the same time there is not unfrequently a tendency to the dribbling away of a few drops towards the end of the emission of urine, and after its apparent cessation. There is also an occasional escape of urine at night. When complete retention occurs, whether this take place gradually or suddenly, the bladder slowly enlarges, rising at last out of the pelvis into the abdomen, stretching up into the hypogastric region, reaching even as high as the umbilicus. On examining the lower part of the abdomen, the organ will be felt hard, elastic, rounded, and pyriform in shape, projecting above the pubes, and feeling much like an enlarged uterus. In this situation, also, percussion will elicit a dull sound ; and on exploring the part through the rectum, the bladder will be found to project in this direction also ; and on tapping with the fingers above the pubes, fluctuation may be felt through the wall of the gut. After the bladder has once become distended, it commonly happens that a quantity of urine continues to dribble out of it ; in fact, the amount that escapes in this manner may be very considerable, though the retention continue unrelieved. This *retention with dribbling* is a condition of much practical importance, as the continued escape of urine may lead the patient, and even the surgeon, to overlook the true nature of the disease ; the more so, as in elderly people retention slowly induced often occasions but little incon-

venience. I have drawn off nearly a gallon of urine from a patient in whom it had not been suspected that retention existed, in consequence of the continuance of this dribbling. In women, retention is not by any means common as in men, but the bladder will sometimes attain an enormous size, rising as high as the umbilicus; and such large bladders have been known to grow under the supposition of the tumour being an ovarian cyst, or even of cancerous growth. I once witnessed such a case in which the surgeon, to his regret, on tapping the tumour, drew off a quantity of clear and healthy urine instead of ovarian fluid; fortunately no bad effects followed. Retention with dribbling occurs in consequence of the bladder, as it rises above the pelvis, elongating its neck; and as the body becomes bent forward, the pubes a sharp curve or angle is formed at the junction of the neck and body of the viscus, through which a small body of urine continues to pass away, and escapes rather by its own gravity than by any expulsive action of the part of the patient.

Diagnosis.—Retention from atony can easily be diagnosed from retention from obstruction: for, on introducing the catheter when the patient is lying on his back, the instrument will not only readily enter, but the urine will simply flow out in a slow uniform stream, not being projected as in obstruction, by the contraction of the walls of the organ, but rising and falling in accordance with the respiratory movements. The urine that escapes in a case of retention will always be found to be high-coloured and very ammoniacal, its specific gravity is also considerably increased, in consequence probably of the retention of its more watery constituents.

Results.—The habitual retention of a small quantity of urine in the bladder which is incapable of discharging completely the whole of its contents occurs much more frequently than is suspected. The quantity retained will vary from an ounce to half a pint: the patient believes he has emptied his bladder, but the introduction of a catheter proves the existence of retained urine. This condition will be a source of great inconvenience, and eventually of disease, to the patient. In consequence of the bladder never being completely emptied, there will be frequent, and almost irresistible calls to pass urine, so as to simulate irritation of the bladder. The retained urine becomes offensive, ammoniacal or foetid, and mixed with mucus or muco-pus. The constituents of the urine, when become absorbed, give rise to impaired nutrition, and, being eliminated through the skin, irritate it and occasion intractable forms of skin-disease. The continuance of complete retention of urine from paralysis of the bladder, will probably give rise to fatal consequences, a violent inflammation taking place in the mucous membrane of the organ, which passes into a sloughy condition, accompanied by symptoms of a typhoid type; in some instances coma supervenes, owing to the poisoning of the system by the absorption of the urinary constituents. Even though the retention is relieved, this condition is apt to come on; vesical catarrh with febrile action supervening, the tongue becoming brown, and low fever setting in. It is very seldom that the bladder ulcerates or bursts when the retention is continued from paralysis of that organ independent of any mechanical obstacle. Continued dribbling preventing this consequence.

Treatment.—The treatment of this form of retention must have reference to the cause of the atony or paralysis of the bladder; but under all circumstances the urine must be drawn off regularly. A large gum catheter must accordingly be introduced twice a day, even though retention be not complete, in order to empty the bladder of the small quantity of residual urine left in it after the apparent evacuation of its contents.

in doing this, care must be taken that the beak of the instrument properly enters the body of the bladder, which is further removed from the pubes than usual; for it will sometimes happen that it may enter the dilated prostatic part of the urethra, or elongated neck of the bladder, when, an ounce or two of urine escaping, it may be supposed that there is no more left, though in reality the viscus is immensely distended. In order to get the catheter well in, its point should be closely hooked round the pubes and raised by depressing the handle between the thighs. In cases of paralysis, the catheter should not be allowed to remain in the bladder, lest the pressure of its point against the mucous membrane increase the tendency to low cystitis, or give rise to sloughing.

If the retention arise from paralysis dependent on injury or disease of the spine, it will occasionally be found that strychnine, either administered internally or applied endermically, will tend to lessen it. If the atony arise from old age, the administration of cantharides, or the application of a blister to the sacrum, may be of use. In some cases the application of cold to the inside of the thighs or to the abdomen will facilitate the contraction of the organ; hence it is the custom of some old men labouring under this affection to press the chamber utensil against the inside of the thighs, and I have known a patient find more relief from sitting on the marble top of his commode, than in any other way.

INCONTINENCE OF URINE arises from weakness of the neck of the bladder, in consequence of which there is not sufficient power to hold the contents of the organ, and the urine dribbles out. In most cases, the sphincter-like action of the neck is perhaps not quite lost, so that a small quantity is ejected from time to time; the urine, in fact, escaping as soon as enough has accumulated to overcome the slight resistance offered by the partial contractility of this part of the bladder. When there is paralysis of the body of the bladder as well as of the neck, the urine dribbles out as fast as it is poured in by the ureters.

Causes.—Incontinence of urine, consequent upon weakness of the neck of the bladder, may arise from a variety of causes; it is most frequent in children, in whom it occurs during sleep, the patient losing the command over the sphincter as soon as a small quantity of urine has accumulated behind it. In old people it may arise from simple debility, and is commonly associated with a tendency to retention. In many cases it is sympathetic, dependent on the irritation of piles, stricture of the urethra, or stone in the bladder; and occasionally it results from nervous causes, more particularly in women of an hysterical temperament. Over-distension of the bladder will occasion incontinence of urine, not from paralysis, but from a kind of strain of the muscular structures of the part; in this way a patient, who from circumstances has been unable to empty his bladder for a considerable time, may suffer from incontinence. In children of a strumous habit, incontinence of urine is very apt to occur, the child wetting its bed an hour or two after it goes to sleep. In such cases, the urine will generally be found to be loaded with lithic acid crystals.

Treatment.—The treatment must depend upon the cause. When the incontinence occurs in weakly children, if it be not connected with worms or gastro-intestinal irritation, which should then be removed, the administration of tonics will be found useful—either quinine or the tincture of sesquichloride of iron, alone or conjoined with tincture of cantharides. If there be irritation of the mucous membrane of the bladder, the administration of alkalis, in conjunction with a tonic, as the potassio-tartrate of iron, or a little opatha mixed with honey, will be found very serviceable. Cold

sponging, light clothing at night, and means calculated to break the habit, such as waking the child at the time at which it generally occurs, changing his position in bed, &c., should not be omitted. When it occurs at an advanced period of life, if there be any source of sympathetic irritation, this must be removed; if none can be discovered, tonics, especially iron, with strychnine and galvanism, must be had recourse to, together with cold douching or shower-baths.

HYSTERICAL RETENTION AND INCONTINENCE OF URINE not unfrequently occur in nervous girls, and require to be treated by antihysterical remedies, amongst which preparations of sesquichloride of iron, either alone or with valerian, will be found most useful. Cold douches are also of great use. In cases of hysterical retention, it may sometimes be necessary to use a catheter; but under such circumstances it is well not to employ this instrument too frequently, as the patients are apt to get into the habit of its introduction, and will, with that morbid propensity that characterizes hysteria, continue for a length of time to require its introduction. As to themselves, though the bladder may become much distended, it will burst, but will probably empty itself without further trouble, particularly if the patient be put into a tub and well douched over the hip and with cold water. In some cases, these morbid conditions in women appear to be connected with some local irritation about the urethra or uterus, and then proper treatment must be directed to these organs before the bladder can be removed.

PAINFUL CONDITIONS OF THE BLADDER.—The bladder is often the seat of severe pain, either continuous or remittent, without any disease being discernible in it on the closest examination; the pain being either a kind of neuralgic condition, especially occurring in hysterical or hypochondriacal patients; or else being sympathetic with, and dependent on, disease at some distance, as in the kidneys, uterus, rectum, &c. At the same time it may be borne in mind, that the secretion of acid or irritating urine will, in some individuals, be a source of much and constant suffering; and that any disease seated about, or coming into contact with, the neck of the bladder, as the prostate, &c., is especially apt to give rise to severe suffering, and will, in some cases, be accompanied by frequent desire to micturate, with much distress about the part.

CHAPTER LXVIII.

DISEASES OF THE PROSTATE.

The prostate is subject to Acute and Chronic Inflammation, to Hypertrophy, to Scirrhus, and to the formation of Calculi.

PROSTATITIS.

ACUTE INFLAMMATION OF THE PROSTATE, OR PROSTATITIS, very rarely occurs as an idiopathic affection. When met with, it is usually the result of gonorrhoea, or of the use of stricture-instruments, more especially in middle-aged men.

Symptoms.—These are deep-seated dull pain, with heat and weight in the perineum, a frequent desire to pass urine, and very great and acute pain accompanying the act; in fact, the irritability that is set up about

neck of the bladder is perhaps the most marked and distressing feature in the disease. These symptoms are, however, common to various inflammatory affections of the urinary organs, and they can only be distinctly referred to the inflamed prostate by rectal exploration. On introducing the finger into the gut, the prostate will be found much enlarged and exquisitely tender to the touch; and the patient often suffers considerably from the pressure of the inflamed organ upon the rectum during defecation.

Treatment.—This should be of an active antiphlogistic character, so as to prevent, if possible, the formation of abscess. The perineum must be cupped or well leeches; warm hip-baths and poppy fomentations assiduously employed; and salines with antimony administered. In this way, the formation of abscess within or around the prostate may, in many cases, be prevented.

PROSTATIC ABSCESS may happen either as a consequence of acute inflammation running into the suppurative stage, and in this way it is not very unfrequently met with as a complication of gonorrhoea; or it may occur with comparatively little antecedent inflammation—as sometimes happens in pyæmia, or if the organ be accidentally bruised during lithotomy. In these cases, abscess perhaps as frequently forms in the cellular envelope as in the organ itself. Idiopathic suppuration of the prostate, irrespective of any of the above causes, is, however, of rare occurrence; but it may occur in individuals of broken health, the matter then usually accumulating in large quantity, and discharging itself into the bladder.

Symptoms.—When inflammation of the prostate terminates in abscess, rigors, with strangury, and perhaps retention of urine, occur. In many cases the perineum becomes brawny; in others, tenderness of the gland and deep fluctuation may be felt through the rectum. When left to itself, the abscess most usually gives way into the urethra or neck of the bladder; but it may, especially when occurring in the prostatic capsule, open externally into the perineum, or even into the rectum. In many cases, the abscess presenting on the urethral surface of the prostate is burst during the introduction of the catheter, used for the relief of the retention of urine induced by the pressure of the tumefaction; the matter escaping along the side of and through the instrument.

Treatment.—It not unfrequently happens that the first certain indication afforded to the surgeon of the formation of a prostatic abscess is the escape of pus by the urethra, or mixed with the urine, so as to give this fluid a thick milky appearance. In such circumstances, the only available treatment is that which is directed for the relief of the strangury and local vesical irritation on ordinary medical principles, such as have already been described. But if, as sometimes happens, the pus come forwards into the perineum, then a more decided line of treatment is required. In these cases a hard brawny mass will be felt lying deeply on the side of the perineum; and into this a deep incision should be made. The surgeon must not wait for fluctuation, but must cut deeply in the direction of the matter, keeping, however, as nearly as possible in the mesial line, with the back of the knife towards the rectum. Even if no pus escape at first, it may do so if the part be well poulticed for a few hours; and thus communication with the urethra or rectum may be prevented.

RETENTION OF URINE FROM PROSTATITIS.—In prostatitis, retention may occur from the swelling of the organ, from the infiltration of exudation-matters around it, or from the formation of pus in it. In these cases the neck of the bladder will be carried to a considerable distance from the surface, and may very probably not be reached by an ordinary catheter, which may be buried up to the rings and yet not enter the cavity of that

organ. In these circumstances, a silver prostate-catheter should be employed; and this must be carefully introduced, first, by entering cavity of an abscess which has already burst *per urethram*, it might be supposed to have entered the bladder itself. In introducing the instrument under these circumstances, care should be taken to keep its point constantly in contact with the upper surface of the urethra, and to hook it round the pubes. The upper surface of the urethra is a sure guide to the bladder; any abscess, false passage, or irregularity of direction, will always first affect the lower aspect of this canal, being surrounded by yielding strata, whilst the upper part, being firmly supported by bone and ligament, can so readily alter its direction.

CHRONIC ENLARGEMENT OF THE PROSTATE.

Chronic Enlargement of the Prostate may be looked upon as a disease, seldom occurring before the age of fifty, and being commonly with after this. At that period of life, as Sir B. Brodie observes, the hair becomes grey and scanty, when atheroma begins to be deposited in coats of the arteries, and when the *areus senilis* forms on the cornea, the prostate often becomes increased in size. At the same time, however, changes take place in the genito-urinary system; thus the urethra becomes dilated and the bladder thickened; and, unless the enlargement of the prostate advance in too great a proportion to the other changes, so as to interfere with the free escape of the urine, no disease can properly be said to be established. If we look upon the diseased enlargement of the prostate as such an amount of hypertrophy of this organ as interferes seriously with the discharge of the urine, we shall probably not find it so frequent in old men as is generally supposed. Guthrie states that it is not common found in the pensioners at Greenwich Hospital. H. Thompson found an enlargement appreciable after death existed in 30 per cent. of those above the age of fifty; but that such a degree of enlargement as to give rise to symptoms during life was only met with in 12 per cent. of those he examined. Though age must be looked upon as the primary cause of particular hypertrophy of the prostate, there can be little doubt that it is predisposed to by any continued source of irritation of the urinary organs, such as gonorrhoea, strictures, or hard living.

CHARACTERS.—Enlargement of the prostate is principally due to the degeneration of that organ, with phosphatic deposits in it, the texture of the gland is usually indurated, though sometimes it has been found softer and looser than natural.

The enlargement may occupy the whole of the organ, causing its increase to that of a large egg or small orange; or it may be confined principally to the lateral lobes, which may either both or singly become hypertrophied. When this is the case, the urethra becomes greatly elongated, tortuous, winding round the promontories formed by these lobes, and sometimes assuming the form of a sinus, being irregularly dilated, or a considerable change may take place, not only in the direction but in the shape of the canal, which becomes elongated from above downwards into a kind of S-shape, or else is flattened out laterally. In all cases of enlarged prostate, however be its shape, the corresponding portion of the urethra becomes enlarged and wider than natural. The elongation of this canal is due to the enlargement of the prostate, in which the canal that traverses it necessarily partake; and its expansion to the outward growth of the organ. So capacious does this portion of the urethra sometimes become, that it will hold two or three ounces of urine, and in consequence of its elongation

carry the neck of the bladder upwards, and behind the pubes, to a considerable distance from the surface.

The urethral portion of the prostate may become greatly enlarged in size, with or without accompanying hypertrophy of the lateral lobes. It then usually assumes a nipple like appearance, but sometimes becomes constricted at the base and expanded above, so as to be truly pedunculated, constituting at last a round and solid tumour overlapping the urethro-vesical orifice, as in the accompanying cut (Fig. 472), which represents the prostate thus enlarged; the "third" or "median lobe" forming a pedunculated tumour, which acted like a valve—obstructing the exit of the urine from the bladder, though it did not offer any obstacle to the introduction of a catheter. Occasionally the verumontanum alone appears to be affected, forming a kind of thickened valvular projection, which interferes materially with the flow of the urine.

The nature of the tumours met with in the prostate has been carefully studied by Thompson. The following remarks embody his observations.

"The existence of solid tumours of different kinds is by no means rare in the prostate. They were pointed out by Sir E. Home, and by him supposed to be of the nature of apoplectic clots. Subsequently they have been regarded as fibrous tumours; and more lately it has been shown that some possess a structure approaching very nearly to that of the secreting tissue contained in the prostatic substance around. It is shown that enlargement of the prostate is very frequently associated with the development, more or less marked, of such growths in some one of three forms; in short, that the production of defined tumour is more frequently than otherwise the essential element of the pathological condition known as hypertrophy of the prostate. Of fourteen enlarged prostates, six exhibited numerous fibrous tumours in the substance of the lateral lobes; the others showed polypoid enlargements, single, binary, or multiple, springing from the 'posterior median portion.' The varieties may be briefly noticed as follows:—

"1. A simple fibrous tumour, small, nearly isolated, made up of closely packed organic muscular fibres, with areolar tissue, intimately resembling those found imbedded in the walls of the uterus.

"2. A tumour composed of the same elements as the preceding, but containing, in addition, some of the glandular substance of the prostate, more or less imperfectly developed. This also may be imbedded, with or without a cyst, seeming sometimes to partake more of the character of a local enlargement, limited to a small portion or lobule of the prostate tissue, and only partially isolated. Although separating this class from the previous one for facility of reference, it is more than probable that the two nearly merge into each other at the adjacent limits, the latter approximating to the former by insensible gradations; so that some tumours which appear to be purely fibrous at first may be found to exhibit slight traces, in parts of their structure, of the glandular element. In all, however, the basis is the organic muscular fibre.

"3. A tumour composed entirely of the ordinary structures of the prostate

Fig 472.—Enlargement of Urethral Portion of Prostate

fully developed, and enjoying activity of function in common with the rest of the organ. It assumes a pyriform shape even in its earliest stage, and springs from the posterior median portion. It may vary in size from that of a pea to that of a middle-sized pear. The analogy between these and the polypoid tumours of the uterus are considerable, pointed out by Velpeau and others, modern researches seem to indicate them as plainly."

MECHANICAL EFFECTS.—These enlargements are productive of various inconveniences with regard to the passage of the urine, giving rise either to retention or to incontinence, or to a kind of mixture of both. While the lateral enlargements cause the urethra to assume a somewhat tortuous course, the middle lobe, if hypertrophied, may readily occasion retention, by projecting against the entrance to this winding channel, falling over it like a valve whenever the patient attempts to pass urine (Fig. 472). Then, again, if the middle lobe continue small whilst the enlargement of the lateral lobes takes a direction up towards the bladder, well as they go, the vesical neck may be so dilated that incontinence and a continuous dribbling will occur through a kind of fissure that extends between the lateral lobes.

The obstacle offered to the passage of the urine by an enlarged prostate

Fig. 171—Result of Enlarged Prostate. Bladder thickened and enlarged. Ureters dilated. Chronic Disease of Kidneys.

will usually eventually give rise to a chronically thickened, fasciated, and sacculated bladder, the fundus of which descends below and behind the enlarged gland, forming a large pouch that cannot empty itself, in which mucous and morbid secretions are apt to collect. The ureters often become dilated and the kidneys chronically diseased, a series of changes well illustrated by the annexed cut (Fig. 473).

SYMPTOMS.—The symptoms of an enlarged prostate arise primarily from the mechanical obstacle offered to the escape of the urine. The first symptoms usually consist in the feeling of a necessity to strain slightly before the urine will flow, and then, after the bladder has been apparently emptied, in the involuntary escape of a small quantity of urine. The patient also finds that he is much longer than usual in emptying the bladder, for, though the stream flows for a long enough so soon as it has once begun to escape, yet it cannot be properly projected, the viscus having, to a certain extent, lost its tone.

About this time changes begin to take place in the urine, which now becomes somewhat fetid, even while it continues acid, and is often mixed with more or less viscid, stringy mucus; though in many cases it is clear, pale, and not in any way altered in character. The symptoms often come on in a very gradual manner, the patient straining and

experiencing much difficulty in the extrusion of the urine for months or even years before retention will occur. As the disease advances and the bladder becomes less capable of emptying itself, two or three ounces or more of residual urine are left, which becomes dark, mixed with adhesive, sticky mucus; and, at last, if the mucous membrane of the bladder fall into a chronic state of inflammation, it assumes a milky appearance from an admixture of pus, and becomes horribly offensive, blackening the silver catheter.

The exact condition of the enlarged prostate can only be ascertained by examination through the rectum and urethra. By rectal exploration with the finger, the degree of enlargement of the lateral lobes can best be ascertained; though, as in many cases the end of the finger cannot reach the further extremity of the gland, it will be impossible to say to what extent the hypertrophy has extended. The urethral exploration must be conducted by means of a long gum-elastic or a silver prostatic catheter, and will afford information that rectal exploration cannot give; and by it are ascertained approximately the size of the middle lobe, and the condition of the urethra as to elongation and curve.

RETENTION OF URINE constitutes the great danger in advanced cases of enlarged prostate. It commonly comes on gradually, the patient having for some time before experienced considerable difficulty in passing his urine, and he will often find that the more he strains in his efforts to do this the less readily will it come away; whereas, when he remains quiet, it will usually flow with more freedom. The retention from prostatic enlargement is of the mixed kind, there being always more or less incontinence conjoined with it. When the bladder has become tense, and the prostatic portion of the urethra put upon the stretch, the escape of a certain quantity of urine will take place, until, by the relief of the tension of the over-distended bladder, the parts about its neck and the enlarged prostate become relaxed, so that they again fall together, and thus, the urethra resuming its tortuous condition, the outlet is occluded. In these cases error may always be guarded against by the surgeon feeling the enlarged bladder rising up above the pubes, and reaching perhaps as high as the umbilicus. This condition is an extremely dangerous one, not so much from any risk of the bladder or urethra giving way in consequence of over-distension, which very rarely happens in retention from enlarged prostate, as from the occurrence of paralysis of the bladder, or the probability of the early setting in of chronic inflammation of its mucous membrane, which is specially apt to take place. The bladder has usually not emptied itself completely for a considerable length of time before the retention is complete; and a quantity ofropy mucus, having collected in the fundus behind the prostate, whence it cannot be expelled, becomes putrid, and thus disposes to the supervention of that form of chronic inflammation of the vesical mucous membrane, which, occurring in a depressed state of the system, is especially apt to give rise to a brown tongue with quick pulse, and typhoid symptoms. In fact, when death occurs from prostatic disease, it usually takes place in this way.

TREATMENT.—In the treatment of enlarged prostate little can be done by medical means; though the patient's condition may be somewhat ameliorated by treatment calculated to lessen irritation about the urinary organs, and to improve the condition of the urine. With this view, if it be very acid, alkalies with henbane should be given; if neutral or alkaline, the dilute nitric acid with henbane or opium; if mixed with ropy mucus or muco-pus, the infusion of buchu, or the balsams of copaiba, Peru, or turpentine should be administered. If hemorrhage occur, tincture of sesquichloride of iron,

infusion of uva ursi, or gallic acid, application of iodine, and other means of the enlarged gland, will be found a serious annoyance to the patient.

In the treatment of enlarged prostate catheter regularly, in order to empty of the bladder behind the prostate; at urethra, tends to collect an accumulation which the patient cannot expel with the impaired. The removal of these masses, independently of any retention, they may, to typhoid infection. The bladder is twice every day. This may best be catheter of full size, which should be patient should be taught to do himself the bladder, or retention in it of a quantity all the accompanying constitutional order to reach and empty the bladder be used. This instrument should be equal to about No. 12. In order to be carried away from the surface by the catheter be about four inches longer than an ordinary catheter. The viscus is usually pushed up high upwards of the lateral lobes, the curve and longer than usual. I find the best curve of which is exactly the third and-a-half inches in diameter. The catheter I have found it of use to have the lower piston-plate, so that, by withdrawing through the eyes of the instrument.

Fig 474.—Enlarged Middle Lobe of Prostate

curved gland the bladder nor one of these. It be taken a portion of well between against the do not swell middle lobe and valve not necessitate the introduction of pushes it certain the body of the correct often close or pouch, containing perhaps half as much as the pouch the catheter may enter and empty, supposing that he has passed the prostate content; but this is a grievous error, and the pouch.

TREATMENT OF RETENTION OF URINE.—When retention has occurred, relief can only be afforded by the proper use of the catheter, and this should never be delayed, as typhoid symptoms in elderly people rapidly set in. Three questions present themselves in connection with the treatment of this form of retention.

1. As to the *kind of catheter* that should be used, Sir B. Brodie recommends a gum-elastic instrument, long, of large size, and kept on a well-curved iron stylet, so as to preserve its curve when that is withdrawn. This must be introduced either with or without the stylet; if possible, without it. Other surgeons of great authority in these matters prefer the silver prostatic catheter; and I certainly think that *for the relief of retention* a silver instrument is safer, and more easily managed, than the gum-elastic one. It might be supposed that a less chance of mischief would result from the gum-elastic than from the metallic catheter, as being the softer and more yielding instrument; but this is, I think, erroneous, if the stylet be allowed to remain in, as it is then as rigid at the point, as hard, and as likely to penetrate soft structures as a silver one would be. If the stylet be withdrawn, it is often a very unmanageable instrument; it is impossible to know how to direct its point; and if the obstacle be difficult to surmount, it is not easy to guide the instrument over it. With the metallic catheter, on the other hand, the surgeon can feel his way as it were, and will, if he depress the handle well, as soon as the point enters the prostatic portion of the urethra, find little difficulty in guiding it into the bladder. It is the first introduction of the instrument that especially requires care, and as much gentleness as possible; after it has once been introduced, it will almost invariably readily find its own way.

It is a question whether the patient should be placed in the erect or in the recumbent position, when the catheter is introduced for the relief of urinary retention. I certainly think that the recumbent is not only the easiest position in which to introduce the instrument, but the safest. In old and feeble subjects the sudden withdrawal of the urine, by removing compression from the abdominal veins, and allowing these vessels to re-fill, may induce syncope, which occurring in the erect position might prove fatal. I have heard of one case in which the sudden death of the aged patient under such circumstances was attributed to this cause.

2. The next question in connection with the relief of retention in these cases is, whether the catheter should be *left in the bladder*, or be *withdrawn* after the viscus is emptied. As a general rule, it is certainly far better not to leave the catheter in; its presence in the diseased bladder setting up a low form of inflammation, or giving rise to sloughing of the mucous membrane. The instrument should be introduced twice in the twenty-four hours; and care should be taken, if possible, to empty the pouch behind the prostate by depressing its point. When the instrument is used habitually in this way, the gum-catheter may be employed. Should the mucus be very viscid and offensive, the bladder may be washed out with tepid water through a double current catheter. After the bladder has been emptied for the first time, it will be found to refill in the course of a very few hours, usually in six or eight, the secretion of the kidneys appearing to be set free on the removal of the pressure.

Should any great difficulty be experienced in introducing the catheter, it may be thought desirable to leave it in the bladder for two or three days; and then a gum elastic one is always to be preferred, as under these circumstances it presents a great advantage over the silver catheter, becoming soft, accommodating itself to the shape of the parts after the stylet has been

taken out, and not being so liable to irritate the mucous membrane at point, which, dipping down into the pouch behind the prostate, no syphon, emptying this part of the bladder far better than a silver could do.

3. The third question in connection with the relief of retention enlarged prostate, is as to the course that should be pursued if no instrument can be introduced into the bladder in the ordinary way. In those cases, which, however, very rarely occur, three lines of practice may be adopted: puncture of the bladder above the pubes, puncture above the rectum, or catheterism.

Puncture above the Pubes can very seldom be required. Since the University College Hospital was opened, only three cases have presented themselves in which it was thought proper to adopt such a procedure in retention from enlarged prostate; and in one of these cases, which was under my care, the enlargement of the prostate was complicated with a permeable stricture, which was, indeed, the main cause of the retention. The operation consists either in pushing the trochar at once through the abdominal wall; or else, as in tapping for ascites, making a small incision about half an inch in length through the integuments, exactly on the mesial line, immediately above the pubes, and then passing a trochar, with its concavity downwards and backwards, into the

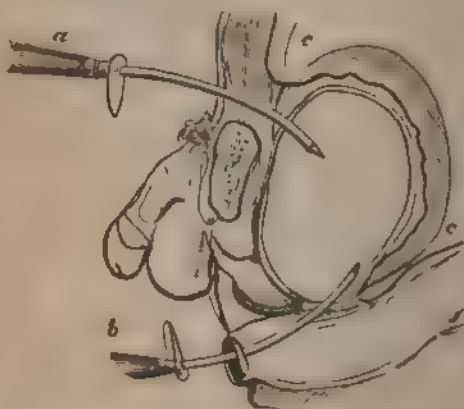

Fig 475.—a. Puncture above Pubes. b. Puncture through Rectum. c. Reflections of Peritoneum.

bladder behind that bone, and subsequently underneath the reflection of the peritoneum (Fig 475, a). After the bladder has been emptied, a cannula or an elastic tube must be left in situ to escape of the urine, the continuity of the passage is being restored. When the bladder is distended, in consequence of retention from enlargement of the prostate or any other cause, the peritoneum is carried up, and a considerable portion of the anterior wall of the organ uncovered by the peritoneum is left above the pubes. In a case of unrelieved retention from stricture, in which the patient died suddenly during the administration of chloroform, and which I had an opportunity of dissecting, I found the fundus of the bladder reached to five inches above the symphysis pubis, and was only two below the umbilicus; that the line of reflection of the peritoneum was $3\frac{1}{2}$ inches above the bone; and that the space covered by serous membrane was $2\frac{1}{2}$ inches wide. The bladder contained nearly forty ounces of urine, the retention having lasted during forty hours.

Puncture through the Rectum is not generally a safe procedure in retention from enlarged prostate, in consequence of this structure encroaching on a part of the inferior fundus of the bladder which is uncovered by peritoneum. When, however, the retention arises from enlargement of the upper portion rather than of the lateral lobes, this operation may be safely

and, indeed, I have known it put in practice with advantage in such cases (Fig. 475, b).

A safer procedure than this, and one that is recommended by Brodie, Liston, and most surgeons of authority in these matters, is *Forcible Catheterism*, or *Tunneling the Prostate*. As the retention is generally owing to an enlargement of the urethral portion of the prostate, relief may be afforded by pushing the point of a silver catheter through this obstacle into the bladder. A false passage is thus formed, in which the instrument should be left for about forty-eight hours, when it will generally enter it with sufficient readiness on being introduced again.

After the retention has been relieved, the bladder will often be paralysed for a time, the urine flowing out, but with no power of expulsion, for some weeks. In these circumstances the catheter should be used twice in the twenty-four hours; good diet, with wine, quinine, and extract of nux vomica may be given, and blisters applied to the sacrum; afterwards the patient should be taught to pass the catheter for himself once or twice daily.

The radical cure of the impediment to the flow of the urine has been proposed to be effected by removing the enlarged middle lobe of the prostate by ligature, by excision with a lithotrite, or by lateral or median incision of the perineum. Such operations, however, from their difficulty and danger, should not be lightly undertaken; perhaps the least dangerous mode of removal would be by median urethrotomy.

MALIGNANT DISEASE OF THE PROSTATE is of very rare occurrence. Its presence may commonly be ascertained by exploration through the rectum and urethra. The passage, also, of bloody urine, or of clear urine followed by a discharge of blood, mixed, perhaps, with the débris of a cancerous growth, will likewise tend to establish the nature of the affection, which is necessarily fatal.

PROSTATIC CALCULI have been already described in the chapter on Urinary Calculus (p. 1128.)

PROSTATORRHOEA.

Prostatorrhœa has been described by Dr. Gross as a discharge of clear glairy mucus from the prostate, in consequence of irritation of that organ. The disease is characterised by the discharge of a few drops of ropy, viscid mucus from the urethra after micturition or defæcation. It is chiefly of importance from its liability to be confounded with spermatorrhœa, and from the depressing effect consequently produced upon the patient's mind.

The *Diagnosis* of prostatorrhœa from spermatorrhœa may be effected by microscopical examination of the characters of the discharge.

The *Treatment* consists in attention to the state of the general health; the administration of tonics, more especially of iron and nux vomica; the removal of any local source of irritation in the urethra, rectum, or anus, as stricture, piles, or fissure; and the local application to the prostatic portion of the urethra of the nitrate of silver. The application of a blister to the perineum is beneficial in some cases.

CHAPTER LXIX.

DISEASES OF THE URETHRA.

URETHRITIS.

Simple Inflammation of the Urethra is especially apt to occur in strumous, rheumatic, or gouty individuals, from slight sources of irritation, either direct or sympathetic, that would not excite it in more healthy constitutions. In strumous children, it may arise from worms in the intestines, or from gastric irritation, and in gouty or rheumatic subjects, it appears to occur in connection with an acid or loaded state of the urine. In other cases, the irritation of a stricture, the passage of instruments, or of urinary sexual intercourse, may occasion the disease, without there being anything of a specific or venereal character about it. Contact with women who are out of health, pregnant, or suffering from leucorrhœa, may also often does give rise to local irritation of this kind. Urethritis, especially when arising from sexual intercourse, is frequently mistaken for gonorrhœa, but from this it may be distinguished by the less intense degree of inflammation, and by the absence of the secondary consequences that frequently follow true gonorrhœa; yet, in many instances, the diagnosis is extremely difficult, especially from the subacute forms of gonorrhœa that are prevalent in London.

SYMPTOMS.—Urethritis is characterised by heat, pricking, and tenderness about the urethra for a day or two, followed by mucopurulent discharges, often rather profuse, and accompanied by some ardor urinae. The symptoms altogether are not severe, and the disease usually subsides at the end of a week or ten days; but sometimes it becomes chronic, especially if conjoined with stricture, and then constitutes an extremely troublesome affection, more particularly in gouty individuals.

TREATMENT.—The treatment of urethritis is mildly antiphlogistic. The bowels should be kept open, and salines freely administered; in chronic cases small doses of colchicum, in combination with alkalies, will be found of especial service in cutting the disease short. The use of emollient and slightly astringent injections, such as opiate lotions, or a very weak solution of acetate of lead, with belladonna, will be found serviceable as the disease is on the decline, but not until then; and when the affection has reached the chronic stage, small doses of copoba may be advantageously administered. The diet in all cases should be of the blandest character, stimulants of all kinds being interdicted.

If the disease be conjoined with slight stricture, it may not unfrequently give rise to temporary retention of urine. This may, however, be commonly be readily relieved by antiphlogistic treatment, cupping, or leeches to the perineum, the warm hip-bath, and salines, with, perhaps, opiate suppositories, and plenty of demulcent drinks. The catheter should not be used in these cases, if it be possible to give relief without it.

URETHRAL ABSCESS occasionally forms as the result of urethritis, a soft fluctuating point being perceived in the neighbourhood of the canal. As soon as this is detected, it should be opened, when the aperture that results will readily close. If left, it will probably not burst externally, but into the urethra, the tissues in this direction being less resistant, and thereby

if it should be opened externally as well, a troublesome urinary fistula will result.

PERINEAL ABSCESS may form as the result of stricture or of urethritis, in whatever way excited; the patient complaining of a sensation of weight, with pain and throbbing, deep in the perineum. On examination, a hard tense swelling will be found, situated a little anteriorly to the anus, and extending along the side of the urethra. It presents no sign of fluctuation until it comes forwards into the scrotum.

The *Treatment* consists in the application of leeches, followed by fomentations, and an early incision through the perineum into the swelling. In some cases, the abscess is situated altogether externally to the urethra, and then the aperture closes readily enough, like that of any other ordinary abscess. In other cases, it communicates with the canal, and then fistulous openings are left, through which a certain quantity of urine escapes. These apertures gradually tend to close if they be not complicated with stricture or other urethral disease; should they be so, they will require special treatment, of a kind that will be described at p. 1186.

GONORRHOEA.

Gonorrhœa is a specific disease, accompanied by inflammation and an abundant muco-purulent discharge; affecting the urethra most commonly, but also the other mucous membranes of the genital organs, as of the prepuce and the glans in the male, and of the vulva and vagina in the female.

The urethra is the usual seat of gonorrhœa in the male; and the disease may be looked on as a specific urethritis, which is usually fixed with greatest intensity in the fossa navicularis; but it may extend itself over a much greater surface, affecting the entire length of the canal, and even the whole mucous lining of the bladder. In the female it commonly spreads over the extensive mucous surface of the internal organs of generation, and sometimes even invades the uterus.

CAUSE.—Gonorrhœa is a truly specific and a highly contagious affection, arising in all cases from the application of a peculiar animal poison, generated by impure or indiscriminate sexual intercourse, to the parts which it attacks, and must not be confounded with the various non-specific inflammatory diseases that may affect the parts commonly the seat of gonorrhœa, and which are all characterised by muco-purulent discharges.

The poison of gonorrhœa differs entirely from that of syphilis, as has been fully proved by the unerring test of inoculation; these diseases not being capable of reproducing one another under any circumstances.

CHARACTER.—Gonorrhœa is usually looked upon as a purely local affection of the genital organs. Some surgeons, however, amongst whom may be especially mentioned Travers, seem to consider it as occasionally assuming a constitutional character; in this opinion I entirely agree. Although gonorrhœa in the early stages is doubtless a strictly local affection, yet it is occasionally followed by a particular train of very characteristic phenomena, that can scarcely be looked upon in any other light than as the result of constitutional infection; the more so, as some individuals never have gonorrhœa without the disease being followed by these sequences, whilst others are altogether exempt from them. The parts that are secondarily affected are chiefly the fibrous tissues, the mucous and the cutaneous surfaces. The affections of the *fibrous tissues* give rise to rheumatism, and to peculiar forms of inflammation of the testicle and of the sclerotic. The affection of the *mucous membrane* displays itself in specific inflammations of the throat, and of the eyes; and the *skin* becomes the seat of certain eruptions.

The occurrence of these various affections, assuming as they do a type so distinctly marked that they can at once be characterized gonorrhoeal, certainly tends to show that the disease impresses the constitution in some peculiar manner, somewhat analogous to syphilis, though in a far minor degree, and with much less certainty, than the disease.

SYMPTOMS.—The symptoms of gonorrhoea in the male may be divided into three stages:—1. The Incubative Stage, or the period of Irritation; 2. The Acute Stage; and, 3. The Chronic Stage.

1. *Incubative Stage.*—The first stage, that of irritation, usually comes from three to five days after connection, when the patient begins to experience some degree of heat, itching, and general irritation about the penis. The lips of the urethra are somewhat red and swollen; its orifice is inflamed, and on squeezing it some muco-pus exudes. This stage usually commences about the time mentioned, but sometimes sets in immediately after connection; in other instances it does not occur for eight or ten days. Lasting for twenty-four or forty-eight hours it terminates in the second stage, which is one of active inflammation.

2. *Acute or Inflammatory Stage.*—The discharge now becomes abundant, thick, and of a greenish-yellow colour; there is great pain in passing urine, with considerable heat and smarting, and the urine flows in a diminished stream, but is passed with increased frequency. The urethra is now firm, and cord-like to the touch; the whole penis, indeed, looks greenish-red and turgid. As the disease advances, and the bulbous part of the urethra becomes affected, tension in the perineum will be complained of. If the prostatic portion be the seat of disease, there will be heat and swelling about the anus. During the whole of this period there is generally a great deal of constitutional disturbance, restlessness, and fever.

One of the most troublesome symptoms in this stage of the complaint is the occurrence of *Chordee*, which consists in painful erections at night, and a twist in the body of the penis, which is usually curved down towards the scrotum.

3. *Chronic Stage.*—These symptoms usually continue for about a fortnight when the third stage, that of subacute or chronic inflammation, sets in. During this period of the affection the inflammatory symptoms gradually subside, but a thin muco-purulent discharge keeps up, with some nocturnal heat and irritation about the urethra, and occasional smarting in passing water. Under proper treatment, this usually subsides in the course of another fortnight or three weeks; but, if neglected, or in certain constitutional conditions, it may last for many months, or even years, then degenerating into *Gleet*. In proportion to the continuance of the affection the inflammatory symptoms subside, though the specific and contagious character does not disappear, and the infection may continue so long as the discharge keeps up. Hunter mentions the case of a girl who had been two years in the Marine Hospital, and who infected a person with whom she had connection immediately after she left that Institution. The persistence of the contagious gleet is, it is true, more marked in women than in men. So long, however, as any discharge continues from the male urethra, the patient must be looked upon as infectious.

The severity and the continuance of gonorrhoea are often opposed to each other. Thus the disease is most severe in young and plethoric persons, and in first attacks; but it is most difficult of cure in strumous and phlegmatic constitutions, more especially if there be a gouty or rheumatic tendency co-existing, and is very troublesome to remove after repeated

attacks. I have observed repeatedly that it is very apt to degenerate into a gleet in people who are subject to chronic diseases of the skin.

The length of time that the infection of gleet will continue in both sexes, but especially in the female, makes it somewhat difficult to say whether the poison of gonorrhœa can be generated *de novo*, as it is not improbable that many individuals communicate the disease, believing themselves to be perfectly cured, though still suffering from slight gleet.

TREATMENT—The treatment of gonorrhœa must be conducted with reference to the stage to which the disease has attained, but especially with regard to the amount of inflammatory action accompanying it. It is of two kinds, *rational*, and *specific* or *empirical*. Both plans are useful, and, indeed, usually necessary for a proper cure, but they cannot be adopted indiscriminately. Thus, if specific means be employed during the acute inflammatory stage of the complaint, much mischief may ensue; whilst, if antiphlogistic treatment be persevered in for too long a time, the disease may be kept up indefinitely.

It has been proposed to adopt what has been termed the *abortive* or *revulsive* treatment, during the earliest stages of gonorrhœa; indeed, during the *incubative* period. This method consists either in the injection of a very strong solution of the nitrate of silver into the urethra, or in the application to the inflamed mucous membrane of a strong ointment of that salt by means of a bougie smeared with it; other surgeons, again, have recommended the administration of very large doses of copaiba at this period. These various plans, have, however, I think, deservedly fallen into disrepute. I have on several occasions seen most intense inflammation produced by this mode of treatment, and never, in any case, any good result. Independently of this, it is impossible to know whether the case, in the earliest stage, will prove to be one of simple urethritis or a specific gonorrhœa.

In the *acute inflammatory stage*, attended by heat, swelling of the organ, great ardor urinae, and abundant muco-purulent discharge, the treatment must be entirely antiphlogistic, the activity of the measures being proportioned to the intensity of the inflammation. If this be very severe, leeches may be applied to the perineum, or to any very tender point along the urethra. If it be not so intense, warm hip-baths, poppy fomentations, or the envelopment of the penis in warm-water dressing, will be of essential service. At the same time the urine must be diluted, and its acidity lessened, by the patient drinking large quantities of alkaline diluents,—barley-water or linseed tea containing a little nitre or carbonate of potash in solution, or soda-water; and the skin and bowels may be kept in action by the administration, every fourth or sixth hour, of a powder composed of a drachm of sulphate of magnesia, 5 grains of nitre, and $\frac{1}{12}$ th of a grain of tartar emetic, dissolved in a wine-glass of water. All stimulants must be avoided, the diet being restricted to light slops, and perfect rest enjoined. By such means as these, the activity of the inflammation will be gradually lessened, the discharge becoming thinner, the smarting in micturition not so severe, and the erections less painful. The patient should also be desired to pass his urine frequently, so that it may not be too concentrated.

When the *third stage* of the disease has been reached, specific treatment may be employed with great advantage; while, if recourse were had to it at an earlier period, it would certainly increase the inflammatory action and give the patient much distress. Even in this stage the specific remedies, such as copaiba and cubebæ, must be cautiously given; the surgeon feeling his way with them, and being prepared to discontinue them and to return to strictly antiphlogistic measures, if he find that they increase the irritation.

Should the disease, however, from the commencement, have assumed subacute character, the specific treatment may with safety be adopted at much earlier period.

Copaiba and cubebs are the remedies that are almost universally used at this stage of gonorrhoea. Of these copaiba is the least irritating, and consequently most generally to be preferred. It may be administered in a variety of ways; in capsule, pill, draught, or extract. The capsule is generally to be preferred, on account of the nauseous taste being thereby readily disguised; but in many cases it acts with more certainty, and to better effect, if given in either of the other forms. When the capsules are given, the patient may take from six to eight or ten in the day, and at the same time have an alkaline mixture, which increases the medicinal effect of the drug. A very excellent mode of administering copaiba is to rub it down into a mass with burnt magueesia, and to let the patient swallow about a drachm of this paste three times a day, in a bolus wrapped in paper; or, if the taste be not much objected to, he may take it most advantageously in mucilage, with liquor potassae and tincture of henbane.

In some relaxed constitutions, and more particularly after frequent use of cubebs will be found to cure the patient more readily than copaiba, and most successfully if given in combination with it. An excellent preparation is to put about half an ounce of powdered cubebs into a mortar, and to mix it up with as much copaiba as will form a stiff paste, of which the patient should take a drachm as a bolus thrice daily. The effects of this preparation are often most striking; but it can only be used in the milder cases, as indicated, and after the more active inflammatory symptoms have subsided.

It is during the third stage of gonorrhoea that *injections* may advantageously be used. Much and very unfounded prejudice exists against their use in the minds of many; but surely it is as safe to apply proper local applications to an inflamed urethra as it is to an inflamed conjunctiva. The bad consequences, such as stricture and inflamed testicle, which have sometimes been referred to their use, have either been due rather to long continuance and to the severity of the disease itself than to the remedies employed, or to their application at too early a stage or of too great strength. It is in long-standing cases of gonorrhoea, in which the disease continues for months or years, that stricture results, not in cases of short duration; and in these it is the result of the chronic inflammation, thickening of the mucous membrane, and has no more to do with injections than with the copaiba or salves the patient may have taken. When the ardor urinae subsides, emollient and slightly astringent injections may be used. The best is perhaps the acetate of lead in tepid water, of the strength of two grains to the ounce. If this induce irritation, a few grains of watery extract of opium may advantageously be added. As the disease subsides, a stronger astringent is required, and then one or two grains of the acetate of zinc may be added to each ounce of the injection; or a very weak solution of sulphate or chloride of zinc may be employed, gr. ij of the first, and gr. iij of the second, to each ounce of water; or an injection of gr. ʒ of the muriatic acid to the ounce may be used. During the whole of this stage, the diet and habits of life must be carefully regulated, and all stimulants interdicted. The injections should be discontinued as soon as the discharge has completely ceased, unless this be done, they may re-induce it.

The mode of injection is of importance. A glass syringe should always be used, with a smooth rounded nozzle. The patient, sitting on the edge of the chair and holding up the penis, should carefully insert the end of the syringe between the lips of the urethra, and then slowly squeeze in the in-

tion as far as it will go. Although the inflammation is usually confined to the anterior portion of the urethra, yet it may extend to the bulb, and the injection should be applied to the whole length of the inflamed mucous membrane. If any enter the bladder it cannot signify, as it will immediately be decomposed by the salts and mucus of the urine.

In *gleet*, much difficulty will often be experienced in curing the patient of his discharge. Here much depends not only on the administration of proper remedies, but in care being taken attentively to regulate his habits of life. It will constantly be found that, after the disease has apparently been cured, excesses at table, and more especially the drinking of beer, or of effervescing or acid wines, will bring back the discharge. It will also return after connection, though it have previously ceased entirely. This is especially the case in strumous, gouty, or rheumatic constitutions, in which all urethral inflammations are with difficulty removed. In these cases, then, abstinence from all stimulants, dietetic as well as alcoholic, and improvement of the tone of the system by change of air, sea-bathing, &c., will often be of essential service. At the same time, the electuary of cubebs and coraiba, or one composed of cubebs and the sesquioxide of iron, may be administered with advantage. In other cases, especially in relaxed constitutions, tincture of sesquichloride of iron, alone or conjoined with a few drops of spirits of turpentine or tincture of cantharides, will produce much advantage.

In chronic *gleet*, local applications will be found to be necessary for the cure of the disease. Amongst these I have found none more useful than one composed of ten grains of chloride of zinc and one scruple of gallic acid to eight ounces of water. In some cases, injections of nitrate of silver, of the strength of half a grain, or of bichloride of mercury, in the proportion of a quarter of a grain to the ounce, will be serviceable. And, indeed, in most instances it is beneficial to vary the injections; the mucous membrane appearing to become accustomed to the same stimulant after a time, and thus not being impressed by it in a proper manner.

After the *gleet* has continued for some months, more benefit will often be derived from the introduction of a full-sized metallic bougie every second or third day than from any other local means, even where no stricture exists. The instrument should be left in for about ten minutes, and should be of the largest size that the urethra will admit.

COMPLICATIONS OF GONORRHOEA.—Gonorrhœa, when acute or virulent, seldom runs its course without local complications of some kind, the result of the propagation of the inflammation to neighbouring parts, often of considerable severity, and occasionally even hazardous to life;—such as chordee, phimosis, sympathetic bubo, perineal abscess, irritability of the bladder, retention of urine, hemorrhage from the urethra, &c. Many of these complications present no special features, but require to be treated on general principles, without reference to their specific cause. Others demand more special management, and these we may briefly consider here.

Chordee, or painful erection of the penis, with twist of the organ, coming on at night, is often a most distressing and troublesome symptom. It is usually best relieved by the application of cold to the part, but more especially by the administration at bed-time of a pill composed of gr. j of opium with gr. v of camphor, the camphor acting as a direct sedative to the generative organs. Ricord recommends a suppository of camphor and opium, gr. x of camphor, and gr. j of the watery extract of opium, to be introduced into the rectum an hour before bed-time, as the best means of removing the tendency to chordee.

Irritability of the Bladder with Spasms of the Neck, Strangury, and Dysuria,

may be of two kinds; either *inflammatory*, coming on in the earlier stages of the disease with pain in the perineum, and all the symptoms of acute inflammation about the part strongly marked; or *atonic*, supervening at a more advanced period, without any special signs of inflammation. In the first case, leeches to the perineum, hot poppy fomentations, the warm bath, with full doses of Dover's powder, or of henbane and carbonate of potash or nitre, will probably afford much relief. When the disease is atonic, the administration of tincture of sesquichloride of iron, conjoined with local soothing remedies, as the poppy fomentations or bulet, and an opiate suppository, will be beneficial.

Retention of Urine from Gonorrhoea.—The obstruction is usually dependent on congestion and inflammation of the mucous membrane of the urethra. Leeches to the perineum, the warm hip bath, and opiate suppositories will probably afford relief. It is always desirable to avoid using the catheter, as it is apt to lacerate the swollen and softened mucous membrane and thus to occasion troublesome bleeding; and will always produce much pain, and increased irritation of the canal. Should, however, the retention have continued twenty four hours, or longer, it may most probably not give way to the means above indicated, and then it will be necessary to use the instrument, when a full sized silver one should be very carefully introduced; a large instrument entering the bladder as easily as a smaller one, and with less risk of injury to the tender walls of the canal.

When the catheter has been introduced, it is often somewhat difficult to determine whether it should be left in or taken out. If it be left in, the inflammatory action is increased. If it be taken out, the surgeon may not be able to introduce it again. The solution to this question is to be found in the facility with which the instrument is passed. If it have been introduced without much difficulty, it is better to withdraw it after the bladder has been emptied, and to continue the antiphlogistic treatment, when a second introduction may not be required. If, on the other hand, the catheter have been passed with great difficulty, and be firmly grasped either by spasm or stricture, it should be left in; but very active treatment must be employed to prevent it from exciting too much inflammation.

It must, however, be remembered that the retention may be due to more serious conditions; to prostatitis, to abscess in the prostate or in the perineum, or to inflammatory exudation in the tissues about the neck of the bladder. In these circumstances, more active antiphlogistic measures will be required, with the use of the catheter twice in the twenty four hours, and probably free incisions into the perineum, if there be pus or urine extravasated into that region.

In many cases of gonorrhoeal retention, there is an old stricture as well as the clap. Here the employment of energetic antiphlogistic measures with the use of the catheter are indicated; but, as the stricture is the chief cause of obstruction, the treatment must be directed to it.

Hemorrhage from the Urethra may occur either as the result of chemical and consequent rupture of some blood-vessels of the mucous membrane, or the consequence of attempts at passing the catheter, or as a kind of exudation from the mucous membrane. Most commonly it may be arrested by the application of cold, and the employment of moderate local antiphlogistic treatment. Should it be abundant, pressure by means of a bandage to the penis or perineum, and the introduction of a large gum elastic catheter, will arrest it.

SEQUENCES OF GONORRHOEA.—The sequences, or more remote complications of gonorrhoea, are partly local and partly constitutional. Amongst the

local, we find more particularly *Warts* about the prepuce and glans or within the urethral orifice, which require to be treated by excision or caustics; and *Stricture*, the management of which is fully described elsewhere. In some cases, also, in consequence of extravasation of blood, or the effusion of plastic matter into the corpus spongiosum or the corpora cavernosa, limited and localised *Induration and Thickening of the Penis* may result, attended by chordee, painful erections, and a permanent twist in the organ. In such conditions as these, absorption of the effused mass may be attempted by the administration of small doses of bichloride of mercury, with theunction of iodide of lead ointment.

After the cure of a clap that has been of long continuance, the generative organs are often left in a *weak and irritable state*; the penis, scrotum, and spermatic cords being lax and elongated, with an apparent want of power, and often painful and dragging sensations about the cords and groins.

Besides the strictly local complications of gonorrhoea, a certain set of sequences to which some constitutions are especially liable, occasionally occurs as the result of this disease; viz., inflammation of the testes and of the eyes, rheumatism, cutaneous eruptions, and sore throat. Some of these, as the affections of the eyes and testes, may be either local or constitutional; the others are clearly constitutional.

Gonorrhoeal Inflammation of the Testis is certainly the most common of these sequences. It almost invariably affects only one testis, and commences in the epididymis, whence it extends to the body of the organ. It usually occurs in individuals who have a lax and long scrotum, with very pendulous testes. It seldom sets in before the third week after the occurrence of gonorrhoea, but may occur at any period during the continuance of the discharge, though it is more frequent between the fifth and sixth weeks than at any other time. In cases of gleet, also, it not uncommonly occurs at a later period. In many instances it is referred to some slight injury—a blow, or squeeze, received during the continuance of the gonorrhoea; but in other cases it would appear to arise from extension of the inflammation along the ejaculatory duct; and in others from a kind of metastasis of the morbid action from the urethra to the testis. That the disease commences in the epididymis, may be advanced in support of the first opinion; whilst the fact that the discharge usually ceases when the inflammation of the testicle comes on, and returns as it subsides, may be adduced in support of the doctrine of its metastatic origin. As the symptoms and treatment of gonorrhoeal inflammation of the testicle present nothing peculiar, I shall reserve their consideration until we speak of diseases of this organ.

Gonorrhoeal Inflammation of the Eyes is fortunately not of very common occurrence. It may affect either the conjunctiva or the scleroticæ.

Gonorrhoeal Conjunctivitis is one of the most destructive forms of ophthalmia, giving rise, not unfrequently in the course of forty-eight hours, to the most intense chemosis, with opacity and softening of the cornea, followed by staphyloma and a discharge of the humours. In the majority of instances only one eye is affected; but, in some, both are involved to an equal extent. The disease commences with the ordinary symptoms of conjunctival inflammation; itching and swelling of the eyelids, velvety redness of the conjunctiva, muco-purulent discharge, with much lachrymation. The chemosis sets in early, and is very severe; and, unless treatment afford speedy relief, the consequences are most disastrous to vision. Lawrence states that, of 14 cases that fell under his observation, 9 had only one eye affected and 5 both. Of the 9 in whom one eye only was diseased, the organ was lost in 6 cases, of the 5 in whom both eyes were affected, both organs were destroyed in

one case; in 2 one eye only was lost; one patient recovered imperfectly and in only one did complete recovery ensue.

It has been a question with surgeons, whether gonorrhoeal ophthalmia is the result of the direct application of the specific pus to the conjunctiva, or occurs as a constitutional disorder. There can be little doubt that the introduction of the pus to the surface of the conjunctiva might occasion the disease, but at the same time it is perfectly certain that in many instances there is no evidence of contact; the inflammation occurring in both eyes without patient having apparently communicated it; and, though it is somewhat difficult to adduce positive proof on this point, it is but reasonable to suppose that such cases may be constitutional.

The Treatment of this dangerous affection must be of an active nature. Blood should be taken freely from the temples by cupping, or, if the patient be sufficiently robust, from the arm, as strongly recommended by Lawrence, who places great reliance on it; he must of course be kept in a strict diet and on strict antiphlogistic regimen. The disease must, however, be treated, and the eye can alone be saved, by active local treatment. The most powerful topical agent that we possess is the nitrate of silver. The use of this as astringent, originally introduced by Latell, has been much imitated by Guthrie, Walker, and others, and is generally adopted at the present time, being certainly the most useful agent that we possess. Surgeons are somewhat in opinion as to the strength of the application, some of the Germans especially, advise that the solid stick should be used; whilst others employ it in solution, of the strength of a drachm to the ounce of distilled water. Wharton Jones employs a weaker solution, one of four or five grains to the ounce, and I have seen cases very successfully treated by this, so much so, indeed, that I am disposed to prefer it to the stronger solution. A few drops must be introduced about twice in the twenty-four hours, into the inner canthus of the eye; the lids in the meantime being kept open by compresses dipped in weak alum lotion, and the purulent discharge, if it accumulates, carefully washed away by tepid alum injections. In the use of this, great care must be taken that none of the discharge comes into contact with the eyes of the surgeon or nurses, as it is highly contagious, and almost to a certainty produce the disease; instances are recorded in which in this way, the attendant's vision has been destroyed. If the chemosis is considerable, it must be incised; and, as the inflammation subsides, the donna lotions may be employed with advantage, and the use of the nitrate of silver gradually discontinued.

Gonorrhoeal Scleritis is by no means of such frequent occurrence as conjunctival inflammation; when it happens, it will commonly be found to be associated with gonorrhoeal rheumatism, and not unfrequently with inflammation of the testicle, occurring apparently in individuals in whom there is a tendency to affection of the fibrous tissues. This disease is evidently of constitutional origin, as it cannot possibly arise from local contagion; it is attended by the ordinary signs of sclerotic inflammation, and is usually accompanied by some degree of iritis.

In the Treatment there is nothing very peculiar. Cupping or leeching the temples, with belladonna fomentations, are the principal local means, and calomel and opium, continued until the gums are affected, constitute the chief internal remedies; these means must be persevered in until the anterior chamber clears, and any effused lymph is absorbed. As the inflammation declines, and especially if the patient be somewhat debilitated, acids, rhubarb and bark in powder may be given internally, and blisters kept open on the temples.

Inflammation of the Nose, attended by profuse suppuration, is a complication that I have more than once had occasion to observe in gonorrhoea. The swelling of the organ is considerable, the tenderness great, and the discharge abundant; a condition, indeed, of the Schneiderian membrane that seems analogous to the inflammation of the conjunctiva just described.

The *Treatment* that I have found to succeed best, consists in fomentations followed by astringent lotions or injections.

Gonorrhoeal Rheumatism principally occurs in young, florid, and otherwise healthy men. It is of two kinds; in one, the most common, and indeed the typical variety, the fibrous and muscular structures are affected; in the other, the joints are implicated. The fibrous or muscular form of rheumatism is not unfrequently associated with inflammation of the testicle or of the sclerotic. It commonly affects the fleshy parts of the body, as the hips, the shoulders, and the thighs, and not infrequently occurs in the soles of the feet. It is always painful at night, but is not commonly attended by any very severe constitutional disturbance. The synovial form presents the ordinary characters of rheumatism of the joints, the knees and ankles being those chiefly involved.

In the *Treatment* of these affections, calomel and opium, or Dover's powder with colchicum, must constitute the most important elements until the acute stage is passed, when iodide of potassium may be advantageously given.

Cutaneous Eruptions, chiefly consisting of roseola, with slight pityriasis, and perhaps a few patches of psoriasis with very flimsy scales, occasionally occur in rather severe cases of gonorrhoea, usually appearing from six weeks to three months after the commencement of the attack. They are chiefly diffused about the chest and belly, and present no sign of coppery redness. At the time of their occurrence, the fauces commonly become similarly involved, presenting, as was first pointed out by Travers, a diffused superficial redness on the velum palati and pillars, with perhaps superficial ulceration on these, the tonsils, or the uvula. The occurrence of these affections is usually preceded by slight febrile action, which, however, subsides on their full evolution. The roseolar eruptions, occurring during gonorrhoea, have occasionally been attributed to some peculiar influence exercised by the copaiba, but I think not on sufficient evidence. I am not aware that copaiba, when administered for other diseases than gonorrhoea, ever produces such eruptions; and they will occur, as I have seen in several instances, when no copaiba is being given.

The *Treatment* of these affections should consist in the administration of salines, followed by iodide of potassium in small doses. Mercurials are never required.

GONORRHOEA IN THE FEMALE differs from the same affection in the male in not being so severe, though it is usually more extensive, and of longer duration. The severity is less, on account of the shortness of the female urethra preventing the occurrence of the retention of urine as in the male, and also from the absence of such parts as the prostate, testes, &c., the implication of which constitutes the principal source of difficulty in men. Gonorrhoea in the female may affect the part to very different degrees; thus the vulva alone may be implicated, or, as most commonly happens, the inflammation may spread to the whole of the mucous membrane of the vagina. The urethra is less commonly the seat of disease, though occasionally implicated with other parts; and, lastly, the interior of the uterus may become affected by this specific inflammation. In some cases, it will even spread along the Fallopian tubes to the ovaries; and I have known one or two cases in which rather acute

attacks of peritonitis, probably induced in this way, have complicated disease.

The *Symptoms* of gonorrhœa in women are sufficiently well marked in early stages, when there is an abundant muco-purulent discharge from parts affected, with a good deal of inflammatory irritation, accompanied by pain in micturition, and a frequent desire to pass urine. As the disease becomes chronic, however, it is more difficult to determine its true character, it being apt to be confounded with some of those accidental and leucorrhœal discharges to which females of all ages are subject.

Diagnosis.—In the majority of cases, gonorrhœa may be distinguished from all other muco-purulent discharges of the female organs, by the presence of inflammation about the external parts, and the mucous membrane of the vagina and urethra. In these cases it will be found, on introducing a speculum (which, however, occasions considerable pain, and is firmly grasped by contraction of the vagina), that the discharge comes from the vagina, and that the uterine orifice is free from it, or nearly so; whereas in leucorrhœa the discharge proceeds in a great measure from the interior of the uterus, the os and cervix of which will probably also present signs of inflammation. It must, however, be borne in mind that the discharge in gonorrhœa may occasionally be in a great degree uterine; and that that of leucorrhœa may be an exudation from the mucous membrane of the vagina. In such circumstances, when the disease is chronic, it is almost impossible to arrive at a correct conclusion as to the nature of the case from simple inspection; and in these cases of doubt the surgeon had better give a guarded opinion, lest he be led into the error of inculpating an innocent woman. The difficulty is increased, and a good deal of obscurity thrown over the case, by the fact that leucorrhœal discharges will occasionally give rise to urethritis in the male, which closely simulates gonorrhœa. Girls also are occasionally subject to an acute inflammation of the vagina, nymphæ as the result of simple irritation, of constitutional disturbance, or teething; these cases require to be recognised, as they have frequently been the cause of unfounded accusations.

The *Treatment* of gonorrhœa in the female must vary, according as the disease is acute or chronic. In the acute stage, general and local antiphlogistic means—salines, low diet, rest in bed, and emollient sedative fomentations—must be used. As the disease subsides into a chronic one, the astringent injections must be employed; a weak solution of acetate of lead, or the liquor aluminis composuit largely diluted with tepid water, being especially useful. In other cases, a weak solution of nitrate of silver may be used with much advantage. These injections should be employed three or four times a day, and in large quantity. As they have been thrown up, a piece of lint well soaked in the lotion should be introduced between the opposed mucous surfaces, so as to prevent their coming into apposition, the discharge being in a great measure kept up by their friction against one another. In order that the injection may be properly given, the woman should lie flat on her back, and pump in the fluid by means of one of Kennedy's elastic bottles. In the treatment of gonorrhœa in women, specifics are of no use unless the urethra be affected, when mercury may be given, as in the male. The disease is apt to degenerate into a chronic gleet condition, leaving a thin muco-puriform discharge, which will continue to be infectious for a great length of time.

STRICTURE OF THE URETHRA.

Much discrepancy of opinion has for a long time existed as to the structure of the urethra, some surgeons admitting, others denying its muscularity. Though the presence of muscular fibres in the urethra had been suspected by many in consequence of the phenomena presented by some forms of stricture being solely explicable in this way, it is only in recent times that their existence has been demonstrated; Kolliker and Hancock having shown that the tube is surrounded through its entire length with an organic muscular coat. Hancock has demonstrated the course of these fibres. He has pointed out that the fibres of the inner layer of the muscular coat of the bladder pass forwards underneath the mucous membrane of the prostatic portion of the urethra, and those from the outer layer of the muscular coat of the bladder outside the prostate. These two layers join at the membranous portion of the urethra, forming the muscular covering of this portion of the canal. At the bulb these two layers divide again; the inner lying underneath the mucous membrane, separated from it merely by cellular tissue; the external lying outside the corpus spongiosum, between it and its fibrous investment. At the anterior extremity of the urethra they unite again and form its lips. Thus the urethra is surrounded through its whole length by muscular fibres, a double layer of which invests it at the membranous portion, and again at the external meatus. The prostate and corpus spongiosum are included between planes of these fibres. The vesicles and ducts of the prostate are surrounded by layers of organic fibre; those of the ejaculatory ducts coming from the organic layer of the vas deferens. These fibres are totally distinct from the common muscular apparatus of the perineum; and their existence proves the urethra to be, as had often been suspected, a musculo-membranous canal.

By *Structure of the Urethra* is meant a narrowing of the canal at one or more points. These may proceed from three distinct conditions; viz.—1, Spasmodic Action of the layer of the organic Muscular Fibres situated outside the mucous membrane; 2, Congestion of the Mucous Membrane of the canal; or, 3, Organic Changes in the Mucous and Submucous Tissues, consisting of thickening, induration, or the deposit of plastic matter within them. According as the disease arises from one or other of these causes, it may be termed a *Spasmodic*, a *Congestive*, or an *Organic* stricture. These different forms of the disease having the one condition—narrowing of the urethra—and its consequences, in common and in practice, being often associated together, present so much variety in their symptoms, in the treatment they require, and in the constitutions in which they occur, as to require separate description.

SPASMODIC STRICTURE.—The existence of this form of the disease has been much cavilled at. Surgeons, disregarding the evidence of their own senses, and being led away by an imperfect anatomical examination of the urethra, have denied the possibility of spasm of this canal, not being able to demonstrate the existence of any muscular fibres in sufficiently close proximity to the mucous membrane to influence it by their action. The possession of muscular contractility by the urethra is, however, obvious from the facts that a bougie may occasionally be introduced with sufficient ease, but that the surgeon, on attempting to withdraw it, will find it tightly grasped: so also occasionally, on introducing the instrument, he will feel it meet with an obstruction, which on steady pressure will yield with that species of quivering that is peculiar to spasm of muscular fibre. Again, the fact that a patient will at one time pass his urine with the most perfect freedom, whilst,

if it be rendered acrid or acid by drinking spirits, other potent wines, other similar beverages, almost complete obstruction will ensue, and will prove the existence of an occasional spasmodic constriction of the urethra. These facts, though sufficiently convincing to many surgeons, had not carried proof of the existence of spasmodic stricture to others, until the researches of Kolliker and Hancock, which have already been referred to, the question of the muscularity of the urethra finally at rest.

Causes.—The causes of spasmodic stricture are generally such as to occasion a relaxed and irritable state of system, as long residence in warm climates, especially if conjoined with habitual excesses in drinking, eating, living, and venereal indulgences. The more immediate causes are any circumstances that occasion irritation of the urethral mucous membrane, which, being propagated to the organic muscular fibres beneath, call them into activity and thus gives rise to the spasmodic affection. The nature of these are those conditions of the system in which the lithates are not eliminated; as exposure to cold and wet, by which the action of the system is suspended; or too free an indulgence in spirituous and acid liquors—as red or effervescent wines, beer, or punch—which are well known to give rise to an attack in many constitutions.

Symptoms.—In spasmodic stricture we find evidence of narrowness of the urethra, and consequent impediment to the free flow of urine, varying under the influence of certain causes, and as speedily subsiding in a patient, for instance, in his ordinary health and passing urine freely, he take such food or drink as will give rise to a very acrid condition of fluid, if he be exposed to cold, or get out of health in any way, and finds himself able only to pass his urine in a small stream by drops with straining, or may even be seized with complete retention. Under appropriate treatment these symptoms rapidly subside; recurring, however, on application of any exciting cause. At the time of the occurrence of a spasm there is often a sensation of weight and uneasiness in the penis with evident irritation of the urethral mucous membrane, as shown by reddening of the lips of the orifice: in fact, a tendency to a combination of congestive with the spasmodic form of stricture. There will often be found to be a very slight organic stricture in cases of the spasmodic form of disease; so that, when the spasm subsides, the urethra will not be so free as natural.

Treatment.—If the patient be suffering from spasmodic difficulty in passing urine, a suppository, consisting of a drachm of laudanum in a little oil, should be thrown up the rectum, the warm hip bath used, and a few grains of Dover's powder administered. As the opium begins to take effect, the urine will usually be passed without much difficulty. The bougie should be made to act, when the patient will usually be relieved. If the spasm continue, as it often does, for some days or weeks after this, a fusiform bougie should be introduced every second or third day, in order to overcome the irritability of the urethra. In some cases this is more effectually done by the use of a plated bougie, well warmed and oiled. Whatever instrument used should be of large size, from No. 8 to 10. A small bougie will be arrested, and will create much irritation, when a large one will pass readily. If the use of the instrument cause irritation and increase of spasm, it is better to omit it entirely, and to trust to constitutional treatment. Let the surgeon must not be discouraged, if the first few introductions of the bougie appear to increase the irritation; as the urethra becomes accustomed to the use of the instrument, relaxation of the spasm will take place. At the same time the patient's general health should be carefully attended to, the bowels

must be kept open, and the diet regulated; all acids, stimulants, and sweets, being carefully avoided. During the time when the bougie is being used he should take, three times a day, a draught, composed of twenty minims of liquor potassæ, with the same quantity of tincture of henbane and sweet spirits of nitre, in camphor julep.

As a *precautious treatment* of these attacks, a careful regulation of the diet, warm clothing with the use of flannel, and keeping the skin in action by means of horsehair gloves and tepid baths, will be found serviceable.

CONGESTIVE STRICTURE.—Many surgeons look upon *spasmodic stricture* as essentially dependent on congestion of the mucous membrane of the urethra, overlooking altogether the existence of spasm, or considering it as the result of irritation of the perineal muscles, and not of the true organic muscles of the canal. That the two conditions of congestion and spasm are frequently associated in the urethra, in the relation of cause and effect, there can be no doubt; and this is the most frequent condition in which spasmodic strictures are found. Indeed, congestion plays an important part in all forms of stricture; it may, as we have just seen, be connected with the spasmodic variety; it may occur alone; or it may be associated with organic stricture. Some parts of the urethra appear to be more subject to congestion than others; thus, for instance, the membranous and prostatic portions, especially the folds of mucous membrane constituting the verumontanum, are peculiarly liable to become congested.

Causes.—Congestive stricture frequently occurs as the result of chronic and long-continued inflammation of the urethra, or of the passage of urine that has been rendered irritating by being too concentrated, or by an admixture of an undue proportion of lithates. It is especially in gouty or rheumatic subjects who suffer from irritability of the skin and mucous membranes that this condition occurs. In these cases there is no true or permanent obstruction, but the disease is transitory, and solely due to a swollen state of the membrane of the part.

Symptoms.—In congestive stricture we not only find the common symptoms occasioned by an impediment to the free passage of the urine, but some swelling of the lips of the urethra, with reddening and eversion of them. There is also slight gleet-like exudation, and not unfrequently an abundant puriform discharge, in fact, urethritis of a marked kind, with a sense of weight or fulness in the perineum, pain in micturition, and sometimes uneasiness in defecation. This state of things constitutes a very troublesome affection, intimately connected with the various forms of urethritis, and exceedingly apt to relapse from apparently very trivial circumstances, slight errors of diet, dyspeptic derangements, or any local sources of irritation.

The **Treatment** in these cases should consist in careful regulation of the diet and habits of life, and especially in the administration of the alkaline and sedative mixture above indicated in combination with small doses of copala. In many cases a course of Plummer's pill, in conjunction with compound decoction of aloes, will be found of essential service. If there be much tenderness or weight about the perineum, the application of leeches to this part, together with the use of the warm hip-bath, will be serviceable.

Congestive stricture, though more influenced by constitutional than by local means in many cases, yet requires the introduction of bougies in order to prevent the constriction from becoming permanent. In some instances a wax, in others a silver or pewter instrument, will be found to answer best. Whatever is used, care should be taken to introduce it slowly and with every possible gentleness. With all care, some hemorrhage usually follows the passage

of the instrument ; not from laceration, but simply as the result of excision of the mucous membrane ; and the discharge of blood appears rather to be beneficial than otherwise.

ORGANIC STRICTURE.—This form of stricture is the result either of continued inflammation of the urethra, leading to changes in the membrane, or of some injury to the canal from blows or laceration perineum, by which a portion of it is destroyed or sloughs away. Syphilis, gonorrhoea and long continued gleet are the most fertile causes of this disease. In the urethra as elsewhere, plastic matter is deposited and around the mucous membrane in the submucous cellular tissue as a result of inflammation ; consolidation of this takes place, followed by traction of the canal. The long continuance of inflammation is more dreaded than its intensity in occasioning this mischief, hence it is of importance not to allow gleet to run on indefinitely, as they are sure to a certainty be followed by constriction of some portion of the urethra.

Seat.—The seat of organic stricture varies considerably ; indeed, any part of the urethra may be affected by it, except the prostatic. It appears to be a common belief amongst surgeons, that the membranous portion of the urethra is the most frequently affected by this disease. This, however, there is little doubt, is an erroneous opinion. H. Smith has examined 98 specimens of stricture contained in the different London museums, of which he found only 21 seated in the membranous portion of the urethra, 77 were anterior to the triangular ligament ; the majority of these were either in the bulbous portion of the urethra, or a little in advance of it. H. Thompson, in his excellent work on *Stricture*, states as the result of his numerous observations, that stricture is more frequently met with at the junction of the spongy and membranous portions of the urethra, about one inch anterior to this ; and most rarely, so far back as the membranous portion itself ; lastly, he states, “ I can confidently assure that there is not a single case of stricture in the prostatic portion of the urethra to be found in any one of the public museums of London, Edinburgh or Paris.” Not unfrequently strictures are met with at the mouth of the urethra ; and occasionally they are multiple, two very frequently occurring and sometimes as many as four or five. When there are several strictures, one will always be found at the bulb or in the membranous portion of the urethra.

Characters.—The characters of organic stricture vary greatly. In some cases it is annular, encircling the whole of the canal, and occasionally some little distance. The elongated annular stricture usually arises from consolidation of the corpus spongiosum by plastic matter compressing the urethra, as in Fig. 478. In other cases, again, annular strictures are narrow and sharp edged, and are then called “ pack-thread ” or “ lamina ” strictures ; consisting of bands stretching across the urethra (Fig. 479). Sometimes there are several of these in close proximity to one another, leaving merely narrow passages between or under them. These bands occasionally stretch directly across the canal, but at other times and more commonly they take a somewhat oblique direction (Fig. 477). It is not clear how these bridles or fræna stretching across the urethra are formed ; they can scarcely be by the effusion of plastic matter ; it is more probable they are occasioned by a valvular projection of the mucous membrane which has been perforated, perhaps by the point of the catheter, and thus narrow apertures produced in it. These various kinds of organic stricture are hard and elastic ; sometimes, when old, almost cartilaginous in their feel, and feeling gristly and rough to the instrument that passes over them.

Amount of Constriction.—This varies greatly in organic stricture, from merely slight narrowing of the channel to almost complete obstruction of it.

Fig. 476.—Bridle-Stricture.

Fig. 477.—Stricture at the Anterior part of the Urethra.

Fig. 478.—Stricture from Condensation of Corpus Spongiosum.

A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed upon the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures may occasionally, though very rarely, occur; the channel being so narrow, oblique, or tortuous, that the instrument cannot be passed through it. Strictures, however, of this description, may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" is meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and, even with such an aperture existing, I have never heard of or seen a case in which no urine whatever escaped by the meatus, unless in consequence of injury or disease a portion of the whole calibre of the urethra had sloughed away; and it is clear that, so long as any passes out in this way, a stricture cannot be looked upon as truly impermeable.

Mechanical Results.—When an organic stricture is once formed, it will continue unless removed by surgical means; and as it usually becomes more closely contracted, it will offer an increasing obstacle to the free flow of the urine, and thus eventually tend to give rise to important structural changes in the urinary apparatus.

The urethra behind it becomes increased in diameter, sometimes dilated into a true pouch, in which sabulous masses, and even small calculous concretions, occasionally collect. The bladder, subjected to increased pressure by the necessity of overcoming the obstacle to the passage of the urine, becomes thickened and fasciculated. The ureters are often found dilated, from a tendency to a reflux of the urine, or to compression of their vesical orifices, in consequence of the altered structure of the bladder. The kidneys become irritated, congested, and at last the seat of some of these various structural

changes which, by impairing their functions, and interfering with the general depuration of the blood, may eventually destroy the patient.

Symptoms.—The amount of constitutional disturbance set up by a stricture will vary greatly in different cases. In many, and in most instances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and extent of the stricture; but it is surprising how much constitutional disturbance is set up in some systems by a stricture, even though it be not very tight. Interference with the free flow of the urine causes irritation of the bladder and kidneys, the secretion from which becomes less abundant than usual. In consequence of this, the actions of the skin and other depurative organs are deranged, and thus the system at large is influenced and suffers. In some cases, again, the constitutional symptoms are rather of a nervous character, the patient suffering not only great pain in micturition, but being attended with rigors, followed by nervous prostration, each time the urine flows over the tender and irritable surface.

The *Local Signs* of stricture are always well marked, are very constant, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the free escape of the urine. The disease commences with the retention of a few drops of urine after evacuation of the contents of the bladder. The patient finds that he has to pass urine more frequently than usual, particularly at night; there is some straining, and a slight gleet discharge, and a feeling of weakness about the perineum. The stream of urine has changes impressed upon it during its passage, and the stricture, by which its shape and direction are modified, thus it becomes forked, scattered, twisted, fan like, or be discharged in two currents—one projected directly forwards, the other dropping perpendicularly downwards. As the disease advances, these signs necessarily become more marked, until they may terminate in complete retention; they, however, often come on in a very insidious manner, and when the patient receives advice he is found to be already the subject of a very tight and extensive stricture; indeed, in some cases, the first circumstance that directs the attention of the patient to his complaint is the sudden occurrence of retention of urine.

Examination of the Urethra.—The existence of stricture can be determined with certainty only by the introduction of an instrument down the urethra. In exploring the canal in a suspected case, two points have to be ascertained—the existence of a stricture, and its degree of tightness. The existence of a stricture is best determined by passing a plated steel sound, or a catheter of medium size, about No. 8, well oiled and warmed. This will readily pass as far as the constricted point, but will then be arrested. In this exploration, too small an instrument must not be used, lest it hit the fossæ of the urethra or against the verumontanum, and this would be mistaken for the obstruction produced by the stricture, and it might pass through the stricture, and thus mislead the surgeon. The existence of a stricture having been ascertained, the next point is to determine its degree of tightness. This is best done by withdrawing the instrument just used, and then introducing a smaller one of about the size of the stream of urine that the patient passes. If this fail to enter the stricture, a smaller one still must be used, until that size is reached, which can be introduced with but a moderate degree of force. In this way the existence, the extent, and degree of tightness of the stricture, are ascertained. The tact of an experienced surgeon will also lead him to judge to a certain extent of the length, degree of induration, &c., of the constriction.

The employment of soft wax bougies has been recommended with the view of taking a mould of the size, shape, and direction of the stricture, by pressing the end of the instrument into it; but no possible advantage can be derived from this proceeding, and a surgeon accustomed to the use of metallic instruments can obtain all this information with more certainty by the finer touch afforded by them.

Treatment.—The treatment of stricture of the urethra may be conducted by four methods:—1, *Gradual Mechanical Dilatation*; 2, *Caustics*; 3, *Forcible Expansion or Rupture*; and 4, *Division of the Contraction*. Whatever plan of treatment be adopted, the surgeon must bear in mind that his operations have to be conducted upon a tender canal endowed with exquisite sensibility, which sympathises closely with the conditions of the general system, and in which improper violence or too active measures may set up a degree of irritation that will readily extend to neighbouring structures, and thus jeopardise the life of the patient. But, though it is necessary to recollect all this, he must not run into the opposite and equally dangerous extreme of adopting inefficient measures for the removal of the obstruction. A bad stricture is one of the most serious diseases to which the human frame is liable, and will almost inevitably, if left to itself, terminate fatally by the induction of renal disease; and we must therefore not hesitate to adopt sufficiently energetic measures for its removal; and if these be properly conducted, there is scarcely any affection in which the surgeon can afford his patient greater relief than in this. At the same time, however, that local means are being used, constitutional treatment should not be neglected. Organic stricture is often more or less associated with spasmodic or congestive stricture, and requires the same constitutional treatment, modified according to circumstances, that is necessary in these affections—proper regulation of diet, avoidance of all articles of food that generate lithates, care not to allow the urine to become too concentrated; and attention to the maintenance of the healthy action of the liver and skin will tend much to increase the patient's comfort, and to ward off the more serious consequences of stricture.

1. **GRADUAL MECHANICAL DILATATION**, as it is erroneously termed, is the usual and certainly the most successful mode of treating ordinary strictures; but it is not the mere stretching or forcible dilatation of the stricture that cures it. The means employed to produce dilatation tend to promote the absorption of those plastic matters effused in and underneath the mucous membrane, which especially constitute the stricture, and thus to occasion a permanent cure.

The instruments that are used for dilatation are either metallic, such as silver catheters, steel sounds, plated or pewter bougies; or made of some soft and yielding material, as gum-elastic catheters, catgut, wax, or elastic bougies. Though each surgeon will mostly prefer one kind of instrument to another, it is well not to be too exclusive in the use of any one; for it will be found in particular strictures and certain constitutions that it is advantageous to depart from the ordinary practice, and that the surgeon may modify with great benefit to his patient the mechanical means that he adopts. As a general rule, I think that metallic instruments are decidedly preferable, more especially when the stricture is tight, cartilaginous, and of old standing; nothing will pass such a stricture as thus so readily as a well-made steel sound or silver catheter.

The shape and curve of *Catheters* and *Sounds* is of much importance; the best curve for these instruments, I think, consists of the one fourth of the circumference of a circle $4\frac{1}{2}$ inches in diameter. If sounds be used, they

should be made slightly conical, so numbers between the point and the bend of the instrument. They are particularly useful when the ment. The sound should have a sensation communicated to the p. use in passing catheters through re netrable for months or years with

Gum-elastic Bougies and Catheters, and Wax Bougies, are not nearly so manageable as metallic instruments, as they usually bend back against tight strictures; in fact, it is only in those of a spasmodic and congestive kind, in which a large instrument will readily pass, that they are of much service. They are usually best introduced whilst the patient is standing, and they generally glide most readily into the bladder if they have been slightly curved before being passed. When they are of wax, it is useful to smooth them down between the fingers before introducing them. In using the elastic catheter, a stylet is usually required; but in some cases the instrument appears to enter more easily without this. In others, it may be passed with the stylet down to the stricture; and then, on partially withdrawing it, the point of the catheter will start up, and thus more readily slip in.

Results of Introduction of an Instrument.—The introduction of an instrument usually gives rise to a smarting, painful sensation in the urethra; it is generally most severe as the point approaches the neck of the bladder, and is then sometimes attended by nausea and sudden faintness. As a general rule, the instrument should be passed every second or third day, and when introduced should be left in for about five minutes, or until the spasm about the urethra induced by its introduction has subsided. If, however, the stricture be extremely tight, a very small catheter only having been introduced, the instrument may be left in for twenty-four or forty-eight hours, when it will be found that, however tightly grasped it originally had been, it has become loosened; a slight discharge being at the same time set up from the urethra. It may then be readily withdrawn, and, when the irritation has subsided at the end of a couple of days, a considerably larger one may be introduced.

The augmentation of the size of the instrument should be very gradual. It is fully sufficient to increase it by one number at each time of introduction. Many urethra will not bear even this, and it becomes necessary to pass the same instrument on two or three successive occasions before a larger size can be introduced. The size of the instrument may be gradually increased until that is reached which the urethral orifice readily admits; beyond this, the surgeon should not go; but so soon as the full size, usually No. 12 or 14, can be introduced with ease, it should not be passed so frequently as before; once a week or ten days, and gradually with less frequency. But for some length of time it will be necessary to introduce it at least once a month or six weeks, lest contraction take place again.

If the size of the instrument be increased too rapidly, irritation may be set up, and inflammation of the testicles, and abscess in the perineum or prostate, induced. I have more than once had occasion to regret being in too much haste to increase the size of the instrument; and, by augmenting it by two or three numbers at one sitting, have seen the patient thrown back for weeks by the supervention of some of the affections just mentioned.

When the stricture is situated solely at the urethral orifice, the best instruments for dilatation are *nail-headed styles* of graduated sizes. These strictures are, however, very troublesome, and have a great tendency to relapse.

By gradual dilatation, properly carried out, most strictures may be considerably relieved in the course of a few weeks; and the majority may be cured by continuing the treatment for a sufficient length of time. Some, however, cannot be cured in this way; it would appear that the tissue of which they are composed is so contractile that, although they may be expanded up to a certain size—say up to No. 5 or 6—it is impossible to go beyond this. In other cases there is a great tendency to relapse, and

to a return of the constriction; the stricture rapidly becoming tight soon as the introduction of instruments is discontinued, even though the stricture be dilated up to the full size of the urethra, up to a No. 10 catheter, for instance. In some instances the relapse is almost instantaneous, micturition being as difficult as before as soon as the catheter is withdrawn. In these cases recourse must be had to other measures, which will be described.

Accidents attending Catheterism.—The introduction of instruments occasionally gives rise to certain troublesome and even dangerous accidents. Amongst these, syncope and rigors, hemorrhage, and inflammatory action about the urethra or testes, are the most common. In certain constitutions, usually of a nervous and irritable character, there is a great tendency to the occurrence of *shivering and faintness* after the passage of an instrument, more particularly as it approaches the neck of the bladder. These usually go off after the withdrawal of the catheter, but in some cases may continue for many hours, or even come on after the lapse of some time, the rigors in these circumstances being very distinct and intermittent, much so as to resemble an ague-fit. In such cases as these a full dose of opium powder, or of laudanum, in some warm brandy and water, will usually afford the patient most relief. This accident is seldom attended with any danger, should the kidneys happen to be much disorganised, death may ensue. In one case I have known this happen at the expiration of nine hours after the continuance of the syncope; in another instance, in two days, from retention of urine, and this even though no material difficulty was experienced in passing the instruments.

Hemorrhage, which is sometimes rather profuse, may follow the introduction of a catheter, especially if the stricture be congestive, and the instrument employed, small. It generally ceases of itself; but, if it be troublesome, application of cold will check it.

The inflammation about the urethra and in the testes that occasionally occurs during the treatment of stricture, is best guarded against by using too large catheters, and by directing the patient to abstain from exercise during the time of their introduction.

False Passages are occasioned by the instrument passing out of the urethra through its coats into the surrounding tissues. They are especially apt to occur in tight bridle-strictures, when a small instrument is used, and more especially if the direction of the constriction be somewhat oblique, so that the point of the sound is thrown against the side of the urethra (Fig. 476). The extent and situation of a false passage necessarily depend according to the position of the stricture; and the danger is usually in proportion to its depth. The false passage usually takes a direction downwards and to one side of the urethra. If the stricture be far forwards, it may pass into the corpus spongiosum, but if in the usual situation, it may perforate the lateral lobe of the prostate, or run between this and the rectum, and be unable to extend upwards on account of the rigid nature of the stricture in this situation. When the false passage merely perforates the corpus spongiosum, running parallel to the urethra, and opening again into the urethra, or when perforating a portion of the prostate it enters the bladder, it is necessarily attended with much danger; but when it enters the cellular tissue between the bladder and the rectum, breaking up this structure to a great extent, admitting urine into the recto-vesical space, and ascending to the neck of the bladder, then the most serious consequences, such as inflammation and abscess in this neighbourhood, are apt to ensue, which are almost invariably followed by the death of the patient.

At the moment when a false passage is made during the introduction of an instrument, by the surgeon using too much force or pressing in the wrong direction, he feels the point make a sudden slip, which the direction of the shaft indicates to be to one side of the urethra. The patient complains of severe pain, and is often conscious of a laceration; there is a grating or rough sensation communicated by the tissues against which the instrument has passed; and though it have entered deeply, it will be found not to have reached the bladder. On the surgeon introducing his finger into the rectum, he probably feels the point of the instrument in the cellular tissue between the gut and the bladder; on withdrawing it, it will be found covered with blood, and there will be free hemorrhage from the urethra.

The surgeon knows when he has entered an old false passage by the change that takes place in the direction of the instrument, by its not reaching the bladder, and by the rough sensation communicated to it, very different from that afforded by the smooth lining of the urethra. The patient is often conscious of the existence and of the entry of the instrument into the false passage, and will warn the surgeon of it. If the surgeon be aware that he has made a false passage, he should, if possible, at the time of the accident pass a larger catheter into the bladder, and leave it there for a few days until the laceration has healed. If there be an old false passage he must be careful, by keeping the point of the instrument away from it, not to enter it, lest during the introduction of the catheter he raise with the point of the instrument the valvular angle that intervenes between it and the urethra; every time that this is opened up it tends to lessen the chance of a closure of the aperture, whilst, overlapping the urethra, it interferes with the onward passage of the instrument into the bladder. By withdrawing the instrument and changing its direction, the false passage may often be avoided, and the bladder reached. Should there have been much difficulty in introducing the catheter, the better plan will be to allow it to remain in the bladder for two or three days, when the false canal may possibly close.

It has already been stated that in certain forms of stricture, gradual dilatation does not succeed in effecting a permanent cure. In these cases three plans of treatment have been recommended—the destruction of the stricture by caustic, forcible dilatation, and its division by the knife. These methods will now be described.

2. CAUSTICS.—In the treatment of stricture by caustics, two objects are endeavoured to be attained; the first is the destruction of the stricture; the second, the diminution of the sensibility of the surrounding mucous membrane, so that the irritability and spasm of the canal may be lessened. The following is the way in which the caustic is applied. A wax bougie, well-oiled, is passed down to, but not through the stricture; the surgeon then, with the thumb nail, makes a notch on that portion of the instrument opposite to the meatus. Another bougie of similar length and size is then armed by a piece of potassa fusa of about the size of a small pin's head, placed in a depression at its end. A mark is now made on it, at a point corresponding to the notch on the first bougie; it is then passed rapidly down until this mark comes opposite to the meatus, and then pressed firmly for two or three minutes against the stricture, upon which the caustic exercises its action. This application, which is followed by a gleet discharge, is to be repeated every second or third day until a proper sized bougie can be introduced; and then the dilatation may be proceeded with in the usual way. This practice, stigmatised, not unjustly, by Liston as "most atrocious," has now but few advocates; and, indeed, there appears to be nothing useful

effected by it, beyond what can be accomplished much more safely and by a catheter or sound in an ordinarily skilful hand.

3. **FORCIBLE EXPANSION OR RUPTURE.**—Forcible and rapid dilatation causing the expansion and rupture of the stricture, is a method originally proposed and practised many years since by Luxmoor, Dr. and Buchanan of Glasgow, has of late years been revived in principle, ingeniously modified in detail, by many surgeons, among whom Maisonneuve, Perreve, Wakley, Holt, and Thompson are the most conspicuous. However varied the means by which strictures are thus the instruments employed may be arranged in three groups: *a.* Those that act as sliding tubes; *b.* Those that expand by a screw mechanism. Those that act on the principle of a wedge.

a. Sliding Tubes were first employed in the treatment of stricture by Desault at the close of the last century, subsequently by various surgeons, and of late years by Hutton of Dublin, and very extensively and successfully by Wakley. The mode of application of these tubes is as follows. A long conductor is passed through the stricture into the bladder, and over this a catheter, either of gum or silver, is passed, which on turn is made to serve as a conductor to a larger one. In this instrument the conductor, or "urethral guide," consists of a small catheter, which, after being passed through the stricture, has a long rod screwed into it. Over this a silver tube is passed, which is also made to serve as a conductor; and thus the stricture may be rapidly dilated by passing one tube over another until a full size is reached. The difficulty in this very ingenious method—which is, however, common to every other plan of treating stricture by dilatation—consists in the introduction of the "urethral guide;" when that has once passed the stricture, the tubes must follow as a matter of necessity. They may possibly go wrong; and, as no laceration or rupture of the stricture can be effected by the instrument, it appears to be a peculiar means of employing rapid dilatation when circumstances seem to require it.

b. The method of forcibly expanding a stricture by the introduction of a small two- or four-bladed instrument, fashioned somewhat like a narrow beaked sound, and which, by screw mechanism in the handle, of being opened out so as to stretch the stricture to an extent corresponding to the distance at which the blades are screwed apart, has many advantages, and various ingenious contrivances have been invented to effect this. More than half a century ago, Luxmoor attempted it by the use of a two-bladed instrument. Subsequently Civiale invented a structure-expander, and of late years two-bladed instruments, having this end in view, have been introduced into practice by Perreve, Lyon, and H. Thompson.

Fig. 480.—Thompson's Stricture-Expander.

The accompanying drawing (Fig. 480) is a representation of the instrument by the latter gentleman; it answers admirably the intended purpose of expansion of the blades being effected by a screw worked by turn of the handle. This should be done very slowly, several seconds being allowed to elapse between each turn of the handle, so that the tissue composing the stricture may be gradually stretched, and the canal of the urethra at the point of stricture dilated beyond the full size, so as to be over-stretched, the

of dilatation may be carried up to 16 or 18, and is marked on a scale attached to the handle of the instrument. If this operation be done slowly, little if any bleeding results, and there is no evidence of laceration of the wall of the urethra at the strictured spot. A large gum catheter may then be passed, and the urine drawn off. It is not usually necessary to leave the catheter in the bladder, though there can be no objection to doing this for forty-eight hours, after which the patient may have one passed occasionally in order to maintain the dilatation.

c. The rupture or splitting of the stricture by an instrument acting on the principle of a wedge, has been recommended by Reybard and Holt, and very extensively and successfully employed by the latter excellent surgeon. The instrument used by him is represented in the accompanying figure (Fig. 481). It consists of two grooved metallic blades joined at the extremity

Fig. 481.—Holt's Instrument for Splitting Strictures.

Between these a tube is slipped along a wire, which in its descent separates the blades at a considerable angle, and thus splits up the stricture. In this way the contracted part of the urethra is at once enlarged to its normal diameter, so as to admit a full sized catheter, by which the urine is then drawn off. The introduction of the catheter should be had recourse to at first on alternate days, and afterwards at longer intervals. Holt has treated nearly three hundred strictures with this instrument, with the most perfect success, and without the occurrence of infiltration of urine, abscess, or other mischief. He believes that the effects of the dilatation are entirely confined to the morbid contraction, the healthy portion of the urethra not being injuriously disturbed by the expansion of the instrument.

4. DIVISION OF THE STRICTURE may be practised either from *within* the urethra, or from *without*, through the perineum.

INTERNAL URETHROTOMY.—The division *from within* may be performed in two ways; either by cutting through the stricture from before backwards, or by passing a proper instrument through it, and dividing it from behind forwards.

The first method—that of perforating the stricture *from before backwards*—consists in passing a concealed steel stylet down to the stricture, and then pushing forwards the lancet like knife, attempting to perforate the obstruction. This plan is necessarily attended by the most dangerous consequences, if an attempt be made to thrust a stylet through the stricture without a guide; the probability, indeed almost the certainty, being that the pointed cutting blade will pass by the stricture and divide the healthy wall of the urethra. It is, indeed, almost banished from surgical practice, and is only applicable with safety to those strictures that are situated in the part of the urethra anterior to the scrotum, where the canal is straight. In the deeper and more curved parts, any attempt at perforation would obviously be fraught with danger; for, as it would of course be impossible for the surgeon to guide the stylet exactly in the direction of the urethra, it would be more likely to perforate the walls of this canal than to pass through the stricture. In hard and resisting contractions, however, in the straight portion of the canal anterior to the scrotum, such an instrument may occasionally be used with advantage. A very convenient form of cutting stylet is the one figured here, which has a probe end, that is introduced through the stricture, and serves as a guide

to the blade, which is projected and the action of a spring (Fig. 482).

Fig. 482.—Lancetted Stylet.

The other mode of dividing strictures is from behind forwards. This is done by passing a stylet through the stricture, and then the instrument is withdrawn, notching the obstruction. The stricture must be of considerable size to admit of a No. 6 catheter, it is usually sufficient, and this procedure will therefore succeed if the stricture is situated at the meatus, or in the bulb, or in a narrow probe-pointed bistoury; and if the stricture is down the canal, its section may be effected by a slender sheathed blade, which is then divided as the instrument is withdrawn.

The internal division of strictures has always been a favourite method of treatment, and is not a few complicated and dangerous operations, but by a process of cutting or laceration, may be effected. Civiale, however, to whom the operation is owing, has invented various instruments, has invented a

Fig. 483.—Civiale's Instrument.

division of the stricture may be safely effected, however, as with all other urethrotomy, the instrument must be about No. 5. The end of the instrument is a small blade having been made to pass downwards by a firm and steady pressure. The blade is then shut into the stricture, and a No. 10 catheter is passed, and the operation being afterwards completed, the patient is confined to bed for three or four weeks. This operation is attended with much pain, and usually by the loss of blood.

In performing internal urethrotomy, it is of great importance to bear in mind that the stricture may be pushed back by the instrument to the distance of about an inch, with a view to steady the urethra by drawing the stricture back, and then the section of the stricture is attempted by a sawing motion rather than by a cutting motion.

The operation of internal urethrotomy, as mentioned, appears to be attended with much pain, and diminishes in exact proportion as the stricture is removed from the urethra. It is of course only reg-

chiefly resilient or very irritable strictures. In resilient strictures dilatation fails, because the stricture, though admitting of expansion, immediately relapses. In very irritable strictures, the patient cannot bear the pain of dilatation. In both these classes of cases, the division of the stricture from within removes at once all difficulty in treatment; and I have of late years employed this very simple method in several cases of this kind with the most marked and permanent success. In fact, in strictures of the scrotal or penile portions of the urethra, where one or other of the above conditions—resiliency or irritability—generally prevails, I now very commonly notch the constricted portion of the canal by means of Civiale's arethrotome, and thus at once, and with great ease, obtain much, if not all, the space required.

EXTERNAL URETHROTOMY.—The division of the stricture *from without* by incision through the perineum, may be performed by two distinct operations: the one being only applicable to those strictures that are pervious to an instrument; the other to those which are impermeable. In the first case, a grooved staff is passed through the stricture, and the section is made upon this. In the second case, the surgeon attempts to cut into and through the stricture, without any guidance except such as his anatomical knowledge may afford him.

Operation for Permeable Stricture.—The first of these operations introduced by Syne as *Urethrotomy*, and commonly called the *Perineal Section*, is comparatively a simple procedure. The instruments required for its performance are a staff, a No. 8 silver catheter, a pointed scalpel, and a broad director. The staff should vary in size from No. 1 to No. 6, according to the tightness of the stricture; it should be grooved along its convexity, either the whole of the way, or better, merely for the lower third (Fig. 484). The stem is smooth and of full size, and joins into the lower grooved part by a distinct shoulder, which, being passed down as far as the stricture, forms by its projection a guide to that part of the urethra requiring division. In those cases in which there are false passages, a hollow staff of the same size and shape may be advantageously used, the flow of urine through it indicating with certainty its passage into the posterior part of the urethra.

Performance of Perineal Section.—The operation is performed as follows. The staff having been passed well through the stricture, so that the shoulder rests against the upper part of the constriction, the patient is tied up as for lithotomy, and the surgeon, seating himself in front, pushes the scalpel, with the back of the blade downwards, into the mesal line of the perineum a little above the rectum, and cuts upwards for an inch or more in the raphe. The dissection is carried on very carefully exactly in the median line until the staff is reached, when the knife must be entered into its groove behind the stricture, and carried forwards through this. The staff, having then been pushed on to ascertain that all is free, must be withdrawn, and a No. 8 catheter introduced, which is to be kept in for forty eight hours; it must then be taken out, and at the end of eight or ten days the urethra must be dilated by the introduction every second day of a full sized silver catheter. Urine escapes for some little time by the perineal incision, but as this heals by granulation, the flow of fluid gradually lessens and at last ceases entirely.

The principal points to be attended to in this operation are—

1. To see that the staff is fairly through the stricture, and to be especially careful in determining this if false passages exist.

Fig. 484.—Shouldered Staff for Perineal Section.

2. To cut carefully in the middle, where there can be no danger what might happen if any lateral vessel, indeed, which is at all, this may always be avoided by cutting towards the side of the incision.

3. To enter the point of the knife by cutting forwards in the groove of the urethra.

4. Not to turn the edge of the knife, so that the deep perineal fascia may be opened without inflammation incurred.

5. Much difficulty has occasionally occurred in passing a broad director, with the view of dividing the stricture of the urethra after the stricture has been drawn. As the catheter is passed and guided by this onwards into the bladder.

When there are more strictures, the use of the catheter is usually alone necessary; the other is not.

Result.—The result of the perineal operation is usually satisfactory; in which a fatal termination has been known to occur. It is for this reason to believe that these cases are not advocates of this operation have ever, there are no trustworthy statements to enable us to speak positively as to the result of the operation. Occasionally, an incurable stricture of the perineum; and not unfrequently a stricture, such as inflammatory oedema, have been found to supervene.

The whole value of urethrotomy in the case of a stricture to return after its division by any means satisfactorily determined which it has been practised has in the present session; and until this has been determined by operation as established, except in the kind just mentioned. Much dilatation of the urethra for some time, a catheter of full size being passed, and no precaution be neglected, relapses are not infrequently attended to they are. Against urethrotomy it has been argued that the urethra might occasion a cure, and eventually tend still further to less. *Mortem* examination of patients in whom the operation had been performed has shown the cicatrix being linear and scarcely different in the result, between cases in which it was transversely and those in which it was linear. In the first instance, a dense and contracted stricture; in the second case, a linear and scarcely perceptible stricture.

Comparison of Methods of Treatment.—The connection with the several operations is as follows:

should be practised. That most strictures may be cured by gradual dilatation, there can be no doubt; most practitioners holding with Liston, that whenever a catheter will pass through a stricture, its cure by dilatation is in the hands of a skilful surgeon. Though this may be generally true, instances not unfrequently occur, in which simple dilatation fails to effect a cure; the stricture being highly contractile, and not admitting of expansion beyond a certain point, or relapsing whenever the dilating means are removed. In other cases, also, the patient suffers so much pain and irritation whenever an instrument is passed, that he cannot bear the repeated introductions that are necessary, more particularly if the stricture be complicated with fistule in perineo or false passages, which render its cure by dilatation tedious and almost impracticable. In such cases as these the surgeon, being unable to benefit his patient materially by dilatation, must choose between the employment of palliative means or more active measures.

It appears to me that there are four classes of cases in which more energetic means than simple dilatation may not only be advantageously employed but are absolutely required.

1. In *very old dense cartilaginous strictures*, often of traumatic origin, which admit an instrument with great difficulty, and cannot be dilated beyond a certain point, owing to the conversion of the urethral structures into a kind of dense, fibrous, almost cicatricial tissue, which neither admits of expansion nor of absorption by the pressure of instruments; and in which a considerable extent—half an inch or more—of the urethra is involved.

2. The same kind of stricture, complicated with *fistulæ* in the perineum or scrotum, with perhaps considerable plastic infiltration of these parts. In both these classes, I think that the perineal section or external urethrotomy is the preferable operation.

3. *Very tight structures*, accompanied by *excessive sensibility* of the urethra; in which each introduction of the instrument is attended by intense suffering, spasmodic movements of the limbs, and rigors, so that the patient cannot be induced to submit to a proper course of bougies.

4. *Very elastic*, though perhaps *narrow strictures*, that can be dilated readily enough, even up to the admission of full-sized instruments; but which, when the treatment is discontinued, immediately begin to contract again, so that the patient is never out of the surgeon's hands, and sees no prospect of cure.

In these last two classes of cases, I am of opinion that internal urethrotomy with Civiale's instrument, or the forcible expansion or rupture of the stricture, is the best method of treatment; the perineal section being too severe and dangerous, whilst simple dilatation is too feeble a means of treatment.

Impermeable Stricture.—In order to perform the perineal section, the stricture must be pervious to a grooved staff, however small this may be; and this, it might be supposed, would limit materially the cases in which the operation can be performed. But complete obliteration of the urethra cannot take place except as the result of sloughing, usually from injury; indeed "impermeable" strictures, though frequently spoken of, are very rarely met with. Syme, indeed, denies their existence, and states that if urine can escape through a stricture, a bougie can be introduced. A surgeon may often be foiled in his first attempts in passing an instrument through a very tight stricture; but I believe that, with patience, by attention to constitutional treatment, so as to lessen urethral irritation, and especially by the administration of chloroform, he will usually at last succeed in making an

instrument of some kind pass through the very worst strictures. In case in which I performed the perineal section, almost all the urine twelve years been discharged through fistulous openings in the perineal scrotum; and the principal portion escaped through a large hole inside of the left thigh, a few drops merely occasionally passing out lips of the urethra. No instrument had been passed for four years; repeated attempts had been made by different surgeons. Being introducing a catheter into the bladder the first time I tried, I patient in the Hospital for two or three weeks, attending careful constitutional condition, but without making any further effort. then placed under chloroform, when I succeeded in passing No. 5 urethra was then dilated up to No. 5, beyond which no instrument passed, when the perineal section was performed. The patient an excellent cure, the fistulous openings closing, and the urine being discharged by the natural channel. In another case, which I attended with Mr. persevering attempts had been made for five years to make an instrument enter the bladder, but without success, the stricture not only being very tight, but the urethra acutely sensitive; under chloroform I succeeded in introducing No. 4 silver catheter into the bladder, and speedily cured patient. In a case of extravasation of urine following stricture, caused on injury of the perineum, sent to me by Mr. Corrie of Funcher, no catheter had been introduced for eight years, it was found at that, although the urethra had been converted into a mass of cicatrix at the part injured, it was yet permeated by a narrow tortuous channel through which the urine had escaped.

The influence of *Anæsthetics* in facilitating the passage of instruments through apparently impermeable strictures is very marked. Since the introduction of ether as an anæsthetic agent, Liston was enabled to pass through a stricture that had resisted all attempts made by his numerous hand at introducing an instrument into the bladder, but it was the patient put on the table and fairly rendered insensible. No. 8 silver catheter, which had been passed down as far as the point of which was to serve as a guide to the knife, slipped out of the bladder, and thus rendered a dangerous operation unnecessary.

Yet no surgeon can doubt that cases do occasionally, though rarely, in which, in consequence of extravasation of urine and old inflammation, the urethra has become so tortuous and narrow, and the parts indurated and disorganised, that an instrument cannot be passed, even though urine pass out readily. It must be borne in mind that the urethra may be permeable to urine, but impermeable to a catheter, even most dexterous hands. It does not follow necessarily that, because urine will trickle out of a narrow and tortuous channel, a catheter or bougie can be passed into it from without. Hence cases will occasionally occur in which the perineal section is not practicable.

In the event, therefore, of a stricture being so tight and tortuous that no instrument will pass through it, or where, a portion of the urethra having sloughed away, its canal is obliterated, neither the cure by division of the urethra nor urethrotomy can be performed, and it may then be necessary to have recourse to incision of the stricture without a guide.

Operation for Impermeable Stricture.—This operation is performed as follows. A No. 8 silver catheter is passed down to the point of the stricture. The patient is then tied up as if for lithotomy; and the surgeon, sitting on a stool, pushes a bistoury with the back turned towards the rectum, and divides the urethra as far as the apex of the prostate, or as far as possible, if possible,

the dilated urethra *behind* the stricture. He then cuts *forwards* through the stricture on to the point of the catheter, and having thus opened a passage, endeavours to pass that instrument on into the bladder. It is often extremely difficult to find the posterior part of the urethra; but in some cases this part of the operation may be facilitated by passing a grooved director or straight female catheter into it to act as a guide. When the tissues of the perineum are hard and gristly, altered by the effusion of plastic matter, and condensed by repeated attacks of inflammation and the existence of fistulae, it is a most difficult matter to dissect through such an altered mass and hit the urethra beyond it; and the difficulty is still further increased by the bleeding, which is often profuse.

This operation, I have no hesitation in saying, is perhaps the most troublesome in surgery. I have more than once seen the most skilful operators foiled in their endeavours to accomplish it, and compelled to relinquish the operation without concluding it, or only succeed after prolonged and most painful attempts. Fortunately this operation is now scarcely ever necessary; with patience and under chloroform the surgeon may almost invariably pass a staff, however small, into the bladder; he then has a sure guide upon which to cut, by following which he must certainly be led through the stricture into the urethra beyond it. In all cases, therefore, urethrotomy should, if practicable, be substituted for the division of the stricture without a guide.

COMPLICATIONS AND RESULTS OF STRICTURE.

RETENTION OF URINE.—This has a tendency to occur in all tight strictures, from the gradual and progressive contraction of the canal. It most usually, however, takes place in consequence of a congestive spasmodic condition being superadded to the organic constriction. It commonly happens that a patient having a moderately tight organic stricture commits an excess, or becomes exposed to cold and wet, and thus gets such a congested condition superadded, that the urine will not pass at all, or only in such small quantity by drops, and with so much pain and straining, that the bladder cannot be completely emptied. In these cases the retention always eventually becomes complete; the bladder speedily fills, and rises above the pubes; there is much distress and constitutional disturbance; and, if relief be not afforded, the distended portion of the urethra behind the stricture will ultimately give way, and extravasation of urine ensue. In these circumstances, it becomes imperatively necessary to empty the patient's bladder as speedily as possible.

Treatment.—This varies with the severity of the symptoms and irritability of the patient. If the retention have not continued very long, and if the patient be not very irritable, an endeavour might be made at once to give relief by passing a small catheter into the bladder. In this the surgeon may often succeed more readily than might have been expected, the stricture frequently yielding before an instrument, more easily when there is retention than when this condition does not exist. Even if the catheter do not enter the bladder, its point or that of a catgut bougie merely being introduced well into the stricture, it will generally happen, as Brodie has pointed out, that, on the withdrawal of the instrument, the urine will follow in a full stream; but if a sufficiently small catheter be used (in many cases not larger than half of No. 1 is admissible), the instrument may usually be made to fairly enter the bladder. If the patient be very irritable it is better, before attempting the introduction of the instrument, to give him an opiate enema of a drachm of laudanum in about two ounces of starch, and to put him in a warm hip-bath; the introduction of the catheter may now be

attempted, and will very generally of the inhalation of chloroform should may be made to pass without the degree of force. There are no cases of value than in these; under its influence will not pass. After the instrument be left there, being tied in by means the patient's thighs, to a bandage of elastic remedies must then be employed, purge, leeches to the perineum if salines with antimony. The catheter end of forty-eight hours, when it should be discontinued proceeded with in the usual way.

If, however, the surgeon be unable to pass the catheter in the ordinary way through the stricture, the bladder in some other way, lest it rupture, urine may occur. The bladder may be opened 1, by making an opening in the Scrotum; 2, by making an Opening in the Perineum; 3, by Puncturing the Viscus, and puncturing it above the Pubes.

1. *Forcible Catheterism* is a method of passing the catheter. Nothing can surely be more important than to pass the catheter, pass it down to the stricture, and drive it on into the bladder. In the attempt at reaching the viscus, but the tissues around the neck of the bladder are great, and perhaps even fatal, unless some fortunate accident, reach the viscus, and forcible expansion of the stricture, and burrowing through the corpus, as it has been termed—until he again reach the neck of the bladder.

2. *Opening the Urethra behind* the stricture. In cases of retention of urine that we are now discussing, the mode of affording relief after the incision into the middle line of the scrotum, behind or through the stricture. It is in cases of retention, than when the urethra being distended by the swelling of the patient, it sometimes attains this be not the case, the operation is not the same. The operation, which is essentially the same as the operation for stricture, described at p. 1180, is to the stricture; opening the distended urethra, cutting upwards through the stricture, then passing the instrument on until urine flow from the aperture thus made. It must be taken to keep strictly in the middle line, to wound vessels of importance. On the stricture may by it be cured at the same time, and as the incisions do not extend to the urethra, there is less danger to the patient.

Another advantage of the perineal operation is, that unfrequently happens that urinary

vasation of a few drops of urine has taken place sooner than the surgeon may have had any idea of: and if so, the incision through the perineum will afford an exit for any extravasated matters, at the same time that it relieves the patient from the distress and danger of the retention. Should any mischief of this kind have taken place, it is not necessary to be so particular about opening the urethra with the knife; for, an aperture having already been established in it, the urine will readily flow through the artificial channel thus formed by free incision into the inflamed or suppurating perineum.

3. *Puncture of the Bladder through the Rectum.*—After emptying the bowel by means of an enema, the surgeon passes the left index-finger well into the gut, feeling for the posterior margin of the prostate; he then carries the trochar and cannula, which are long and somewhat curved, upon this as a guide, and, when the extremity of the instrument has reached the posterior edge of the prostate, he pushes it upwards into the bladder (Fig. 475, b). The seat of the puncture between but in front of the ureters is well shown in Fig. 485, which represents the bladder and strictured urethra of a man who died some days after this operation had been performed for retention from stricture. In performing this operation, the surgeon perforates the bladder in that portion of its fundus which is uncovered by peritoneum, being bounded behind by the reflection of the serous membrane, anteriorly by the prostate, and on each side by the vesiculae seminales. In order to avoid wounding any of these structures, he should keep strictly in the mesial line, and puncture immediately behind the prostate. In introducing the instrument into the rectum, the surgeon should withdraw the point of the stylet into the cannula, so as to avoid wounding the gut, and not push it forwards until he has the end of the cannula fixed against the spot where he intends to make the perforation. After withdrawing the stylet and emptying the bladder, the cannula should be tied in by means of tapes, and left for a few days until urine begins to pass by the natural channel, or until means can be taken to restore the passage through the stricture, when it must be withdrawn and the aperture left to close. In consequence of the irritation of the urine being removed from the urethra, a catheter may often be passed a few days after the operation; and the stricture will readily yield to dilatation in the ordinary way.

This operation has the advantage of being far easier of performance than the last, and may doubtless occasionally be required in those very rare cases of retention from stricture in which there is no sign of abscess or extravasation in the perineum, in which the urethra appears not to be dilated behind the stricture, in which the prostate is not enlarged, and in which, under chloroform, and with patience, a catheter cannot be passed into the bladder; a combination of circumstances that will but very rarely indeed occur to a surgeon skilled in the use of his instruments.

The operation of puncture through the rectum is not devoid of danger; urinary infiltration, and pelvic inflammation and abscess, may result from it. In a remarkable case that was under my care at the Hospital (in 1859), a sequence occurred which I have never seen noticed; viz., the diffusion of rectal flatus through the cellular tissue of the pelvis and down the thighs

Fig. 485. Seat of Puncture through Rectum in a case of Stricture.

and nates, producing an emphysema, and death of the patient. The case was had suffered from traumatic stricture in childhood. He was admitted with a catheter, or could be passed, I punctured the bladder, and the cannula was removed on the fifth day, and continued to do so up to the withdrawal of the cannula he felt no tangible complaint. The next day the part of both thighs were emphysematous with air. The emphysema extended to the arm, appeared even in the right arm. He died on the following day, the only trace of pelvic inflammation, suppuration, or abscess, was not found; but there was much infiltration and in the cellular tissue between the thighs, probably passed through the sciatic foramina. It was fetid, like intestinal gas.

4. *Puncture of the Bladder above the stricture*, is but seldom resorted to, more especially Paget of Leicester practised it. This operation, which is doubtfully easy of performance, and the danger of infiltration of urine into the tissues of the perineum, and of the inconvenience of a fistulous opening, cases to which it appears to be applicable, had occasion to practise it; viz., in a case of stricture, in which there co-exists a large prostatic abscess, and the perineal section dangerous, and the surgeon's finger not being able to pass, and here undoubtedly the safest, the suprapubic puncture.

After the bladder has been punctured, the surgeon may think proper to adopt, the removal of the urethra, so as to prevent the urine from passing into a permanent fistulous opening, and the urine to be voided by the urethra, the stricture in the bladder, where it should be retained, and the small instrument may usually within four to six days. At the expiration of the stricture by dilatation may be removed.

EXTRAVASATION OF URINE.—In the organisation of the coats of the urethra, the stricture, and the urine become infiltrated into the part of the urethra that gives way, the canal, just anterior to or between the two, where it is weak, being least usually most dilated and attenuated, and subjected. This circumstance is a great disadvantage, that stricture of the urethra never occurs in a deeper situation than we do. Was it altogether behind the deep perineal

into the cavity of the pelvis. But, as it is, the connection of the triangular ligament with the ramus of the pubes and the ischium prevents the extension of the infiltrated urine in that direction; and the manner in which the superficial fascia of the perineum is connected with the deep fascia uniformly causes the fluid to take a course forward into the perineum, scrotum, and upwards upon the external organs of generation, the groins, and the anterior abdominal wall; so that it ascends contrary to its gravity rather than soaks back into the more dependent parts of the body, as it would do, were it not for the particular connection of the fasciæ that has just been alluded to. I have, however, known the superficial fascia to give way, and the urine, then gravitating backward, to give rise to extensive sloughing in the ischio-rectal fossæ and about the nates, denuding the rectum.

Local Effects of Extravasated Urine.—The effects of urine that has become acrid and concentrated by long retention, are most deleterious upon those tissues with which it comes into contact. The vitality of whatever portion of cellular tissue it infiltrates is immediately destroyed; the tissue becoming converted into a kind of putrid stringy slough, intermixed with and soddened by a quantity of fetid dark-coloured acrid pus and urine. The ravages of extravasated urine are often extensive; the urethra giving way suddenly behind the stricture, the fluid is driven with all the force of the vital and physical contractility of the over-distended bladder into the perineum, and thence rapidly finds its way through the scrotum upwards. In other cases, again, the extravasation occurs more slowly; a few drops appear first of all to escape from the urethra through a small rent or ulcer in it; these give rise to inflammation in the surrounding structures, by which the progress of the extravasation is for a time limited. It is especially upon the cellular tissue of the scrotum that the effects of the extravasation manifest themselves in their full intensity, causing great distension and rapid sloughing of it. The skin speedily participates in this action, becoming of a dusky-red or purple colour, and then falling into a state of gangrene. In this way the testes may become denuded, and the cords exposed. It is remarkable, however, if the patient survive these destructive effects, with what rapidity reparative action goes on in this region. It is seldom that infiltration extends higher than the groins, or the anterior portion of the abdominal wall; but it may reach the costal cartilages before proving fatal.

When the extravasation is deep, the urethra being opened between the layers of the triangular ligament, the patient, after suffering from retention, experiences a sensation of relief, and as if something had given way in the perineum, followed after a time by throbbing and pain. There may be but little swelling for a day or two, but then a doughy red diffused intumescence takes place in the scrotum and rapidly extends forwards. When the rupture is altogether anterior to the deep perineal fascia, then rapid swelling and infiltration, partly urinous, partly inflammatory, take place in the scrotum and penis: these parts become enormously distended, cedematous, crackling, and emphysematous, with the local signs that have already been mentioned.

The *Constitutional Disturbance* is always considerable; at first it is of an irritative type, but speedily followed by asthenic and typhoid symptoms, by which the patient is at last carried off.

The *Treatment* consists in making a free and ready outlet for the urine as early as possible. This should be done, as soon as the extravasation is known to have occurred, by a deep incision into the middle of the perineum. So soon as any pain and throbbing, with diffused swelling, occur in the perineum, with redness and more or less cedema of the scrotum, the patient should be

drawn to the end of the bed and placed in the position for lithotomy, the surgeon should next introduce his left index-finger into the rectum, the gut may not be wounded, and then, pushing a long sharp-pointed deeply in the raphé of the perineum, cut upward to a sufficient extent the extravasation, and in the direction of the urethra. A catheter then, if possible, be introduced, secured in the bladder, and left unobscured in this way no further effusion can occur, an outlet will be afforded to the matters already effused, and the greater part of the urine will consequently be found to escape after a time by the aperture thus made. Should the extravasation not be seen until extravasation has spread widely, a free incision should not be made into the perineum, extending to the aperture in the rectum, but also into the scrotum on each side of the septum, into the perineum wherever else swelling is observed. The sole chance of safety for the patient lies in making these free incisions, through which the parts may, to a certain extent, empty themselves. However extensive the infiltration of the parts, the mischief may be, we need not despair of the patient if a free outlet can be obtained for the acrid and putrescent urine and effused matter. In order to secure this, the infiltration must be followed by an incision as high as it extends. The parts must, at the same time, be covered with chlorinated and yeast poultices; and the constitutional powers of the patient must be supported by good nourishment and a sufficient quantity of stimulants.

If the patient survive the immediate impression upon the system by the gangrene and the urinary infiltration, he must be prepared to undergo a severe trial to his constitutional powers, in the separation of the sloughs, the profuse discharge, and other sources of irritation that will follow. During this period he will require abundant support, the best being a mixture of egg, ammonia and bark, with any nourishment that he can take, and much attention should be paid to the removal of the sloughs, and to keeping the patient as clear as possible from all local irritation as possible.

URINARY ABSCESS may be considered in many cases as a limited collection of urine mixed with pus, and circumscribed by plastic matter that is deposited in the tissues with which the urine comes in contact. It is generally occasioned by the irritation of the passage of instruments, but may arise from the effect of stricture, or from inflammation of some of the urethral glands. From some cause of this kind a small abrasion or aperture is made in the urethra, a drop or two of urine escapes into the subcutaneous tissue, and this becomes bounded or circumscribed by plastic deposit, so that extravasation does not occur. Such an abscess as this may be situated in any part of the urethra; but it is most frequently met with in the perineal part, appearing to take its origin from the bulb or membranous part. It is not dangerous, but is chiefly of consequence by being commonly followed by urinary fistula.

Symptoms.—An urinary abscess is indicated by the formation of a somewhat circumscribed, hard, and painful tumour, situated in the neighbourhood of the urethra. It is usually unattended by constitutional disturbance; unless it attain any considerable bulk, when some pyrexia ensues. It is principally in the perineum that it attains any degree of magnitude, then constituting a perineal abscess, characterised by a deep, hard, tense tumour, brawny and without fluctuation, attended by considerable weight and throbbing in this region. It does not readily pass to the manner in which it is bound down by the superficial fascia.

Treatment.—Early incision is required. When the abscess occurs

scrotum or anterior to it, the surgeon should wait for fluctuation ; but when it is seated in the perineum, he need not do so, making a free incision through the mesial line into the hard, brawny mass, which must then be well poulticed.

URINARY FISTULE commonly form in the perineum and scrotum as the result of abscess in these regions communicating with the urethra ; occasionally, however, they are met with in other situations, as in the groin, the anterior abdominal wall, or the inside of the thigh. They usually communicate with the bulb or with the membranous portion of the urethra, but occasionally occur anterior to this. In number they vary considerably ; when occurring in the scrotal and penile portions of the urethra, they are usually single ; but when in the perineal, they are often pretty numerous ; several apertures being occasionally met with about the perineum, scrotum, and nates. In one case Civiale found as many as fifty-two. Their size also differs considerably ; some only admitting the finest probe, whilst others are large cloaces. In a case under my care, the patient had a tunnel of this kind in the groin that would readily admit three fingers. They are usually tortuous, elongated, and narrow ; sometimes constricted externally and more widely dilated behind. The surrounding parts are greatly condensed ; the whole of the scrotum and penis is enormously enlarged, indurated, and almost cartilaginous in structure. The urine may escape almost entirely through the fistule, scarcely any being discharged through the urethral orifice ; or there may be but a slight exudation from the fistulous openings.

The *Treatment* of urinary fistula varies according as it is complicated with stricture, and as it is situated in the anterior or posterior parts of the canal.

If there be a stricture, this, as the cause of the fistula, will require removal either by dilatation or by the perineal section. If the stricture be not very tight and hard, dilatation commonly succeeds ; the instrument being introduced every second or third day, until the urethra is dilated to its normal size, when the fistulous tracks will in many cases close. In some instances, however, the frequent introduction and withdrawal of the catheter is a source of irritation, and then it had better be left in. When this practice is adopted, a moderate-sized elastic catheter should be used. If this be too small, the urine will flow between it and the sides of the urethra, and thus escape through the fistula ; if too large, it stretches the urethral orifice of the fistula injuriously.

If the stricture be very tough and irritable, the better plan is to perform urethrotomy at once, as much time and pain are thus saved. In the majority of instances, internal urethrotomy with Civiale's instrument appears to me to be the safest and simplest procedure, which I have very advantageously practised in such cases. But if the fistula be very numerous, so as to riddle the perineum and scrotum in all directions, perhaps the better plan is to perform the perineal section. In this way we not only divide the stricture, and thus at once remove all obstruction, but give a free exit to the urine, which, instead of escaping by tortuous and sinuous passages, finds its way out readily through the new aperture that has been made, which will eventually granulate and heal by the second intention.

The fistula, especially if small and recent, will sometimes heal kindly enough after the removal of the obliteration ; but if extensive, old, and cartilaginous, they are of course little disposed to take on reparative action ; and although the cause that in the first instances gave rise to them may be removed, yet they constitute an independent affection which requires special treatment for its cure.

The special treatment for urinary fistula must vary according to the size

of the canal, but more particularly with regard to the part with which it communicates; whether it be a *Perineal*, a *Scrotal*, or a *Penile* fistula.

If the fistula be *Perineal*, and of small size, a probe coated with nitrate of silver, or a wire made red-hot in the ordinary galvanic current, and passed down it occasionally, may cure it. If it be large, a gum-catheter should be kept in the bladder, and the edges of the fistula freely rubbed with the nitrate of silver, or brought together by quilled sutures. If the fistula be numerous, it will be better to pass a grooved director down the canal, and slit them up so as to throw the several sinusses into one.

When the fistula is *Scrotal*, it often requires to be laid open, made to granulate from the bottom, when it may be found with large sloughy and ill-conditioned cavities in this situation.

When *Penile*, the fistula is usually much more troublesome, the edges are thin, and the track is short and shallow.

Urethroplasty may in such cases be advantageously practised. Operations of this kind require for their success very careful management, attention to detail; they very commonly fail in consequence of a quantity of urine or of mucus escaping through the wound, interfering with union of its lips.

In order to prevent this accident, which is fatal to the operation, the patient should be taught to pass a catheter, and to draw off his own urine after the operation as often as necessary. Should this, however, be impracticable, a full-sized gum-catheter should be passed into the bladder, and properly secured there. It should be left without a plug, so as to prevent the escape of urine from the bladder and consequent likelihood of escape of urine from the urethra and the instrument may take the place of a catheter.

To prevent unnoxious diffusion over the penis and scrotum, a vulcanised India rubber sheath may be attached to the end of the catheter, by which means the flow of the urine is directed away from the patient.

Urethroplastic operations may be varied according to the seat and extent of the fistulous opening.

If the fistula be in the perineum or scrotum, the parts around being thickened and indurated, its closure may often be attained by freely and deeply paring the edges, and then bringing them together with the quilled suture, or by Bozeman's button (Fig. 490).

Fig. 486. — Urethroplasty — Scrotal Operation.

When the fistula is *penile*, there is not sufficient thickness of parts for ready union. Nelaton has recommended the following operation, which is fully practised. The edges of the fistula having been pared, to the extent of about one inch must be dissected up

(Fig. 486) through an opening made below the fistula, the edges of which must then be brought together by a few points of suture. The displacement of the skin causes granulations to spring up, by which the fistula is closed. This procedure may sometimes be advantageously modified by paring the edges of the fistula, making lateral incisions, and then passing across but underneath the flap a slip of India-rubber, to prevent contact of the urine from disturbing the adhesions (Fig. 487).

URINARY VAGINAL FISTULÆ.

Preternatural communications between the urinary passages and the vagina commonly arise from injurious pressure upon and consequent sloughing of the anterior wall of this canal, to a greater or less extent, during parturition. They may, however, occur from idiopathic abscess, or from malignant disease involving those parts.

VARIETIES.—Urinary vaginal fistulæ are essentially of two kinds, according as the communication is established between the urethra or the fundus of the bladder and the vagina. Hence they may be divided into *Urethral* and *Vesical*.

Urethro-Vaginal Fistulæ are, so far as my observation goes, of most common occurrence; and this is readily explained by the fact that the urethra passes along the anterior aspect of the vagina for some distance before it terminates in the bladder, and occupies that portion of the vaginal wall which is most likely to be compressed, during labour, under the arch of the pubes. These fistulæ are usually of small size and linear. *Vesico-Vaginal Fistulæ* establish a communication between the neck or fundus of the bladder and the vagina. They are consequently situated further back than the other, and are usually larger and more ragged.

RESULTS.—The existence of an urinary fistula in the vagina is always a source of serious discomfort and distress to the patient. The dribbling of urine through the preternatural aperture is generally continuous; although, if this be situated far back behind the orifices of the ureters, it may be somewhat intermittent, a flow taking place as the lower portion of the bladder fills. The incontinence of urine thus produced gives rise to irritation and excoriation about the external parts, and occasions a strong ammoniacal odour to hang about the patient.

The precise seat and extent of the fistulous opening are best ascertained by placing the patient on her knees opposite a good light, and holding aside the posterior and lateral walls of the vagina with bent spatulæ; when the anterior aspect of that canal will have a tendency to protrude, and thus to expose the fistula, at the same time that the introduction of a bent probe, or of a female catheter, into the urethra, will guide the surgeon to the artificial opening in the urinary passage.

TREATMENT.—The cure of a vaginal fistula can only be accomplished by causing a confluence of its sides. When it is small, about a line or two in diameter, and more especially if urethral, this may best be effected by touching the edges of the aperture with the electric cautery or a red-hot wire, and repeating this application once a fortnight or three weeks, until a cure is effected by their gradual contraction. This little operation is most conveniently effected by placing the patient in a kneeling posture, and then holding aside the posterior and lateral vaginal walls by means of curved copper spatulæ, when the opening will be fairly brought into view.

When the fistula is larger, and especially when vesical, its cure can only be accomplished by paring the edges, and then bringing them together with sutures, and thus attempting to produce a permanent union. This is the first intention. In

effecting this, however, two difficulties present themselves—the either cutting their way out too soon, or the trickling of urine to freshly pared edges interfering with adhesion. In order to overcome these difficulties, a variety of ingenious contrivances have been introduced by different surgeons; amongst which may be especially mentioned those of Dr. Marion Sims and Baker Brown, and the button-suture of Mr. To Sims especially is due the great merit of having substituted catgut for silk sutures in this operation, by which the probabilities of a successful result have been very greatly increased.

Before the operation, the bowels should have been freely opened by oil and an enema. No chloroform should be given, as its administration interferes with the position that the patient must maintain during the operation. This should be on the knees and elbows, on a narrow table, the buttocks well raised and the head low. It is of great moment that the parts should be freely exposed. This is best done by means of the "billed" speculum, by which the posterior wall of the vagina is turned up and out of the way of the operator, and light is reflected on the opening. The edges of the aperture are now to be freely pared, best done by seizing them with a hook forceps or a double-pointed dissecting off the vaginal mucous membrane to the extent of a quarter of an inch all round, by means of a fine small scalpel or pair of knives and scissors properly curved. The dissection should be towards the fissure, and especial care taken that the angles are freed of mucous membrane.

After the edges of the fistula have been freely pared, and all cicatricial constrictions divided, sutures of silver or annealed iron (which does not rust) are passed across the lips of the wound. These are most conveniently passed by means of the hollow needle, or, if not at hand, a silk thread may be passed by means of a narrow needle, a full half inch from the freshened edge of the fistula, and drawn out through a corresponding point on the other side of the vagina, having transixed the mucous membrane of the bladder. As many as necessary having been passed in this way, a piece of silver wire eighteen inches long is attached to the silk, which is then drawn out of the wire to occupy its place, so that its centre corresponds to the middle of the fistula, both ends hang out of the vagina. Dr. Sims then passes the upper ends through holes made in a narrow leaden bar, on which they are held by having split shot fixed upon them in the same way as is done in the inguinal case. The unclamped wires are now drawn down until the shot is close to the upper suture holes; and a second clamp is then fixed on the lower ends and is pushed up against the lower suture apertures. In this position the edges of the fistula are brought and held together on each side by the shot, which may be allowed to remain in from seven to ten days. It may then be removed by clipping off the flattened shots from the one, which is thus detached from its bed. The posterior one, with the shot attached, may then be hooked up, pushed backwards, and lifted out of the vagina with forceps. Instead of a clamp Dr. Simpson uses a spiral annealed iron wire, which surrounds and supports the tissues of the fistula. In many cases, however, where the fistula is of but small size, the clamp and splint may be dispensed with, and the edges of the fistula brought together with the suture wires only.

In the after-treatment, especial attention is required, and the first point is to prevent the contact of the urine with the edges of the wound. With this view a catheter should be introduced, and worn in the

that no urine may collect in this organ. For this purpose, Sims has invented a very ingenious catheter, represented in the annexed cut (Fig. 488), which may be worn with more comfort, and with less chance of slipping, than the ordinary instrument. After the patient has been put to bed, and the catheter introduced, a full opiate should be given, and continued throughout the treatment, with a view of preventing the action of the bowels, a point on which Sims lays much stress, and to which the success of his operations may be in a great measure attributed. It is very seldom that they are required to be opened for ten or fifteen days, provided the patient be kept on a rigid diet. During this treatment the catheter may be removed once or twice a day, in order to be cleansed and to be kept free from phosphatic or mucous accumulations; and free ablutions of the external genitals by sponge or syringe and warm water should be practised during the whole of the treatment. After the removal of the sutures, Sims advises that the catheter should be continued, and great care taken that the patient do not move too soon, lest the weak cicatrix be strained.

Fig. 488.—Sims's Catheter

More recently, a very simple and successful mode of closing these fistulæ has been invented by Dr. Bozeman, (the application of which that gentleman gave us an opportunity of witnessing during a visit to this country,) by what he terms the "button-suture." After paring the edges of the fistula, and passing silver wires across in the usual way, he draws the parts together by passing both ends of the wire through an aperture in a steel rod, which being carried along them closes the opening. A thin leaden plate, "the button," properly perforated down the middle, is then slipped along the wires so as to cover the fistula (Fig. 489); and split shot having been pushed along, their free extremities are pressed tightly against the button, the wires are then properly nipped, and the apparatus left on

Fig. 489.

Fig. 490.

Bozeman's Apparatus for Button Suture.

for about ten days (Fig. 490); the shot are then cut off, the leaden plate carefully lifted off, and the suture wires, having been straightened out, are withdrawn.

Whatever kind of suture is employed, it is always of great importance that the edges of the fistula be brought together *transversely* to the long axis of the vagina. Should the abnormal aperture be close to, or even implicate, the cervix uteri, this part may be drawn down and transfixed with the sutures, thus adding materially to the support of the posterior lip of the fissure.

TUMOURS OF THE URETHRA.

Small *Polypoid Tumours* are not unfrequently met with inside the urethral orifice. They have occasionally a gonorrheal origin, though they commonly arise irrespectively of such disease. They are always very vascular,

and are most frequently met with in or around the female urethra; they are of a bright red colour, have a florid hue, bleed freely, and are composed of a spongy kind of erectile tissue; they are conoidal or oval, encircling the urethral orifice on one side, or a complete zone around it. They grow slowly, and seldom increase in size than that of a raspberry. They are not unfrequently the result of a vast deal of sympathetic irritation, great pain in micturition, an admixture of mucus or pus in the urine, uneasiness of the back, the abdomen, and often aching in the loins.

These vascular tumours are far less frequent in the male urethra. When they occur in men, they usually consist of a granular florid mass inside the orifice of the canal.

When seated in or around the female urethra, these tumours frequently give rise to very great and continuous irritation; and after passing urine, radiating through the whole pelvic region, many of the symptoms of stone; so that patients labouring with this affection are often sounded on the supposition of the existence of a stone.

TREATMENT.—Vascular urethral tumours may be removed—by Excision, Ligature, Caustics, or the Actual Cautery.

1. *Excision.* When situated within the male urethra, the tumour may be snipped off by a fine pair of curved scissors. When situated in or around the female urethra, if of small size and pedunculated, it may be removed by the scissors or dissected away; the urethra being encroached on as little as possible. This operation is, however, always attended or followed by very considerable hæmorrhage, which has even, in some instances, proved fatal. Hence, when the tumour is large and the patient is young, the operation should be practised with much caution. If it be done, the hæmorrhage may be arrested by the introduction of a catheter into the urethra, and the firm pressure on the bleeding surface by means of a pad of lint held in place by a T-bandage.

2. *Ligature* is not a convenient mode of removing these tumours; its application is difficult, very painful, and tedious.

3. *Caustics*, particularly strong nitric acid or potassa cum aqua, may be very conveniently employed where the tumour is of small size and is vascular. In applying them, the upper wall of the canal may be protected by a broad director introduced along it.

4. The *Actual Cautery* is the most convenient agent for removing vascular tumours from the female urethra. By it they are removed without hæmorrhage; and the eschar that is formed protects the raw surface from the irritation of the urine. If they be situated within the urethra, and of small size, the galvanic cautery, applied by a wire, will most easily reach them; but if they be at or around the orifice, always employ a small olive-shaped cautery. During its use the surrounding parts must be protected from the action of heat by the introduction of the urethra by a director or silver catheter, which should be held in place by a T-bandage during the operation.

CHAPTER LXX.

DISEASES OF THE PENIS AND SCROTUM.

DISEASES OF THE PENIS.

HYPOSPADIAS.—It occasionally happens that there is an arrest of union in the mesial line of the penis, so that a slit or fissure is left communicating with the urethra. This gap commonly occurs on the under surface of the organ, constituting *hypospadias*, and is confined to the glans and upper part of the penis; though it occasionally extends backwards to the root of the organ, and may then be associated with some of those kinds of malformation that are erroneously considered as examples of hermaphroditism. These conditions are mostly incurable, though plastic proceedings have occasionally been devised for their relief.

EPISPADIAS.—The upper surface of the penis is less frequently fissured; only, I believe, in cases of extroversion of the bladder. This condition, termed *epispadias*, may be looked upon as incurable.

PHIMOSIS.—The prepuce is not unfrequently the seat of malformation or disease. That condition of it in which it is so much elongated that it extends beyond the glans, and at the same time is so much contracted that it prevents the proper exposure of this portion of the organ, is termed *phimosis*. This may be either congenital, or acquired as the result of inflammation or disease.

In *Congenital Phimosis*, the penis is usually somewhat atrophied, and the development of the glans is prevented by the pressure of the narrow prepuce. In congenital phimosis the skin is usually abundant and lax; but the mucous lining of the prepuce is short, contracted, and undeveloped. It is in this situation, and not in the skin, that the congenital defect is situated. In the majority of cases this condition is simply a source of inconvenience; but it may become a cause of disease from the retention of the sebaceous secretion of the part setting up irritation and repeated attacks of inflammation (Fig. 491). In some cases the preputial orifice is so tight as to interfere materially with the discharge of the urine; and irritability of the bladder, often presenting symptoms simulating calculus, may thus be set up. At a more advanced period of life I have known it a cause of impotence, or rather interfering with conception in the wife, by the semen after emission being retained under the tight and narrow prepuce until erection had completely subsided. Congenital phimosis especially becomes a source of inconvenience in after-life if any gonorrhoeal or venereal disease be contracted, as it renders the exposure of the diseased part difficult or impossible, and interferes with the necessary treatment.

Acquired Phimosis usually results from repeated attacks of inflammation, or of specific disease in the part, giving rise to solid ordema, or to false hypertrophy of the prepuce.

Treatment.—Phimosis, when not congenital, must be treated in accordance with its cause: thus, if it have resulted from inflammation, that must be subdued; if from venereal disease, that must be remedied, when perhaps the contraction and elongation will gradually subside. If, however, the phimosis

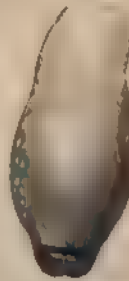

Fig. 491.—Congenital Phimosis.

be congenital, or if, though acquired, to operation; and, indeed, I think children should be operated upon, cleanliness of the parts in after-life.

Operations for phimosis may be performed, and contracted prepuce may be removed.

Slitting up of the Prepuce. This, I think, an objectionable operation, on account of the abnormal length, and more or less of the prepuce. I prefer circumcision as the simplest and the most satisfactory result.

Circumcision for Congenital Phimosis. This is most easily and safely performed when the child has several times had an opportunity of retracting the foreskin slightly forwards, and then, with an instrument of the kind

Fig 492.—Instrument for holding the Prepuce in Circumcision.

perpendicularly, and slightly forwards, the frænum of the prepuce is cut by one stroke of the mucous membrane with the thumb along the back so as to be the skin. A small organ in the middle of the mucous membrane is removed by its pressure. Union is perfected in the eighth day after

Fig 493.—Circumcision in the

front of that structure. He then makes an incision in front of the glans with a pair of scissors, and gives to an assistant, who must

the bistoury he cuts off all that portion of the integument which projects beyond the forceps, which are then taken away (Fig. 493). It will now be found that he has only removed a circle of skin, but that the mucous membrane lining it still tightly embraces the glans; this he slits up, by introducing the point of a pair of scissors at the preputial orifice; and then, trimming off the angles of the flaps of mucous membrane and snipping across the frenum, he turns back the mucous membrane, and attaches it to the edge of the cutaneous incision by five points of metallic suture, two on each side and one at the frenum. Before introducing these, he will generally find it necessary to ligature a small artery on each side of the penis, and one or two in the frenum. Union readily takes place by simple dressing; and a very narrow line of cicatrix is left, by which the patient is by no means inconvenienced. In some cases I have found adhesions between the prepuce and the glans; these require to be dissected through, but no inconvenience results from this slight addition to the operation.

If sloughing of the prepuce have occurred, allowing the glans to protrude, as in Fig. 494, circumcision must be practised.

PARAPHIMOSIS—In *paraphimosis* the prepuce has been forcibly drawn back behind the glans, which becomes strangled by the pressure exercised by the preputial orifice, so that the parts cannot be replaced in proper relation to one another. This accident principally occurs in boys, or in individuals who have naturally a tight prepuce, and who, on uncovering the glans, find it difficult to get this part of the organ back. This difficulty is speedily and greatly increased by the swelling from congestion that is set up in the constricted glans.

Treatment.—This is sufficiently simple. The surgeon should first try to reduce the swollen organ. He may often succeed in doing this by seizing the body of the penis between the index and middle fingers of each hand, and then endeavouring to draw the prepuce forwards, at the same time that he compresses the glans between the two thumbs and pushes it back (Fig. 495). Should reduction not be effected in this way, the constricted and strangulating preputial orifice must be divided. In doing this, the surgeon will observe that the glans is separated from the body of the penis by a deep and narrow sulcus, which is especially evident on the upper part of the organ. This sulcus, which is overlapped on one side by the glans and on the other by a fold of integument, corresponds to the inner margin of the preputial orifice; and it is by the division of this, in which the stricture is situated, that immediate relief will be given. This operation may readily be done by drawing the glans forwards, then passing the point of a narrow-bladed scalpel into the sulcus on the dorsum of the penis, and making a perpendicular incision about one-third of an inch in length through the integuments at the bottom

Fig. 494.—Sloughing of the Prepuce, and Protrusion of the Glans.

Fig. 495.—Reduction of Paraphimosis

of the groove directly across it (Fig. 496). In consequence of stretching of the parts, the incision will immediately gape with

instead of being longitudinal, it will be transverse; and then reduction of the parts will readily be effected.

Fig. 496.—Incision in Operation for Paraphimosis.

and smarting, together with muco-purulent discharge.

Treatment.—The disease requires to be treated on ordinary principles. The continued application of lead lotion, with administration of salines, will generally remove it; but in the most effectual plan will be found to consist in rapidly inflamed surfaces with a stick of nitrate of silver passed down on one side of the frenum, and carried round to the opposite side.

HERPES OF THE GLANS AND PREPUCE is characterised by the small vesicles or excoriated points upon the mucous membrane attended by much smarting and itching, and chiefly occurring in a gouty habit of body, with an irritable mucous membrane.

Treatment.—This slight affliction is often very rebellious. In many instances local means alone will not suffice; for relief may be obtained by powdering the part with the oxide of zinc, or slightly astringent and cooling lotions, yet no permanent cure is derived unless constitutional irritation be removed by the cooling or alterative character, modified according to the character of the case.

HYPERTROPHY OF THE PREPUCE not unfrequently occurs

of chronic irritation or disease; in a limited extent, and requires no special treatment on the part of the surgeon; but in some instances it may become so extensive as to require operative interference. Thus Virchow and figured a case that had attained enormous size, that the organ reached the knee, and was as large as a thigh; the enormous growth was successfully excised.

WARTS on the penis have also been described. They may attain a very large size (Fig. 497), and are best treated by removal with curved scissors.

Fig. 497.—Warts on the Penis.

CANCER OF THE PENIS is of two kinds, occurring as Scirrhus or as Epithelioma. The cancer assumes the Scirrhus form, and springs from the sulcus behind the glans, and may thence invade the neighbouring portion of the organ. It may assume the primary form of tubercle or of infiltrated cancer of the glans. It has been supposed, without much show of reason, that congenital phimosis predisposes to cancer, probably by confining the secretions, and thus keeping up an

part. Hey found that, of 12 patients with this disease who came under his observation, 9 had congenital phimosis; and Travers states that Jews, who are circumcised, are seldom subject to this affection. But as they are a limited community in this country, and as the disease is rare, we cannot draw any conclusive inference from this observation. It is, I think, very probable that the epithelial form of the disease may arise from the local irritation resulting from congenital phimosis. The scirrhus form of the affection, however, can occur in individuals who have not suffered from phimosis; of this we have had several instances at the University College Hospital.

Epithelioma, commencing as a tubercle in the prepuce, may, after a time, give rise to a large irregular and sprouting mass, having a granular fungous appearance, bleeding with much fetid discharge, growing rapidly, enveloping and at last implicating the glans (Fig. 498). In other cases it commences as a hard scirrhus mass of a pale reddish-white colour, situated on the glans, or between the prepuce and the glans. This increases in size, at last cracks, and allows a serous fetid discharge to exude. Ulceration then rapidly takes place. Sometimes the disease appears to be very distinctly localised; but after its removal it will always present the character of infiltrated cancer. It is, I believe, always primarily situated at the anterior extremity of the penis, not occurring in the body of the organ except as a secondary deposit.

Fig. 498. Epithelioma of the Penis.

Diagnosis.—*Epithelioma* of the penis requires to be diagnosed from *fungoid warts*. This may usually be done readily enough, by comparing the indurated state of the malignant with the soft and lax condition of the non-malignant affection. From *chancreous induration* of the glans, the history of the case and the way in which it is influenced by treatment will enable the surgeon to effect the diagnosis of scirrhus. In indurated plastic effusions into the corpus spongiosum, no pain is experienced, and the disease remains in a stationary condition.

Treatment.—The treatment of cancer of the penis will vary according to the nature and extent of the malignant affection.

In the *Epithelial* form of the disease the surgeon may, if he see the case early, whilst the morbid growth is small and limited to the prepuce, content himself with dissecting off the affected patch. Should the epithelioma, however, have attained a large size (Fig. 498), and more particularly if it have implicated the glans, then amputation of the organ is indicated.

The treatment of *Scirrhus* of the penis must be conducted on the principles that guide us in the management of malignant affections wherever situated: viz., to remove the diseased organ at as early a stage as possible whilst the affection is localised, before the glands are implicated and the constitution poisoned. In the penis, this may readily be done by an operation that is simple in its execution and devoid of danger. In many cases, more especially of scirrhus, a return may take place, and that speedily, either in the part itself or in the neighbouring lymphatic glands; yet, even if this occur, it is clearly the duty of the surgeon to rid the patient of a loathsome disease, and to put him in a state of comparative comfort for some months; the more so, as there can be no doubt that, in some instances, the disease may be entirely extirpated from the system,

evinced no tendency to return. Indeed, I believe that amputation for cancer is more successful in its results than the removal of malignant growths from most other situations. In the epithelial disease it is especially an useful operation. In some of Hey's cases continued under his observation, there was no recurrence of the disease several years. I have seen several patients who, after a lapse of years, continued free from a recurrence of the disease; and I have known a gentleman who had his penis amputated for cancer more than twenty years ago, and in whom no return has taken place. The fact is, that in the great majority of those cases in which a recurrence takes place, but those who remain free from a return of the affection do not divulge their cure. It is exceedingly rare in hospital practice to find a patient with recurrent cancer in the stump of the penis, which he would not have if relapse took place. In those cases in which the operation is not performed, it has usually been delayed too long, the disease having already invaded the lymphatic glands in the groin, and thus contaminated the constitution.

Amputation of the Penis may be practised either with the *écraseur*. Whichever instrument is used, the operation should be performed towards the root of the organ, so as to be well above the disease; at the same time, care must be taken not to remove too near the pubes, lest the stump retract under that bone. Division with the knife may readily be done by the surgeon, and the penis upon the stretch, drawing the integument well forward, severing the organ at one stroke of the bistoury. As the corpus cavernosum retract more than the integument, it is well not to leave too much of the flap, falling over the face of the stump, make the search for the internal vessels somewhat difficult, and afterwards pucker inconvenient. Hemorrhage during the operation may be effectually restrained by a narrow tape tightly round the root of the penis. There are three arteries requiring ligature: the dorsales penis, one in each corpus cavernosum, and one in the septum. In securing these, trouble is not experienced in consequence of the retraction of the stump that is liable to this, however, is lessened by tying a tape round the organ before the operation is commenced, or by directing the hand to hold it firmly between the fingers, and thus to prevent the retraction of the stump, which may otherwise draw back and be buried under the skin almost in the perineum. Should it do so, and oozing continue, a catheter must be passed into the urethra, and a firm compress applied. **T-bandage.** During and after cicatrization, the urethral orifice is liable to contract. The liability to this may, however, be lessened by drawing forwards the mucous membrane, making four cuts in it with the scissors, and then stitching it to the edge of the cut skin. If the operation be performed high up, this may be somewhat difficult, and then it is safer to introduce an elastic catheter before the operation, to prevent retraction upon and through this, and to leave it in during cicatrization. When the *écraseur* is used, the skin should similarly be drawn forward, the instrument worked slowly, so as to divide the organ without hemorrhage.

After amputation of the penis, the urine will not be projected, but always passes directly downwards between the legs. An inconvenience in this respect may best be avoided by adopting Ambroise Paré's advice of adapting a funnel, which may be made of metal or wood, and placing it over the pubes over the stump, and thus carrying the urine clear of the perineum.

Other tumours besides cancers are occasionally met with in the penis. I have seen *Necus* situated under the prepuce (p. 689), and *Fibro-plastic Tumour* of this structure extending into the corpus cavernosum. Such morbid growths usually admit of removal without sacrificing the whole organ.

DISEASES OF THE SCROTUM.

INFLAMMATORY OEDEMA of the scrotum is an erysipelatous inflammation of this region, which derives its chief peculiarity from the circumstance of its giving rise to great effusion into and swelling of the cellular tissue, with a tendency to the rapid formation of slough in it, by which the integument may likewise become affected to such an extent that the testes and cords speedily become denuded. This disease usually originates from some local source of irritation, as fissures, cracks, or urinary extravasation (p. 456).

Treatment.—This consists in elevating the scrotum, fomenting it well, and making early and free incisions into it, particularly at the posterior and dependent parts, with the view of relieving the tension to which the tissue is subjected by the effusion into its cells, and thus preventing the liability to slough. Should this occur, the case must be treated on ordinary principles, when cicatrization will speedily ensue, however extensive the denudation of parts may be. The constitutional management must always be conducted in accordance with those principles laid down in the first division of this work, and with especial attention to the maintenance of the patient's strength.

HYPERTROPHY of the scrotum seldom occurs in this country, though Liston once had occasion to remove such a mass, weighing 44 lbs.; but in some tropical regions, particularly India and China, it is of frequent occurrence, and may go on until it attain an enormous bulk, forming a tumour nearly as large as the trunk, and perhaps weighing 60 or 70 lbs. These enormous growths are of a simple character, and constitute the disease termed *Elephantiasis of the Scrotum*. Fig. 499 represents a tumour of this kind, weighing 40 lbs., which was successfully removed by Dr. Rogers of the Mauritius. It is taken from a photograph of the case, kindly sent to me by that gentleman.

Treatment.—Tumours of this kind necessarily require extirpation. In performing such operations there are two points that demand special attention: the first is to preserve the penis and testes if possible, which will usually be found buried towards the upper part of the mass, and which may be saved if the tumour be of small size; and the second is, to endeavour to prevent the hemorrhage from being too profuse. With this view, the operation ought not only to be performed as rapidly as

Fig. 499.—Elephantiasis of the Scrotum.

possible, but the suggestion made by O'Ferrall of elevating above the level of the body, for some time before its removal, empty it of its blood, may be advantageously adopted. If very large, it will be better not to make any attempt at saving the penis, which could only be dissected out by a long and tedious course of which there would be danger of the patient dying from exhaustion.

CANCEROUS OR CANCROID DISEASE occasionally affects the scrotum. If it principally occurs in chimney-sweepers, it has been aptly termed *Chimney-sweeper's Cancer*. This affection appears to be an irritation of the soot lodging in the folds of the scrotum, the common form of canceroid disease. It commonly commences as a wart, which at last tends to crack or ulcerate, presenting characters of cancerous ulceration. After a time, the inguinal glands will be seen to be affected; and the patient, if the disease is extensive, will be found to be cachectic-looking.

The *Treatment* consists in excising widely the diseased scrotum, provided the inguinal glands be not involved, and the constitution poisoned. The disease has a great tendency to recur, and is seldom that the patient long escapes with life when once affected by it.

CHAPTER LXXI.

DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS.

THE testes are, in the foetus, contained within the abdominal cavity. In the normal condition descend into the scrotum a short time before birth. In some cases, some arrest of development this descent may be retarded or altogether prevented; and in other instances it never takes place. An undescended testis may continue to lie within the cavity of the abdomen; or it may descend into the internal ring; or may become engaged in the inguinal canal above the external abdominal ring. In these several situations the testis may be quiescent; but it may become the seat of inflammation or of cancerous degeneration, simple or malignant. It may also, when undescended, become stated at p. 1009, become complicated with a hernia, and may present great diagnostic difficulties. Inflammation of the testis retained in the abdomen may be considered at p. 1203. When an undescended testis is the seat of structural degeneration, it may require removal from the body. In the testis may be met with in other abnormal situations; thus, I saw a case in which one of these organs was situated in the pelvis, close by the anus, having apparently missed the scrotum; and another occurred in which they have been met with in the interior of the thorax. The organ may sometimes be turned hindsid forward, but so that the epididymis is placed in front. In a case of this kind, I had an opportunity of examining after death a few years after the patient's death. The epididymis and vas deferens were considerably larger than natural, and in such a case, it will be seated behind the testis.

There is a very important question connected with mal-

testis, viz. : Is the organ when undescended prolific ? There is reason to believe that it is not. Such testes are small, hard, and granular in structure ; and when they are examined under the microscope, spermatozoa are not found in them. When only one testis is undescended, the other one, being in its proper position, carries on the functions of the two organs ; but when both testes are retained in the canal or in the abdomen, being undescended, the individual who is the subject of such malposition will most probably be sterile. He may have the usual erotic feelings, full power of erection, and of emission of a spermatic fluid ; but the secretion will have no fecundating power.

NEURALGIA OF THE TESTIS.

A painful or irritable condition of the testicle may occur without any actual disease of the organ ; the pain being either seated in the epididymis, which is the part naturally the most tender, in the body of the testis, or stretching along the cord to the loins and groins. It is usually paroxysmal, and is accompanied by great tenderness, and commonly by some fulness of the organ, which feels soft and flaccid ; but it is difficult to make a proper examination, on account of the agony that is induced by touching the part. This disease chiefly occurs in young men of a nervous and excitable temperament, and is frequently associated with great mental disquietude and despondency, often amounting to a suicidal tendency.

The *Causes* are obscure ; in many cases the disease appears to be connected with a neuralgic temperament, but in others it is associated with some dyspeptic disorder, or may be dependent upon local irritation ; thus external piles, or the pressure of a varicocele, will often give rise to it.

The disease is usually of a very chronic character. In some instances, however, it ceases spontaneously, after having lasted for weeks or months.

Treatment.—When the neuralgia is dependent upon constitutional causes, the treatment is extremely unsatisfactory. The administration of tonics, such as iron, zinc, or quinine, the local application of sedatives, as of atropine ointment, or the tincture of aconite, may be of service. In other cases, cold bathing or douching will be beneficial ; and, in all, keeping the part supported with a suspensory bandage will be advantageous. In the event of there being any local irritation, that should be removed ; thus I have known the disease to cease after the excision of external piles ; and when it is connected with varicocele, proper measures must be adopted for the relief of that affection. In extreme cases, Sir A. Cooper recommends castration ; but such a proceeding is altogether unjustifiable in a disease that is either constitutional, or dependent on local causes which are readily removable.

INFLAMMATION OF THE TESTIS.

Inflammation of the Testicle, considering the organ as a whole, may be of two distinct kinds, varying as to seat and as to cause. Thus it may be seated in the body of the organ, constituting *Orchitis* ; or the epididymis may alone be affected, constituting *Epididymitis*. As to cause, it may be rheumatic, traumatic, or gonorrhoeal.

ACUTE INFLAMMATION.—The *Seat* of the inflammation, at the commencement of the disease, depends greatly upon its cause, which may be in the urinary passages or elsewhere. Irritation in any part of the urethra, occasioned by the passage of instruments, by the lodgment of calculi, or by gonorrhoeal inflammation, usually causes the epididymis to be primarily affected, and the body of the organ to be inflamed in a secondary manner. When, on the other hand, the inflammation comes on from injuries, blows,

strains, or other causes acting generally, the body of the testis first affected. To all this, however, exceptions will often occur; may supervene as the result of gonorrhoea, or epididymitis from orchitis in such cases is in all probability a kind of constitutional inflammation intimately associated with inflammation of other fibrous tissues with gonorrhoeal rheumatism; the inflammation of the epididymis from gonorrhoea or other irritation of the urinary passages, a result from direct extension of morbid action along the vas deferens.

SYMPTOMS.—These necessarily vary to a certain extent, not only as the disease is of an acute or a chronic character, but as it attacks the body of the testis or the epididymia. When it commences in the body of the testis, it is the inferior globus that is commonly first affected, which is swollen, hard, and tender. The disease may be confined to this part; but most frequently it invades the whole of the organ, which is uniformly enlarged and somewhat ovoid; it is frequently accompanied by a good deal of effusion into the tunica vaginalis, then constituting a *Hydrocele of Velpeau*. As the inflammation subsides, the difference is presented by the enlargement of the two constituents of the organ is no longer apparent. The swelling is therefore due partly to general enlargement of the organ, but in some cases to inflammatory effusion into the tunica vaginalis, and this may either be of a purely serous, or partly of a plastic nature.

The pain is always very severe, with much tenderness and a heavy weight, and commonly extends up the cord into the groin and is generally greatest when the body of the testis is affected, owing to the enveloping fibrous tunic preventing the expansion of the organ. It is often spasmodic and paroxysmal, extending up the course of the cord. There are usually considerable swelling and redness of the scrotum, a tumescence of the scrotal veins, and a congested state of the system, with sharp pyrexia, nausea, and perhaps occasional vomiting.

As the disease subsides, the body of the testis first resumes its normal character and shape, the epididymis often continuing hardened at first for a considerable period. In fact, the induration that forms in the epididymis may become somewhat permanent, owing to the effusion of matter into it, leaving a hardened mass, and implicating the whole of its convolutions.

SUBACUTE ORCHITIS usually comes on with the same symptoms, but in a less marked form than in the acute variety. The swelling is considerable, though of a softer kind. When the disease is of the chronic type, the testis often becomes permanently enlarged and hardened, assumes an irregular shape, being smooth, heavy, and uniformly expanded, with a great weight, dragging and severe pain, and a good deal of tenderness. This form of orchitis occasionally occurs in old people.

TREATMENT.—The treatment of *Acutely Inflamed Testicle*, whether constitutional, is essentially antiphlogistic. Blood should be abstracted from the part by puncturing the veins of the scrotum—a far better method than applying leeches, the bites of which are apt to become irritated. The operation may be very effectually done by directing the patient to lie on his back and to foment the scrotum for a few minutes with a hot spirit, which will distend the veins; these may then be punctured at various points with a fine lancet, and the parts well fomented afterwards, so as to ensure a free flow of blood. In this way six or eight ounces may be taken in the course of a few minutes; when enough has escaped, the further flow may be arrested by laying the patient down and elevating the part.

The patient should be kept in bed with the testis raised on a support.

between the thighs, poppy fomentations being diligently applied. If there be much effusion into the tunica vaginalis, constituting acute hydrocele, relief may be afforded by puncturing this sac with the point of the lancet.

The *Constitutional Treatment* during the acute stage consists in the administration of salines and antimony, with henbane in full doses, so as to give an aperient, a diaphoretic, and a sedative together; when this begins to act, great relief is usually afforded.

As the inflammation subsides, the treatment must be changed. When there is merely swelling and hardness left, with but little pain or tenderness, the testis may advantageously be strapped with adhesive plaster, so as to give good support and to promote absorption of plastic matter. Fricke of Hamburg has strongly recommended strapping in the acute stage; but I cannot say that I have ever seen any advantage derived from it at this period of the disease, though I have many times seen it tried; it has usually appeared to me to increase, sometimes very considerably, the pain in the part and the general uneasiness.

In *Subacute Orchitis* much benefit is usually derived from a short course of Dover's powder and calomel, with early strapping of the testis. When the organ has become enlarged and indurated, as the result of chronic inflammation, it may be advantageously strapped, either with simple plaster, or with one composed of equal parts of the emplastrum ammoniaci cum hydrargyro and soap-plaster; mercury in small doses, more especially the bichloride, being continued for some length of time, until the plastic matter is absorbed and the hardness disappears.

In *Strapping a Testicle*, the scrotum should be shaved, and then drawn tightly upwards on the affected side. The surgeon should next pass a long strip of plaster, about an inch broad, above the enlarged testicle and round the corresponding side of the scrotum, so as to isolate it, as it were. Another strip is now passed from behind, in a longitudinal direction, over the lower end of the testis, and upwards upon the anterior part of the scrotum: and thus, by a succession of horizontal and vertical strips, neatly overlapping and drawn tightly, the organ is completely enveloped and compressed. To be of any service, the strapping must be tightly and evenly applied; but at the same time care must be taken not to strangle the scrotum by drawing down the upper strips of plaster too forcibly. In a case of "tuberculo-syphilitic" disease of the testis, in which I was obliged to have recourse to castration, the whole of the side of the scrotum had sloughed away, leaving the testis exposed and fungating, in consequence of the tight strapping which had been employed before the case came into my hands.

ABSCESS, as the result of inflammation of the testis, is of rare occurrence: sometimes, however, the scrotum inflames at one point, where fluctuation becomes apparent, with thinned skin and evident signs of suppuration; a puncture should here be made, and the pus let out as soon as formed. Sometimes abscess may occur in another way: inflammation is set up in the tunica albuginea, adhesion takes place between the testis and the scrotum, abscess forms under the fibrous coat, and, this giving way, the pus gets vent externally through the integuments. Into the aperture that necessarily results, a portion of the secreting tissue of the gland sometimes projects, and, becoming inflamed, forms a red, granular, and fungous mass, protruding through and overlapping the edges of the aperture. The treatment of this condition will be considered when we come to speak of the scrofulous testicle.

INFLAMMATION OF THE TESTIS IN THE INGUINAL CANAL may sometimes take place, even in adults, when the organ has not descended through the external ring; giving rise to a train of somewhat puzzling symptoms which

closely resemble those of strangulated incomplete hernia ; with ever, it must be borne in mind that it may be associated (p. examination, a large irregular tumour, in some parts hard, is very tender to the touch, and occasioning a sickening sensation will be found in one of the groins, in the situation of the inguinal canal. There are usually a tendency to vomiting and some constipation of the bowels, and pains in the abdomen. These symptoms, however, are generally persistent, and the constipation readily yields to the administration of cathartics. On examining the scrotum, it will be found that the affected side is absent ; and, on passing the finger into the external inguinal ring, the testis can be felt to be lodged in the canal. In consequence of the proximity of the peritoneum to the inflamed testis, this membrane becomes involved in the morbid action ; and, as the result of the extension of the tendinous and aponeurotic tissues in this situation has occasionally occurred. Either of these conditions may lead to termination.

The *Treatment* should be actively antiphlogistic. Leeches applied over the part, and blood should be taken from the arm, if the patient be young and strong ; salines with antimony being at the same time administered, and fomentations diligently persevered in.

INFLAMMATION AND ABSCESS OF THE CORD.—In some cases inflammation of the testis may extend, or the disease may from the beginning be limited to, the cellular tissue of the cord, giving rise to tumour, and a good deal of pain and tenderness along it, and eventually accompanied by the usual signs of suppuration. The *Treatment* of such cases should be conducted on ordinary principles, early discharge for the pus being the object.

HYDROCELE AND HEMATOCELE.

By *Hydrocele* is meant an accumulation of serous fluid, formation with the testis or cord. Most frequently the fluid occupies the tunica vaginalis, constituting a true dropsy of it ; in other cases it appears to be formed in distinct cysts, situated either in connection with the testis, or upon the cord. Hence hydroceles are commonly divided into two classes, those that affect the *Tunica Vaginalis*, and the *Encysted* variety.

HYDROCELE OF THE TUNICA VAGINALIS may occur as the result of orchitis ; the inflammation of the testis causing the effusion of a limpid fluid into its serous investment. This, however, is not the most common variety of hydrocele that is commonly met with ; the fluid so poured out is the result of active inflammation, usually becoming absorbed as the part returns to its normal condition. The ordinary hydrocele occurs as a chronic disease, without any signs of inflammation of the testicle, or, at most, with a slight tenderness of that organ. It is most frequently met with in individuals in the middle period of life, and generally in persons of feeble power, or of a cachectic or gouty constitution, commonly without any evident cause.

In young infants, hydrocele is not unfrequently seen, and it affects two forms : either the ordinary one, similar to what occurs in adults, in whom the tunica vaginalis constitutes a closed sac filled with fluid ; or a less common variety, in which the accumulation of fluid in the tunica vaginalis communicates, by the persistence of a cavity or canal in the peritoneum, with the prolongation of the peritoneum investing the cord, with the general peritoneal cavity. This form of hydrocele is *Congenital* ; and it occupies the same position that intestine does in a congenital hernia. It may readily be recognised by the fluid being made to flow into the general peritoneal cavity, on raising or depressing the tumour.

this may be considered to be the true congenital form of hydrocele in infants, the other variety of the disease also occurs in them when but a few days old, and very possibly even at the time of birth.

Symptoms.—The symptoms of hydrocele are tolerably evident. The disease begins with a degree of swelling and weight about the testis: the swelling may at first be soft, but after a while becomes hard and tense; or it may be so from the commencement. Whatever its original condition, the tumour soon becomes oval or pyriform in shape, being narrowed above, rounded and broad below; it is smooth and uniformly tense and hard, often having a semi-elastic feel. It reaches upwards along the cord, towards the external abdominal ring, which, however, is never invaded by it, and the cord is usually distinctly to be felt above the upper margin of the tumour. Most commonly the size varies from that of a hen's egg to a small coco-nut; but sometimes it may attain a considerably greater magnitude than this, and will then cause much deformity of the parts, as it reaches up close to the external ring, and drags over the penis, causing that organ to be buried in it.

The most characteristic sign of hydrocele is its translucency by transmitted light. This may always be detected, by the surgeon grasping the posterior part of the tumour with one hand, so as to put the integuments of the fore part on the stretch, then placing the edge of the other hand along the most prominent part of the swelling, and having a lighted candle held close behind. On making this examination, the tumour will appear translucent; if, however, the walls of the sac be thick, or the fluid dark, the transmission of light through it may not be perceived unless the examination be conducted in a darkened room.

We have already seen that the ordinary hydrocele of the tunica vaginalis may vary as to size: it may also differ as to shape; in some cases being globular, in others constricted in the middle, or of an hour-glass shape.

Fig. 500.—Hydrocele.

Fig. 501.—Dissection of a Hydrocele, showing its coverings.

The quantity of liquid varies considerably; there is usually from six to twelve or twenty ounces, but I have known a hydrocele to contain more than

one hundred and twenty ounces. The fluid is generally clear and of a straw colour ; but in very large and old hydroceles of a dark-brownish or chocolate hue, owing to the admixture of blood ; and will then be found to contain flakes of cholesterol usually thin ; but in some old cases it becomes thick and of a kind of false membrane, and divided by septa or bands, to an extent as almost to separate it into distinct compartments. If the sac is thick, and the fluid opaque and turbid, there may be difficulty in detecting the translucency.

The testis is generally somewhat enlarged, especially about the time of the complaint, and frequently slightly tender, more particularly in the early stages of the complaint. It is almost invariably situated at the posterior pole (Fig. 500), but may sometimes be found towards its anterior pole ; in this case, the epididymis will be found turned towards the organ being retroverted.

The Coverings of a hydrocele are the same as those of the testis. The integumental structures, aponeurotic prolongations from the columnar and cremasteric fasciæ may be traced over the swelling (Fig. 501).

Treatment.—The treatment of hydrocele is divided into the curative. By the palliative treatment the surgeon simply relieves the patient of the annoyance induced by the bulk or weight of the swelling, but the curative has for its object the permanent removal of the fluid.

The *Palliative Treatment* consists in the use of a suspensory band, or cooling lotion, or in tapping with a fine trochar. These measures may sometimes succeed in effecting a radical cure. The latter will happen that the application of evaporating and discutient remedies remove the effused fluid ; and indeed it is seldom that any other treatment than this is required in young children. The best purpose consists of one composed of ℥j of muriate of ammonium dissolved in ℥vj of water ; with this the scrotum should be wetted ; and, if there be a communication with the peritoneum, the band should be kept applied over the external ring. In adults it occasionally happens that simple tapping of the tumour has effected a radical cure. A gentleman from Cuba consulted me for a small hydrocele which had been forming for several months ; I tapped it with a fine trochar, and it discharged about five ounces of fluid. This was followed by a radical cure. This case bears out a remark made by Sir B. Brodie, that the force of simple tapping to produce a radical cure is more likely to succeed in the West Indians. I have, however, several times seen hydroceles recur after having been tapped a few times, without any other cause than the heat of the climate. This is amply proved by the fact that persons who had never been in hot climates. This anomaly is altogether, however, destitute of danger ; I have known an oedema of the scrotum from inflammatory oedema of the scrotum after being tapped. It usually happens that the hydrocele slowly forms again, attaining its former bulk at the end of about three months. When a congenital hydrocele is tapped, the sac soon fills again by drainage into it from the peritoneum, and, indeed, in such cases the fluid of an ascites has been removed by tapping the tunica vaginalis.

In tapping a hydrocele a few precautions are necessary, the patient should be placed on his back, to avoid puncturing one of the scrotal veins, or injuring the testis. In the majority of cases the testis is situated at the back of the swelling, and consequently altogether out of the way of the trochar, if the patient is placed as it should be, by the surgeon putting the anterior

hydrocele on the stretch by grasping it behind with his left hand, and then pushing the trochar into the lower part of its middle third in front, carrying the instrument at first directly backwards (Fig. 502 a), but, as soon as it has perforated the sac, directing its point upwards (Fig. 502, b). If the testicle have been found, on examination with a lighted candle, to be on the forepart of the tumour, where it may sometimes be felt as well as seen, the hydrocele should be tapped at the side or behind. Before using the trochar, it is well to see that the cannular fits closely round the neck of the stylet; and, above all, that the instrument has not become rusty by having been carelessly put aside after use on a previous occasion.

The Curative Treatment has for its object the excitation of a sufficient degree of inflammation in the tunica vaginalis to restore the lost balance between secretion and absorption; but it is not necessary that the serous cavity should be obliterated by adhesions between its opposite sides, though these not unfrequently take place. The means by which the surgeon sets up this inflammation are either the introduction of a small seton into the tunica vaginalis, or throwing a stimulating injection into that cavity after tapping it. Whichever plan is adopted, a certain amount of inflammation ought to be set up. This is always attended by considerable swelling of the testis, and by the effusion of a fresh quantity of fluid into the tunica vaginalis. As this is absorbed, the part gradually resumes its normal bulk, and the disease will probably not return.

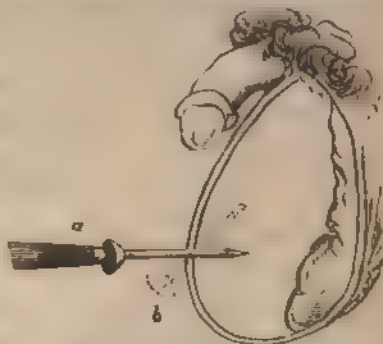

Fig. 502.—Tapping in Hydrocele: a, Introduction of Trochar, b, Position of Cannula.

In order that the radical cure, in whichever way undertaken, should be safe and efficient, it is necessary, in the first instance, that the disease should have been allowed to attain a chronic condition, more particularly if the hydrocele have been of rapid growth. In order to prevent its attaining too large a size, it will be well to adopt palliative tapping once or twice before attempting the radical cure. Care must also be taken to remove all inflammation and tenderness about the testis, before having recourse to this means of treatment. If attention be not paid to this, recurrence of the hydrocele will probably ensue. After the proper amount of inflammation has been set up, it will be well to treat the patient as if he were suffering under an ordinary attack of orchitis, confining him to bed or to the couch for a few days; indeed, I look upon care in the after-treatment as of very considerable importance in securing a favourable result to the case.

The cure by the introduction of a seton, though formerly much employed, is seldom practised at the present day, chiefly on account of the danger of exciting too much inflammation. It may, however, conveniently be employed in the true hydroceles of children, and in some of those cases in which the injection fails, if practised in the manner that will immediately be described.

The treatment by *Injection* is the one that is commonly employed; it consists in tapping the tumour in the usual way, and then throwing a sufficient quantity of stimulating fluid into the tunica vaginalis through the cannula, so as to excite a proper amount of inflammation in it. The liquids

that are employed are generally either port-wine, or a solution of zinc of the strength of $\mathfrak{z}\text{i}$ to $\mathfrak{z}\text{xij}$, or most commonly tincture of iodine. If the port-wine or a solution of the sulphate of zinc of sufficient quantity partly to distend the sac should be injected into an India-rubber bottle or brass syringe that can be adapted to the testis, or eight ounces are commonly required for this purpose, and allowed to remain in for some minutes before being evacuated.

Injection of Iodine ---The injection of tincture of iodine, introduced by Sir J. R. Martin, whilst practising at Calcutta, is preferred as a more certain and a safer mode of treatment. It is usually sufficient to inject about one or two drachms of tincture. It should be left in for a few minutes, in proportion to the amount of pain it occasions, and then allowed to escape. Inflammation will usually be set up, on the subsidence of which a cure will be found to have been effected.

Useful as the iodine injection is, it sometimes fails in producing a radical cure of hydrocele. This is attributable to two causes: the first, in some cases sufficient inflammation is not set up to induce the adhesion of the tunica vaginalis which is necessary for a radical cure. It is that, when a hydrocele is radically cured by injection, it is the adhesion taking place between the two opposite surfaces of the tunica vaginalis and a consequent obliteration of its cavity, but by the inflammation that is artificially induced exciting such a modification of the functions of the tunica vaginalis as to restore the balance between the secretion and absorption by which it is naturally lubricated. Now, in some cases, sufficient inflammation is not induced by the introduction of the irritating fluid, and the natural balance between these two functions of the membrane is not restored. The tunica vaginalis gradually fills again after the injection, as it would after a simple operation of tapping. It occasionally happens that the patient suffers excruciating agony at the time of the injection, from the stimulating fluid with the surface of the testis, and yet the inflammation may be excited. The amount of suffering, therefore, from the operation, is by no means proportionate to the amount of inflammation likely to be set up. Indeed, the reverse would be the case in many instances; and I have often observed that the progress of the cure, which progress most steadily to a radical cure, there is but a small amount of pain experienced at the time of the injection.

There is a second way in which injections would appear to fail. A considerable amount of inflammation is excited, and effusion takes place into the tunica vaginalis, which, in the course of three or four days, tends to the same size, or nearly so, that it had attained previous to the operation; but this effused fluid, instead of being absorbed, at the second or third week, remains unchanged in bulk, or absorbed to a certain point, and then seems to be arrested; the tumor remaining distended with a certain quantity of fluid.

The proportion of cases in which the iodine injection fails to produce a radical cure of the hydrocele is variously estimated by different authors. Thus Sir J. R. Martin states that in India the failures scarcely exceed 1 per cent.; Valpeau calculates them at 3 per cent. I am not aware of the statistics of this mode of treatment in this country have been collected. The general opinion of surgeons would appear to be decidedly in favor of it as being the most successful as well as the safest plan of treatment that has yet been introduced. In this opinion I fully coincide: it is by no means improbable that the success of the iodine injection

country might not prove to be quite so great as is generally believed. I have, during the last few years, seen a considerable number of cases of simple hydrocele of the tunica vaginalis, both in hospital and in private practice, in which a radical cure had not been effected, although recourse had been had to the iodine injection by some of the most careful and skilful surgeons of the day, as well as by myself.

One circumstance connected with the injection of tincture of iodine into the tunica vaginalis deserves note. It is that, although in some cases it occasions but little pain, in other instances the suffering induced by it is of the most severe and agonising character—more so than follows the introduction of any other of the ordinary stimulants into the tunica vaginalis.

Seton.—There can be no doubt that, as a first remedy, iodine injection is preferable to the seton, in the treatment of hydrocele; but when the injection has failed, and this from no want of care on the part of the surgeon, or of attention to the after-treatment of the case, but apparently from insufficient inflammatory action having been set up in the tunica vaginalis to restore the lost balance between secretion and absorption in this membrane, the seton will, I think, be found to be the most certain means of accomplishing our object. It is true that several objections may be urged to the use of the seton; it requires much watching and care, and is occasionally apt to excite a dangerous amount of inflammation in the cellular tissue of the scrotum; and these objections are, to my mind, sufficiently valid to prevent our employing it as the ordinary treatment for the radical cure of hydrocele. But it must be remembered, that the particular cases to which I am now alluding are those in which ordinary means have proved insufficient to excite proper action, and in which, consequently, it would appear as if a greater amount of irritation could safely be borne. Indeed, nothing is more remarkable than the difference in the intensity of the inflammation that is set up in different individuals by the means that are commonly employed in the treatment of hydrocele. In some cases the most irritating injections may be thrown into the tunica vaginalis, or a seton may be drawn through the scrotum and left there for days, not only without giving rise to any injurious inflammation, but without setting up sufficient action to bring about a cure of the disease; whilst in other instances simple tapping may effect a radical cure, or may give rise to such an amount of irritation as to terminate in fatal sloughing of the scrotum.

The seton that I employ in these cases is composed of one or two threads of dentist's silk. It may be introduced by means of a *nævus*-needle, the fluid of the hydrocele being allowed to drain away through the punctures thus made; or, far better, by tapping the hydrocele, and then passing a needle about six inches long, armed with the seton, up the cannula, drawing it through the upper part of the scrotum, and then removing the cannula, cutting off the needle, and knotting the thread loosely (Fig. 149). The thread should not be removed until the scrotum swells and becomes red, with some tenderness of the testis and effusion into the tunica vaginalis. When these effects have been produced, it may be cut and withdrawn, and the case treated in the same way as when the radical cure has been attempted by iodine injection; viz., by rest and antiphlogistic treatment. The length of time during which the seton must be left in before sufficient, or even any inflammatory action is produced, varies very considerably. In most instances, the proper amount of inflammation is excited in from twenty-four to thirty hours; but in other cases it may be left in for ten or twelve days, giving rise to but little inflammation, although a radical cure may result.

It is not always prudent to have recourse to the radical cure in the treat-

ment of hydrocele. In persons advanced in years, or of feeble constitution, the inflammatory action excited in the tunica vaginalis of the mens just detailed may run on to such an extent as to produce inflammatory oedema, and even sloughing of the scrotum, with death. In men advanced in years it is usually safer to treat a hydrocele, and only to tap as occasion arises from the increasing swelling.

ENCYSTED HYDROCELE.—In this variety of the disease the fluid lies in the tunica vaginalis, but is contained in a cyst which projects from the surface of the epididymis or testis, and pushes the serous investment of the gland before it.

These cysts are much more frequently found connected with the epididymis, than with the body of the testicle. Indeed, Curling has

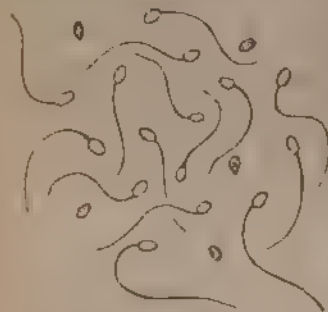

Fig. 503.—Spermatozoa from Encysted Hydrocele

observed the fact, that small peduncles, of about the size of currants, composed of a fine serous membrane, tessellated epithelium, are found beneath the visceral tunic covering the epididymis. These cysts, in structure, contain a fluid, and are very liable to rupture. They are met with at all ages after puberty. According to Gosse, at the age of forty, they occurred in one-third of the testes examined for their presence. Such cysts remain stationary, of small size, and are not to be detected during life,

unless by pathological phenomena; they may rupture into the tunica vaginalis, or they may enlarge and become developed into tumours of considerable magnitude.

The fluid of these cysts possesses the remarkable characteristic, observed by Leston, of containing spermatozoa (Fig. 503); an observation has been fully confirmed by many subsequent observers. The spermatozoa do not always exist in this fluid, yet they are usually met with in small quantities, at others so abundantly as to give an opalescent appearance. This admixture of spermatozoa with the fluid of the cyst is probably due, as pointed out by Curling, to the rupture of a seminal duct into an already existing cyst. Spermatozoa are also, but very rarely, been found in the fluid of an ordinary hydrocele of the tunica vaginalis; and then probably their presence was due to the rupture of one of these cysts into the tunica vaginalis. Hence the presence of spermatozoa in the fluid of a hydrocele may in most cases be considered as characteristic of the encysted variety of the disease.

The *Symptoms* of encysted hydrocele differ in some respects from those presented by the ordinary form of the disease. The tumour of this variety is smaller, more irregular in shape, and does not envelope the testis completely, but is situated behind it, and rather in connection with the epididymis.

The *Treatment* consists in injecting the sac with tincture of iodine, after incising the tumour and allowing it to granulate from the base. The injection by iodine, though successful in some cases, is not so successful as in this as in the last variety of the disease, but usually deserves a trial; if it fail, the incision of the tumour will always effect a cure.

HYDROCELE OF THE CORD.—This disease is characterised by the presence of a round or oval tumour, situated on the cord, below or within the inguinal canal. It is smooth, elastic, and, if of sufficient size, may be semi-transparent on examination by transmitted light. It can be pushed up into the abdomen, but receives no impulse on coughing, and does not alter in size on being steadily compressed. It appears to be formed, in some cases, by the funicular portion of the peritoneal investment of the cord being imperfectly closed and consolidated at points; though it is possible that in other instances it arises as a distinct cystic growth. These tumours may occur at all ages, but are chiefly met with in the young, and are not unfrequent amongst children.

Treatment.—The obliteration of the cyst is best conducted by passing a seton through it, or by making an incision into it, and letting it granulate from the bottom.

DIFFUSED HYDROCELE OF THE SPERMATIC CORD consists in the infiltration of the cord with serous fluid, contained in rather distinct cells, and giving rise to an oval or oblong irregular circumscribed tumour, extending below and into the inguinal canal.

The *Treatment* consists in the application of blisters, or of counter-irritant plasters. Should the disease prove very troublesome, an incision might be made down to and into the swelling, so as to let out the fluid and allow the cyst to become consolidated.

HEMATOCELE.—By *Hematocèle* is meant an accumulation of blood in the tunica vaginalis, distending that sac, and compressing the testis. It is of two kinds, *Traumatic* and *Spontaneous*. The *Traumatic* is the most common form of the disease, usually arising from a blow on or a squeeze of the testis, by which one of the veins ramifying on the surface of the gland is ruptured, and blood is poured into the tunica vaginalis. It may also arise in tapping a hydrocele, from the point of the trochar being pushed too directly backwards and puncturing the testis. *Spontaneous Hematocèle* is a disease of rare occurrence, arising apparently from the rupture of an enlarged spermatic vein into the tunica vaginalis. It attains a larger size, and is altogether a more formidable affection, than the traumatic hematocèle.

Characters.—In whatever way occurring, a hematocèle slowly but gradually increases in size, until it attains about the magnitude of a duck's egg, or even that of a cocoa-nut. It is seldom that it becomes larger than this; but cases are recorded in which the tumour has attained an enormous magnitude. I once operated in a case in which a spontaneous hematocèle had existed for six years; it was as large as a good-sized melon, and contained, besides about a quart of dark thin blood, a handful of partially decolorised and tough fibrine, the greater portion of which was firmly adherent to the inside of the greatly thickened tunica vaginalis in filamentary and laminated masses, with here and there nodules interspersed. The whole of the interior of the tunica vaginalis closely resembled an aneurismal sac.

The fluid contained in the hematocèle, when the disease is recent, consists of pure blood; but when of old standing, it is of a dark and grumous character, owing to disintegration of the blood-corpuscles. It then usually contains an admixture of cholesterine. The blood so effused will continue fluid for years; but at last it may decompose and set up fatal inflammatory mischief; in some rare instances the tumour becomes partly solidified by the deposit of masses of fibrinous coagulum, lining the interior of the tunica vaginalis, which are sometimes decolorised and arranged, as in the case just referred to, and in one recorded by Bowman, in a laminated manner, like the contents of an aneurismal sac.

Symptoms.—These are generally sufficiently obvious. The occurrence of the tumour subsequently to a blow, strain, or injury when tracing a gradual increase in size, its somewhat heavy but semi-elastic feel, its shape, and the absence of transparency, together with the freedom of the cord above and the want of impulse in it on coughing, will indicate its character.

Treatment.—This must vary with the size and duration of the tumour. When it is small and recent, and has fluid contents, the surgeon may attempt the effect of tapping it; it is possible that, after the evacuation of the

FIG. 501.—Hematocoele with Thickened Tunica Vaginalis and Adherent Fibrinous Deposit.

closure and obliteration of the tunica vaginalis will take place. This happened in a case under my care, in which, though the disease had existed for three years, a complete cure followed the operation of tapping. Such simple treatment as this, however, cannot be depended upon; and it is usually necessary to lay the sac open, and to allow it to contract and to granulate from within, when the obliteration of the cavity of the tunica vaginalis necessarily results. In the tumours were of very large size, and the tunica vaginalis much thickened, hard, and parchment-like, with adherent organized fibrine, castration might be required. In the instance to which I have already referred, and which is represented in Fig. 504, this was rendered necessary in consequence of the conditions, and was successfully done.

HEMATOCELE OF THE SPERMATIC CORD has been observed by Pott, Bowman, and others; it is a rare disease, and usually occurs in the form of a tumour of considerable magnitude, suddenly arising after a strain or violent exertion, giving rise to the rupture of a varicose spermatic vein. It commences in the inguinal canal, and thence extends downwards along the course of the cord, through the abdominal ring into the scrotum; but it does not surround or implicate the testis, which can be felt free and movable in its lowest part. On incising such a tumour as this, a quantity of fluid, partly fluid and partly coagulated, has been found, sometimes containing a cavity, occasioned by the laceration and separation of the tunica vaginalis of the cord and scrotum. The most remarkable case of this kind on record is related by Bowman, in which the tumour, after existing for ten years, had attained so enormous a size, that it reached to the patella, and was so large as to require both hands and a considerable effort to raise it from the scrotum. In this case, death appears to have resulted from decomposition of the contents of the tumour.

Diagnosis.—In its early stages, hematocele of the cord would not be considered a risk of being confounded with an inguinal hernia. The fluctuating character of the swelling, however, its irregular feel, and its fluctuating sensation, might enable the diagnosis to be made. Hematocele of the cord may always be distinguished from an accumulation of fluid in the tunica vaginalis, by the testicle not being implicated in the formation, but surrounded by the fluid in the latter instance.

The *Treatment* of this disease must in the earlier stages be of a palliative kind; consisting in rest, support of the tumour, and the application of soothing lotions. Care should be taken not to incise it at this period, lest the loss of blood from the ruptured vein, after the evacuation of the

of the tumour, become uncontrollable. In one instance I have known fatal consequences from this cause to ensue in half an hour after making an incision into the tumour and turning out the coagula. When, however, the disease has reached a chronic stage, and is no longer increasing, it may be incised; and, its contents being turned out, the cavity may be allowed to suppurate and granulate.

VARICOCELE.

Varix, or *Enlargement of the Spermatic Veins*, is a disease that is commonly met with from the age of puberty to about the thirtieth year, seldom commencing later than this. It usually occurs in feeble individuals having the scrotum lax and pendulous; and in some cases appears to have been brought on by venereal excesses. The spermatic veins, extending as they do from opposite the upper lumbar vertebra to the plexus pampiniformis, which constitutes the base of the pyramidal tumour formed by a fully developed varicocele, are necessarily subject to considerable outward pressure from the weight of so long a column of blood as that contained within them, to which they may eventually yield, becoming much dilated and tortuous. The left spermatic veins are far more frequently affected than the right; partly owing to their compression by feculent accumulations in the sigmoid flexure of the colon, and partly to the obstacle at the mouth, occasioned by their pouring their contents into the left renal vein, at right angles to the current of blood flowing through that vessel into the vena cava. The right spermatic veins are rarely affected; and never, I believe, without those on the left side participating in the disease. In these cases of double varicocele, the left is almost invariably the more seriously affected; but I have seen exceptions to this in one or two instances, in which the veins on the right side formed the larger tumour.

SYMPTOMS.—The symptoms of varicocele consist of a tumour of pyramidal shape, having a knotted or knobbed feel, owing to the irregularly swollen and convoluted condition of the veins, with its base upon the testis and the apex stretching up to the external ring. The swelling increases when the patient stands up, if he take a deep inspiration, cough, or make any violent exertion. Its size varies from slight fulness of the veins to a large mass, several inches in circumference at the base. When the patient lies down, it goes up to a certain extent, but immediately returns to its former magnitude when he stands up again. It is attended by a sensation of weight and sometimes of pain, which is occasionally very acute, of a severe and neuralgic character, even in the scrotum, the groins, and the loins, more particularly when the tumour is unsupported. This pain is greatly increased on the patient walking or riding; so much so, that in some cases he is almost debarred from taking necessary exercise, and is prevented from following any active occupation. Debility of the generative organs, with a tendency to seminal emissions and much mental depression, frequently accompanies varicocele. The rupture of a varicocele may occur from external injury, giving rise to an enormous extravasation of blood into the cellular tissue of the scrotum: on one occasion I have known this to be attended by fatal consequences. The tumour having been incised, and large masses of coagula having been turned out, the patient died of venous hemorrhage.

DIAGNOSIS.—The diagnosis of varicocele is always sufficiently easy; its peculiar feel, its broad base and narrow apex, the manner in which it goes up when the patient lies down, and returns again when he stands up, are sufficient to distinguish it from all other scrotal tumours. From *inguinal hernia* disease may be distinguished by attention to the test described at page 10

subject to varicocele, especially those who habitually lead a sedentary and studious life, as, for instance, young clergymen and lawyers. In these persons, a peculiarly hypochondriacal state is brought on by the tendency of the mind to dwell on the condition of the genital organs, and the patient is constantly fidgeting about the local and tangible disease he observes in them.

How should the radical cure of this condition be produced? To this I would answer—By exciting adhesive inflammation of the spermatic veins, through an application of the same principle which sets up that process in the veins of the lower extremity. There are several different ways of doing this; some are very objectionable. The twisted suture, as applied to the veins of the leg, induces too great irritation in the scrotum, and there its introduction is often followed by violent inflammation or sloughing, or by an opening up of the cellular tissue of the scrotum with oedema, and even purulent infiltration. It is better, I think, not to use this method here; in deed I have twice, in the practice of others, seen it followed by death. The plan I have adopted for some years is that suggested and practised by Vidal de Cassis, and is as follows. The vas deferens, readily distinguished by its round cord-like feel, is first separated from the veins, and entrusted to an assistant; next, an iron pin, bored with a hole at each end (Fig. 505),

Fig. 505.—Iron Pin for Treatment of Varicocele.

is passed between the vas and the veins, and brought out, the scrotum being first notched with a scalpel at the point of perforation; then a silver wire, threaded on a needle so constructed that the wire shall follow it without catching (Fig. 506), is passed in at the aperture of entry of the

Fig. 506.—Needle threaded with Silver Wire.

needle, and carried between the integument of the scrotum and the veins, the wire being brought out at the second puncture (Fig. 507). Each end of the wire is now passed through the corresponding hole of the pin, which is twisted round and round repeatedly, each turn causing the wire to be rolled around the pin, and so tightened till the veins are firmly compressed between the pin behind and the loop of wire in front (Fig. 508). By this means the scrotum is quite free and uncompressed, and there is no danger of arousing inflammation or oedema. The wire should be tightened from day to day, as it causes ulceration in the veins until it has completely cut through, which results, usually, in about a week or ten days. Meanwhile, there is much plastic matter thrown out around the veins; this finally contracts and obliterates their channels. This method produces an effectual and permanent cure.

Of late, I have been in the habit of employing a simpler method. I separate the vas in the usual way, and then make a small incision, about half an inch long, in the front and back of the scrotum: afterwards I pass a needle armed with silver-wire, as before described, between the vas and the veins, bringing it out behind; I then return the needle, but this time carrying it in front, between the veins and the skin; and thus the veins are included in a loop of wire, without implicating the scrotum. The loop is then tightly twisted together, so as to constrict the enclosed vessels. This plan has a similar effect to that of the wire and pin combined; by repeated

tightenings the wire gradually effects the veins, which are obliterated by the an-

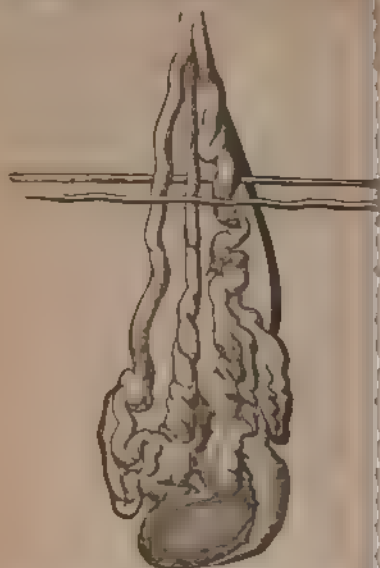

Fig 507.—Treatment of Varicocele: Introduction

It has been objected to this and the testis may take place, from its artery the veins; but, as the spermatic artery is held out of the way with that device mischief is avoided. Nevertheless, the result of long-continued pressure of the wire before the performance of the operation

TUMOURS OF

All solid tumours of the testicle are termed *Sarcocele*; and, when these are within the tunica vaginalis, they are termed *intravaginal*; and are divided into the *Simple*, the *Syphilitic*, and the *Malignant*; which, indeed, comprise a class requiring separate study.

SIMPLE SARCOCELE is a chronic or inflammatory mischief in the organ. It is hard, smooth, solid, though perhaps of an irregular shape, and usually about as large as a walnut, and slightly painful. The cord is usually enlarged, is the seat of pain of a dull or aching kind, and not unfrequently contains serous fluid. The tumour of the testis constituting the disease can usually be distinctly distinguished from the injury, by which inflammation had been produced, is always healthy.

Structure.—On making a section of the testis, it is found to be composed of a quantity

plastic matter, effused within the organ and between the tubuli, and also surrounding the gland, often in a series of solid and very firm glistening layers. In the midst of this, opaque yellow spots or masses, cutting smooth and firm, will be seen. These have been mistaken for tubercles, but are in reality masses of plastic deposit that have undergone fatty degeneration.

Treatment.—Strapping and the administration of an alternative course of bichloride of mercury may be tried. If the testis do not diminish in size by these means, or if it be a source of much inconvenience to the patient, it must be removed.

TUBERCULOUS SARCOCELE, or SCROFULOUS TESTICLE.—This disease, although occasionally met with in individuals otherwise strong and healthy, chiefly occurs in those of a feeble or cachectic constitution, usually in early manhood, and, although commonly associated with a tendency to phthisis, often occurs without any evidence of tuberculation in other organs or tissues than the testes. It commonly results from a blow, squeeze, or other injury, as a sequence of gonorrhoeal epididymitis, or from any cause that may produce chronic orchitis; the inflammation owing to constitutional predisposition becoming strumous and leading to the deposit of tubercle. Sometimes it occurs as the result of ulterior changes in the syphilitic sarcocele. It is essentially characterised by the deposition of tuberculous matter in the testis. The tubercles may occur as grey granulations; they may be infiltrated or encysted, varying in size from a pin's head to a cherry- or plum-stone. When encysted, they are of a bright yellow colour, tolerably firm and lustrous, contrasting strongly with the inflamed gland, in the midst of which they are deposited. Tubercles in all stages of development and disintegration are commonly found in the same organ. They are usually first deposited, and accordingly are more advanced, in the epididymis, more especially about its head. The irritation occasioned by their presence usually gives rise to abundant lowly organised plastic deposit in the organ. Their presence in and between the tubuli eventually produces inflammation, suppuration, and ultimate disorganisation of the structure of the testis, with which they become mixed up, so as to form a pulsatious cream or cheesy mass of a dirty buff colour.

Symptoms.—The strumous or tuberculous sarcocele presents three varieties, the symptoms of which vary somewhat. The first is characterised by a fungous protrusion; the second by a soft pulpy feel; and the third by its association with syphilitic disease.

1. In the most common variety, without any very evident cause, or perhaps after injury, gonorrhoeal inflammation, or venereal excesses, the testes gradually and slowly enlarge, often attaining a very considerable bulk, and usually becoming at the same time nodulated and irregular, hard and craggy; the hardness is confined to the nodules, the gland feeling soft between them; and hydrocele occasionally coexists. The epididymis is most commonly the part that is first affected in this way, though not unusually it is the body of the organ that suffers. Though the disease commences in one testis, both almost invariably at last suffer, either simultaneously or successively. One of the nodulated masses in the affected testis usually gradually increases in size, the skin covering it becomes red, shining, and thinned; and at last adhesion forms between it and the testis, indolent suppuration takes place, and on the discharge of the abscess a fistulous opening is left. Through this aperture a fungus speedily protrudes, which grows sometimes slowly, sometimes rapidly, perhaps attaining a very considerable size (Fig. 509). As the fungus increases, the organ appears to atrophy, but in reality is drawn out of the scrotum and merges into the fungus. This

fungus is not a new growth, but is the tubercle testis and lymph. It

Fig. 204.—Fungous Tubercle in Testis.

granular outgrowth with lymph continuing chronic inflammation, and secreting in the mass. It is, however, this organ a great traversed

2. In testis de enlarging

but uniform and smooth; in fact, an outgrowth of a fungus. In this variety active; and the lowly organised lymph, mixed with debris of the tunica vaginalis, into which it has envelopes of the testis are incorporated.

3. In the third variety of scrofula conjunction with syphilitic sarcocoe being deposited in the midst of a sarcocele.

Treatment.—The treatment of the protruded, must be conducted on the general of scrofula: alternatives, tonics, castor oil, and general hygienic means carefully persevered in for some length of time will consist in the application of discutient iodine lotions, or the iodine.

When the fungus has protruded, means must be taken to repress or destruction of the testis. If it be sprinkled with red oxide of mercury, a piece of lint and strapping. If the surface then dressed with the ointment taken, during cicatrization, to repress the surrounding integument by strapping. It is recommended that the pressure should be an elliptic incision being made round the swelling structure of the testis, it is brought down and then brought over the top. This operation I have practised with large size, so as to include within the organ. On shaving off such a protuberance may be found deeply infiltrated with it is better to remove the whole of any service, and would continue also

SYPHILITIC SARCOCELE, both in its simple and its strumous character, has already been considered at page 545; to which I would refer the reader.

CYSTIC DISEASE OF THE TESTIS, or **CYSTIC SARCOCELE**, may be of two kinds: *simple* or *malignant*. When *simple*, it is a disease somewhat analogous to the cystic sarcoma of the breast. The testis becomes much enlarged, indurated, of a yellowish-white and opaque appearance, and studded with a multitude of cysts that vary in size from a pin's head to a cherry, containing clear amber coloured or brownish fluid (Fig. 510). This affection, consisting in the alteration and condensation of the orchitic structure, with the formation of these distinct independent cysts, must not be confounded with the accidental occurrence of a cyst or two in a serofulous testis. It is a local affection; and, although the organ may attain a considerable bulk, it never gives any indication of malignancy.

Diagnosis.—This affection has been carefully studied by Sir A. Cooper; who, with great justice, adverts to the difficulty of distinguishing it from other diseases of this organ, more especially from *hydrocele*. The points to be especially attended to in distinguishing the cystic sarcocele, are its want of translucency, the more globular shape of the organ, its weight, and the enlarged and varicose state of the veins of the cord. If there be any doubt, an exploratory puncture will resolve this, and should always be practised.

Structure.—According to Curling, cystic disease of the testicle is the result of morbid changes in the ducts of the rete testis. When of an innocent character, the cystic disease is characterised by the presence of tessellated epithelium in the cysts; when malignant, by the presence of nucleated cancer-cells. In addition to this, enchondroma may be met with in both forms of cystic disease; and almost invariably in old cases of the innocent variety.

Treatment—Cystic sarcocele requires removal of the diseased organ.

Cysts containing Coloured Matters.—Occasionally, cystic tumours of the testicle are met with, in which the substance of the organ is atrophied or absorbed, and its place occupied by one or more large thin-walled sacculi containing fluids of different colour and consistence, dark or fatty. One of the most remarkable of these anomalous tumours of the testis that I have seen was under the care of my colleague, Mr. Marshall, at the Hospital. The diseased organ, which was of about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling. After removal, Mr. Marshall found that the sac contained some foetal debris, and was doubtless of an embryonic character. The patient, who was about thirty years of age, had been affected with the tumour from early infancy.

MALIGNANT SARCOCELE, or CANCER OF THE TESTICLE, not unfrequently occurs, and almost invariably assumes the encephaloid character. It is, indeed, a question whether any other form of cancer ever occurs in the testicle. Dr. Walshe agrees with most observers in doubting the existence of the other varieties of malignant disease in this organ.

Fig 510.—Simple Cystic Sarcocele.

spermatic artery and accompanying veins.

The lymphatic glands in the neighbourhood in the iliac fossa especially, as may be ascertained by the flank. The inguinal glands do not in general become implicated by the progress of the disease, but the cancerous cachexy rapidly develops itself.

The *Symptoms* of encephaloid testicle are in the early stages, although they become clearly marked as the disease progresses. The patient first begins to feel a dragging pain and weight in one of the testicles, which is found to be indurated and enlarged, though the enlargement continues until the testicle is as large as a duck's egg, being somewhat tense and firm. As it increases in size, which it usually does, it becomes rounded and somewhat doughy or pulpy in feel, and may almost be semi-fluctuating, though it is not knobby. This alteration in feel is partly due to the nature of the tumour, and partly to its making the scrotum distended, red, and covered by a network of tortuous veins; the scrotum is enlarged, hard, and knobby. As the disease advances, the testicle becomes adherent at some of the softened parts, and projects, which presents all the characters of a cancerous growth. It does not commonly happen, however, that the testicle is so far as this before removal. The pain is not severe, but at a time assumes a lancinating character, extending to the groin.

Treatment.—The only treatment of any value is the removal of the diseased organ. This operation is performed with the view of curing the patient of his disease, and of relieving him from the suffering and inconvenience of the disease.

tised. The operation may be performed in the following way. The patient, having had the pubes shaved, should lie upon his back with the legs and thighs hanging over the end of the table. The surgeon should then take his stand in front of the patient between his legs, and, grasping the tumour at its posterior part with his left hand, make the scrotum in front of it tense. If the mass to be removed be of small size, he makes a longitudinal incision over its anterior surface; if of large size, a double elliptical incision, enclosing a portion of the scrotum. The incision should commence opposite to the external abdominal ring, and be carried rapidly down to the lower part of the scrotum. By a few touches with a broad-bladed scalpel or bistoury, whilst the skin is kept upon the stretch, the tumour is now separated from its scrotal attachments, and merely left connected by the cord, which must then be divided. In some cases, it will be found advantageous to expose and divide the cord in the first instance, before dissecting out the tumour from the scrotum, as in this way a better command over it is obtained.

The *Division of the Cord* constitutes the most important part of the operation, whether this be done first or last; as, unless care be taken, it may be retracted through the abdominal ring into the inguinal canal, where it is extremely difficult to follow it, and where the cut stump may pour out a large and even fatal quantity of blood into the cellular tissue, and between the muscles of the part and into the flank. This accident is prevented by giving an assistant charge of the cord before its division, and directing him to hold it tightly between his finger and thumb (Fig. 511); or, what is better, by passing a sharp hook through it, and thus fixing it. After the removal of the testicle, two or three arteries in the cord will generally require ligature, as well as a few bleeding branches in the scrotum. Sutures are not required, the edges coming into apposition of themselves; the wound must then be lightly dressed, and allowed to heal by granulation; bagging in the lower part being prevented during the after-treatment.

Fig. 511.—Division of the Cord in Castration.

In cancer of the testicle, it is of great consequence to divide the cord as high up as possible, for obvious reasons. It will not, however, be safe to do this opposite the abdominal ring in the way that has just been described, as there would not be sufficient space for the assistant to hold the cord above the part to be divided. In cases of this kind, I have found it a good practice to expose the cord by dissection up to the abdominal ring; then to draw it well down, and to include the whole in a strong whipcord ligature, tied round it as tightly as possible. The section is then made a quarter of an inch below this, and the operation is completed as usual; the cut stump of the cord may retract into the inguinal canal, but cannot bleed if properly tied, and will always be under command by drawing upon the whipcord.

This plan of tying the cord *en masse* was at one time general in all cases of castration, but is not now commonly employed. To it is, that by compressing the spermatic nerves with the after-pan is increased, but this certainly does not always, three instances in which I have done it at the Hospital, but complained of; and the practice in malignant disease of the advantage of enabling the surgeon to divide the cord at a higher point than he otherwise could; which advantage is still further increased by the with in and below the ligature sloughing away, and thus even the section to a level with the point tied.

GENERAL DIAGNOSIS OF SCROTAL TUMOURS

The diagnosis of scrotal tumours is not only of considerable importance, but is often attended with very great difficulty: the more frequently associated with one another, so that much time

Fig. 512.—Encephaloid Testicle with Hydrorachis of the Tunica Vaginalis and of the Cord.

required to discriminate them. Thus it is not uncommon to find a hernia and a hydrocele; or these affections coexisting with a tumour of the testicle. In other cases, as in the annexed figure (512), a tumour may coexist with a hydrocele of the cord.

Tumours of the scrotum, from a diagnostic point of view, be divided into two distinct classes.—1, the Reducible; 2, the Irreducible.

1. REDUCIBLE TUMOURS.—These include the Congenital Hydrocele, Diffuse Swelling of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure.

The patient lying down; reappearing on the removal of the pressure, assuming the erect posture. The mode in which the tumour tends greatly to establish its diagnosis; though the general appearance, swelling, and the history of the case, afford important collateral evidence at this point.

a. In *Hernia* there are the ordinary signs of this affection, as on coughing, &c. On reducing the tumour, it will be found that its return into the abdomen is accompanied by a gurgling noise, and that it slips upwards of evidently a solid body. In the other reductions, the diminution and eventual disappearance under pressure are gradual, and there is no reduction of the mass as a whole.

b. The gradual squeezing out of the contents of a *Congenital Hydrocele* together with its translucency, and the early age at which it is first established, establish its true character.

c. In the *Diffuse Hydrocele of the Cord*, there is an uniform swelling in and near the ring; in which, however, there is no complete and sudden disappearance as in hernia. It is also soft, and has a less distinct impulse on coughing.

d. *Varicocele* may always be distinguished by its pyramidal shape, its knotted, soft, and irregular feel. After being reduced when the patient lies down, it will, when he stands up, fill again, even though

compress the external ring with his fingers. This sign, which distinguishes it from a hernia, occurs also in hydrocele; from which, however, the varicocele may be distinguished by the absence of translucency, the want of fluctuation, and the general feel of the tumour.

2. IRREDUCIBLE SCROTAL TUMOURS are of various kinds; such as Omental Hernia, Hydrocele, Hematocele, the various forms of Sarcocoele, and Cancer of the Testicle. These tumours, though presenting certain characters in common, yet differ somewhat in the predominance of particular signs. Thus, the shape of the tumour is usually pyriform in hydrocele, globular in hematocele, and oval in sarcocoele; though this is subject to much variation. The weight is least in hydrocele and greatest in sarcocoele, proportionately to the size of the tumour. The characters of the surface present considerable differences, being smooth and tense in hydrocele and hematocele; often irregular, hard, or knotted in the other varieties. The rapidity of the formation of the tumour is greatest in hematocele.

a. *Irreducible Scrotal Hernia* may be recognised by its irregular feel, by its impulse on coughing, by its occupation of the canal, and by the testicle being distinctly perceptible below it.

b. *Hydrocele of the Tunica Vaginalis* is always recognisable by its translucency; and the amount of opacity conjoined with this will enable the surgeon to distinguish the degree of enlargement of the testis, and how far there is a sarcocoele conjoined with it.

c. In *Hematocele* the tumour is of sudden or rapid formation, somewhat globular, opaque, but not very heavy or hard, and smooth upon the surface.

d. In *Sarcocoele* generally the tumour is heavy for its size, frequently globular or irregular in shape, sometimes knobbed, and usually attended by a good deal of dragging pain in the groin, and frequently by some enlargement of the cord.

The point of most importance in the diagnosis of sarcocoele is to distinguish the malignant from the non-malignant varieties. In the malignant, the rapidity of the growth, the softness and the elasticity of the tumour, the implication of one testis only, and the early enlargement of the cord, with its indurated and knobbed condition, are important signs; especially if the disease occur in young men. In a more advanced condition, the softening of the swelling at parts with a tuberos condition of the rest, and the occurrence of fungus with speedy constitutional cachexy, will point to the malignant nature of the tumour. In cases of much doubt and difficulty an exploratory puncture may be made, when the contents of the groove in the needle or of the fine cannula will probably determine the character of the growth. In more than one instance, in which there was much obscurity, I have seen the true nature of the disease cleared up in this way.

IMPOTENCE AND SPERMATORRHOEA.

Various forms of debility, of loss of power, or of irregularity of action in the generative organs, are confounded together under the terms *Impotence* and *Spermatorrhœa*. These conditions require a more careful consideration on the part of the educated surgeon than they have hitherto received, as their existence is a source of the greatest mental depression and distress to the sufferer: it is certainly one cause of conjugal infidelity, and occasionally believe, of suicide. These affections, which are of extreme frequency in all classes of the community, but more especially amongst the over-educated, having scarcely as yet received that attention on the part of the profession generally that their importance deserves, the unfortunate sufferers from are too often driven into the hands of those pestilent quacks that do

the metropolis, and infest almost every town in the country, they are not unfrequently ruined in health as well as in part.

We may, I think, recognise at least three distinct varieties of debility and impotence: 1. True Spermatorrhœa, or Seminal modic Spermatorrhœa, or Spermaspasmus; and, 3, that arises from a seminal secretion, or Asperma.

1. TRUE SPERMATORRHŒA, or SEMINAL FLUX, is chiefly met with in men usually from the ages of eighteen to thirty. It is the consequence of masturbation in boyhood, of debility of the system induced by gonorrhœa, or of the continued struggle to resist sexual desires by a life of forced or unavoidable continence. In the disease there is a mixture of irritability and of debility. The genital organs are excited by slight emotional causes, or by trivial physical stimuli—a thought, a look, a word, the movement of the body, the effort of straining at stool, will excite the secretion of semen. In the debilitated state of the parts allows to escape with a feeble effort. In the slighter cases, and in the earlier stages of the disease, the emissions take place but occasionally—three or four times a week, in the morning, in the mid state between waking and sleeping, or by an erection. In the more advanced stages, the emission is more frequent, often in the twenty-four hours without an erection; when discharged, flowing back into the neck of the bladder with each discharge of the urine, or after defecation. The physical and mental state becomes seriously implicated in these cases of spermatorrhœa. His countenance is pallid, anæmic, and sallow; his spirits are drawn; his eyes lifeless; his spirits depressed, often to the verge of despondency and despair. Connection is impracticable, as the emission of semen takes place before erection occurs.

Diagnosis.—This form of spermatorrhœa is apt to be confounded with prostaticorrhœa (p. 1151); but the diagnosis may always be made by microscopic examination of the discharge.

Treatment.—The curative treatment should consist in giving rest, and in lessening the irritability of the genito-urinary organs. This may be obtained by the administration of some preparation of opium, or especially by the habitual daily use of the cold hip-bath. The patient should use every night and morning; remaining in it, at first for three minutes, but gradually increasing the time of immersion to fifteen. In some cases the cold shower-bath appears to give more relief, and then should be preferred. These means, useful as they may be, however, cure the patient. For this purpose, the local irritation should be removed by the application of the nitrate of silver to the bulbous portions of the urethra. It will usually be found that there is a good deal of tenderness in these situations, felt on pressure of the perineum, or on passing an instrument into the urethra, when it enters the bulb, the patient will usually suffer much pain. This irritation certainly keeps up the nocturnal emissions, and the debility of the genital organs, and the nervous irritability characteristic of these cases. It may most effectually be removed by the application of the nitrate of silver, as originally recommended, and, if this be done in a proper manner, a cure will usually be effected. Of late years I have employed, with much advantage in such cases, an instrument here figured (Fig. 513). It consists of a silver rod, about a dozen minute apertures near the end. In the interior of the rod is a slender piece of sponge, about two inches long, fixed to the

of a firm stylet that moves within the catheter. The instrument is charged by filling the sponge with some solution of the nitrate of silver by with-

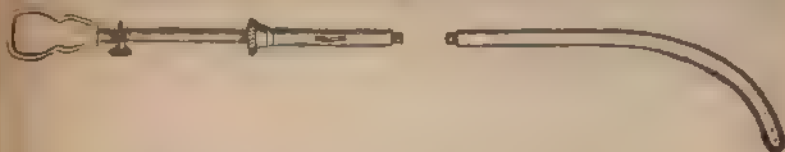

Fig. 513.—Syringe-catheter for applying Caustic to the Urethra.

drawing the stylet. It may then be well oiled; and, being passed down to the spot to be cauterised, the solution is forced out of the aperture by pushing down the rod, which compresses the sponge. I have found this syringe-catheter far safer and more manageable than Lallemand's or any other *parte-cavities* that act by protruding a spoon or sponge, which is apt to be grasped by the spasmodic action of the muscles of the part, often being returned with difficulty into the shaft, and not without risk of lacerating the mucous membrane. I generally use a solution of the strength of $\frac{3j}{\text{ounce}}$ of the nitrate to an ounce of water; though sometimes only a half or a third of this strength can be borne. The application usually occasions a good deal of irritation for a time, sometimes even a muco-purulent discharge, and can only be repeated at intervals of from ten days to a fortnight. Any undue amount of irritation must be subdued by ordinary antiphlogistic treatment.

2. SPASMODIC SPERMATORRHEA, or SPERMASPASMOS, more frequently occurs in men from the ages of twenty-five to forty. It is frequently predisposed to by residence in a warm climate, or by the existence of some disease about the generative organs; such as stricture, varicocele, neuralgia testis, &c. In these cases there is not, properly speaking, a seminal flux; but connection cannot be effected, as erection and ejaculation are either simultaneous acts, or the erection subsides before the emission takes place.

Treatment.—In these cases the treatment that is most beneficial consists in removing or curing, in the first instance, any local irritation that may exist, such as stricture or varicocele, and then endeavouring to give tone to the nervous and muscular structures of the part. For this purpose, I know of no remedy equal to strychnine. This may be given alone, or in combination with iron, 30 minims of the tincture of the sesquichloride with 10 of tincture of nux vomica, or 1-24th of a grain of strychnine with gr. v of citrate of iron twice a day; or gr. j of the extract of nux vomica in a pill with reduced iron, will be found of the greatest possible service in such cases. The irritability of the nervous system, which is associated with debility in these cases, is best remedied by the administration every night of a belladonna and camphor pill. In addition to this, local cold bathing, regular exercise, and absence of all exhausting mental labour, will be found of much service.

3. IMPOTENCE arising from absence of all sexual desire or power, or from premature decay of that power, is not unfrequently met with, and often in individuals who are otherwise strong and healthy; sometimes, indeed, in those characterized by great muscular power, and much given to athletic exercises. This want of sexual desire may be looked upon in many instances as a natural deficiency in the organisation of the individual, for which medical or surgical treatment can do little. In other cases, it arises from exhaustion of the nervous system by habitual physical exertion, carried to a too great and injurious degree. Complete absence of seminal secretion—*Asperma*—except in cases of atrophy or absence of the testes, must be

especially rare. In a patient of mine who died at 54 years of age according to his own and his wife's account, had been completely sterile for the twenty-four preceding years, spermatozoa in considerable numbers were after death found in the testes, which were carefully examined with a view of ascertaining whether they ever secreted semen.

CHAPTER LXXII.

DISEASES OF THE FEMALE GENITAL ORGANS.

SOME of the more important surgical affections of these organs, viz. vagino-vesical and recto-vaginal fistulae, lacerated perineum, and other forms of syphilitic disease to which they are liable, have already been discussed. The remaining affections, implicating the Vagina, the Ovaries, are of considerable practical interest; but, as the details of their treatment would lead me far beyond the limits that can be assigned in this work, I must content myself with a brief indication of the points deserving attention.

INTRODUCTION OF INSTRUMENTS.

SPECULUM VAGINÆ.—Vaginal specula of various shapes and

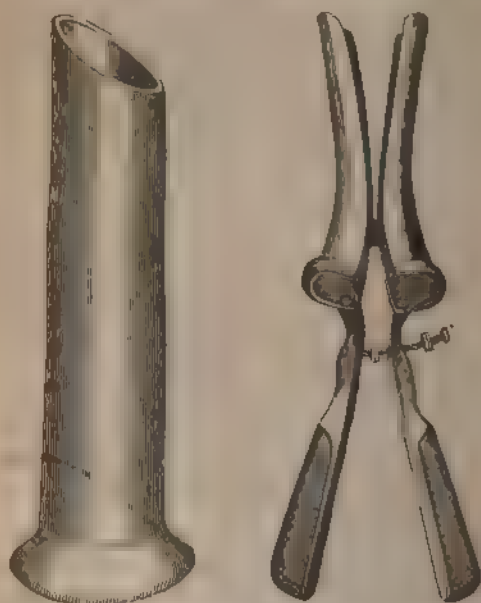

Fig. 514.—Cylindrical Speculum. Fig. 515.—Bivalve Speculum. Fig. 516.—Duck-bill Speculum. commonly used by surgeons. When the os and cervix of the uterus are to be explored, the most convenient instrument is certainly the reflecting glass speculum (Fig. 514); which, being coated with tinfoil, covered by India rubber, always presents internal reflecting surfaces, by which a strong body of light is thrown into the

the tube. It has the additional advantage of being very cleanly, and not stained by any caustics that may be used in it. These specula should be of different sizes, and may be sometimes advantageously bevelled off at the inner end. When the wall of the vagina requires examination, as in some operations on fistula, a bivalve speculum (Fig. 515), a cylindrical one, provided with a sliding side, or the "duck-billed" speculum (Fig. 516) may advantageously be used. These are generally made of plated metal.

Introduction of the Speculum may readily be effected, without any exposure of the person, under the dress or bed-clothes. There are two positions in which the patient may conveniently be placed for this purpose. In the first, she lies upon her back, with the nates well raised or brought to the edge of the bed or couch, her legs separated, and her feet resting on two chairs; the surgeon, standing or sitting in front of the patient, introduces the fore and middle fingers of his left hand into the vagina, dilates its walls, and passes the speculum, well greased, gently and steadily between and under them. This position is the most convenient when caustics require to be applied, but is often objectionable to the patient, as it appears to entail much exposure, though in reality it need not do so. Another mode of introducing the speculum, which should always be adopted when practicable, consists in placing the patient on her left side across the bed, with the knees drawn up, and the nates near the edge; the instrument is then introduced in the same way as before, the surgeon sitting by the patient's side. In whichever way the speculum is used, no force should ever be employed; the patient should be placed opposite a good light, and care should be taken that the instrument be introduced fairly to the uterus, the position of which may have been previously ascertained by tactile examination.

FEMALE CATHETER.—The use of the female catheter is often required in various diseases and operative procedures about the genito-urinary organs of women. It should be introduced without exposure, by the aid of the touch alone. This may readily be done, as the patient lies in bed, under the clothes. The surgeon, standing on her left side, passes his left index finger downwards between the nymphæ until he feels the projection of the meatus urinarius, immediately above the entrance into the vagina; keeping his finger just below this, he uses it as a guide to direct the point of the catheter into the canal.

DISEASES OF THE EXTERNAL ORGANS AND VAGINA.

The vulva and the nymphæ are the seats of numerous morbid conditions, principally consisting of hypertrophy or of verrucous growths from them, or the formation of cysts in their substance.

HYPERTROPHY OF THE LABIA to a limited extent is not unfrequently met with, one labium hanging down considerably below the other. In these cases, it will often be found that the enlargement is due to a kind of solid œdema, originally dependent perhaps upon a fissure or ulcer of the part. In other cases, large fibro-cellular tumours form as outgrowths from the natural structures in this region; these may require removal by simple excision.

LARGE CONDYLOMATA or **VERRUCÆ** are often met with here, as the result of gonorrhœal or syphilitic disease, forming at last irregular pendulous masses, which require extirpation, either by knife or scissors. I have had occasion also to remove a large *Narus* by ligature from this situation; and, in fact, almost any growth that occurs in the fibro-cellular tissue may be met with here.

CYSTIC TUMOURS are not unfrequently met with in the sometimes resemble rather closely the ordinary form of it with which, however, their incompressibility, irremovability, of impulse on coughing, will prevent their being confounded, which require removal by a little simple dissection, usually turbid, or sanguinous fluid, and sometimes atheromatous and free hemorrhage may follow their removal, the excitable tissue being cut into. This may, however, always be arrested by T-baudage. Occasionally they project from the inside of the then require removal by dissection or ligature, as can be seen.

IMPERFORATE VAGINA is occasionally met with in young occasions a good deal of anxiety to the parents. This could may always be very readily and speedily removed by tearing, as it were, by dragging open its walls in opposite directions through the adhesions, which are little more than epithelial, nail, a blunt probe, or the handle of a scalpel, and then with pledget of greased lint.

IMPERFORATE HYMEN is occasionally met with, causing pain, and even danger, by the retention of the menses, which may accumulate to an immense extent, and become covered of chocolate-coloured grumous fluid. This malformation does not attract attention until the age of seventeen or eighteen. When the flux has, however, not appeared, notwithstanding periodical disturbance, an examination is instituted, and the cause of it is revealed. In these cases the hymen, which forms a dense membrane, is pushed down between the vulva, and the accumulation may sometimes be felt as an elastic fluctuating tumour above in the iliac fossa.

The *Treatment* consists in puncturing the hymen with a tenaculum, the opening with a probe pointed bistoury, and thus discharging the fluid, which may be in very large quantity. This operation is usually attended by danger. Suppuration of the exposed cavity may come on, ending in the patient's death. In opening it, it need scarcely be said that wounds of the urethra should be avoided; and, with care, that canal may always be avoided. I ever, seen one case in which it had been slit up by the surgeon, and the membrane.

Occasionally the surgeon's advice may be sought by married women, who are *right and only partially perforate hymen*; when incision with the bistoury, and dilatation with a sponge tent may be required; however, is possible, even though the hymen be not ruptured. It may be necessary during parturition actually to complete the opening of the membrane, if thickened and unruptured, though in most cases it may pass away under the pressure of the foetal head.

ABSENCE OF THE UTERUS AND OVARIES, with imperforate hymen, is occasionally met with in women, otherwise perfectly well, the external organs of generation, labia, and nymphæ being perfectly developed. In such cases, it is remarkable that sexual intercourse exists. The true condition may, however, be detected by examining the rectum, and especially by the introduction of a catheter into the rectum, whilst the finger is in the vagina, when the two cavities will be found in close apposition without the intervention of uterus or ovaries. In cases of this kind in which I have been consulted, there had

epistaxis. No surgical interference can be of any avail in such cases ; and an attempt to restore the vagina would necessarily lead to fatal results by opening the peritoneal cavity. Occasionally, if the woman have been married, the fruitless attempt at coition on the part of the husband has caused dilatation and expansion of the urethral orifice to such an extent that the index finger may be introduced into the cavity of the bladder ; and I have known this expanded urethra mistaken for the vaginal aperture, coitus effected into it, and the existence of the malformation for a time completely overlooked. *Simultaneous* vesical and rectal exploration will always clear up the true nature of the case.

HYPERTROPHY OF THE CLITORIS is occasionally met with ; this organ becoming enlarged, elongated, and pendulous, and in some cases attaining an enormous size. When the clitoris is enlarged, it may give rise to a good deal of irritation, and require excision, an operation that would probably be followed by rather troublesome hemorrhage.

Removal of the Clitoris, even though not much enlarged, has of late years been recommended as a means of cure in some forms of erotomania. I performed the operation for this purpose on a patient of Dr. Horsburgh's, and found some difficulty in stopping the bleeding, which at last required the application of the actual cautery before it could be arrested. The operation was, I believe, followed by marked improvement in the young lady's mental condition.

TUMOURS of various kinds are met with in the interior of the vagina, springing from its walls. These may be of a *Cystic* character ; but occasionally true *Mucous Polypi* are found dependent and projecting from the side of this canal. These may most readily be removed by trussing their base by a double whipcord ligature, and then strangling it. In performing this operation, however, when the tumour grows from the posterior wall, care must be taken to ascertain by proper digital examination, that a portion of the rectum has not been dragged down into its base.

PROLAPUS of the anterior or the posterior wall of the vagina may occur, giving rise, in the first instance, to protrusion of the bladder or *Cystocele* ; in the other, to a *Rectocele*. In either case, but especially in the first, it occasions very serious and troublesome consequences, amongst which chronic irritation of the mucous membrane of the bladder, with perhaps phosphatic deposits in the urine, are the most marked. These protrusions may be supported by the use of properly constructed belts or pessaries.

In some cases the surgeon may feel disposed to undertake plastic operations, in order to narrow the vaginal orifice by freely paring the opposite portions of its walls, bringing together the freshened surfaces by means of the quilled suture, and thus procuring narrowing of the canal and permanent support to the protruded part. The success of such operative proceedings will greatly depend on attention to details. The mucous membrane at the orifice of the vagina should be dissected off from about half an inch below the meatus on one side, to a corresponding part on the other, in a strip about an inch and a half wide ; the dissection being carried well up posteriorly in the fourchette. Two or three deep, and as many superficial, sutures should be passed ; the deep being left in for about five, the superficial for seven, days. Great attention should be paid to cleanliness, the patient lying on her side with a catheter in the bladder communicating with an India-rubber tube to carry off the urine ; and the bowels should be confined by opium.

VARIOUS DISCHARGES connected with the female organs of generation fall under the observation of the surgeon ; these may occur from the external

organs, from the mucous membrane covering the cervix uteri, or the interior of the cavity of that organ. These discharges, when proceeding from the mucous membrane covering the external organ, or lining the vagina, are frequently, though not necessarily, of a gonorrhoeal character; and require to be treated in the way that has been mentioned at page 1227. When they are of a simple nature, proceeding from mere hyperæmia of these parts, astringent injections, and attention to the general health, usually succeed in effecting a cure.

When these discharges proceed from the cervix or the interior of the uteri, they will commonly be found to be dependent upon a chronic inflammation or congested condition of the organ, or upon a papillated, fissured, or ulcerated condition of the mucous membrane, often accompanied with more or less local thickening and induration of subjacent structures. These various conditions, often of a very persistent, insidious, and dangerous character, have of late years been fully recognised by the labours of the French surgeons, more particularly of Lisfranc, Einery, and Jobert. In this country their pathology has been greatly elucidated by Dr. Bennet. To Dr. Bennet especially is due the great credit of having pointed out the true pathology of various uterine diseases that were previously imperfectly recognised, and of having shown that many of the functional diseases of the uterus are in reality dependent on chronic inflammation, and other structural lesions of this organ.

Symptoms. These uterine discharges, occurring usually as the result of chronic inflammation and its consequences, just as we find on other surfaces, as those of the urethra, throat, or eyelids, are attended by symptoms indicative of local distress; such as pain in the back and in the groin, and more especially in the left groin, with dysmenorrhœa, and much sympathy with constitutional irritation, terminating in impatience, malnutrition, and anemia. It is in this condition of the system that many of the so-called hysterical affections are so apt to arise, and the will often find that the most inveterate cases of neuralgia of the face, of the spine, the hip, or the breasts, and of amaurotic and other obscure affections connected with nervous irritation, are primarily dependent on chronic disease of the uterus; and it is only by attacking and removing this, that he will be able to remove the secondary mischief. On examining the condition of the cervix uteri in these cases by means of the speculum, various morbid changes may be observed in them; the cervix is perhaps thickened, indurated, or inflamed on one side; the os is frequently patulous; and the mucous membrane lining these parts will be observed to be erythematous, congested, and excoriated, not unfrequently in a granular condition, closely resembling what may be observed in some forms of granular conjunctivitis. In some cases, again, true ulceration may exist both upon the cervix and within the os. These ulcers, abrasions, excoriations, or by whatever term they may be designated, are unquestionably a fruitful source of mischief in this disease, giving rise to considerable thickening of subjacent structures, and to abundant mucopurulent discharge and much sympathetic constitutional irritation. In their character, they closely resemble corresponding forms of disease met with on the mucous surface in other situations, not attended by loss of structure, but by the development of small pointed granulations or papule, from which the discharge is poured forth.

The Treatment of these various affections of the uterus has been much simplified since their pathology has been better understood, and practitioners are now generally agreed as to the necessity of the employment of local measures for the removal of these morbid states. To the various

is in the habit of managing local disease on other mucous surfaces, and of removing the structural lesions that result from chronic inflammation in other organs, the treatment of these cases can present little difficulty, as it is conducted on precisely the same principles that guide him in the management of similar affections elsewhere.

The employment of caustics is of essential service in these various forms of chronic uterine disease. In cases of simple ulceration or excoriation, the nitrate of silver in stick, applied every third or fourth day, will frequently be found to effect a speedy cure. For this purpose, the hinge caustic-holder will be found an useful instrument (Fig. 517). If there be much chronic

Fig. 517.—Caustic holder.

induration, conjoined with the affection of the mucous membrane, the potassa cum calce, fused into narrow sticks, may very advantageously be used. In doing this, however, care must of course be taken that the cauterising action do not extend too far. Hence the surgeon, after lightly touching the diseased part, whether this be on the cervix or inside the os, should immediately inject some weak vinegar and water, so as to neutralise the alkali. After these applications, which should only be repeated at lengthened intervals, the patient must be kept quiet for some time; and any inflammatory symptoms that may be excited must be combated in the usual way, it very rarely happens, however, that anything untoward will result.

After the removal of the local disease in the way pointed out, any remaining congestion may be got rid of by the application of leeches to the cervix. During the time when these local measures are being adopted, recourse must be had to proper constitutional treatment, with the view of improving the general health on ordinary medical principles. The details of this treatment need not be given here; but for a full exposition of them, as well as for a vast deal of important information on the surgical management of uterine affections, I would refer the reader to the last edition of Dr. H. Bennet's work on the Uterus.

UTERINE DISPLACEMENT.—The various displacements to which the uterus is liable, whether downwards, constituting *Prolapsus*, or in the direction of the axis, being twisted, and either *Retroverted* or *Anteverted*, are causes of much local suffering and constitutional disturbance, and commonly require surgical treatment. These various conditions will frequently be found dependent on inflammatory congestion of the fundus, in consequence of which the organ becomes, as it were, top-heavy, and is tilted to one side, or descends bodily in the pelvis.

The *Treatment* in such circumstances must have reference to the removal of the local turgescence by the application of leeches, the employment of astringents, hip-baths, and the recumbent position; occasionally assisted perhaps, in twist of the organ, by attempts at replacing it by introducing the uterine sound into its cavity, or, when it is prolapsed, by supporting it with appropriate pessaries and the abdominal bandage.

VAGINAL DISCHARGES of a purulent character not unfrequently occur in young female children, as the result of constitutional debility or strumous derangement. Occasionally such discharges lead to the suspicion of the child having been improperly tampered with; and, although they might of course be occasioned by some violence inflicted on the genitals, or even from gonor-

rheal infection, it must be borne in mind that, in the great instances, they certainly arise from constitutional conditions solely in no way referable to external causes. The *Treatment* consists in cleanliness, the use of warm lead lotions, and the improvement of general health.

TUMOURS OF THE UTERUS are of various kinds. The most common are those of a *Fibrous* character. These are often of considerable size, have been found weighing many pounds; they may occupy almost any part of the uterus, either projecting into the peritoneal cavity, occupying the whole of the organ, or dependent into the vagina. These tumours seldom occur in the age of thirty or forty, and are not very amenable to *Treatment*. In some cases, however, considerable benefit results from attention to general health, occasional application of leeches to the cervix, so as to lessen the tension of the organ, and the introduction into the vagina every night of a tampon composed of equal parts of strong mercurial ointment, wax, and lard, containing iodine or the iodide of lead, with the view of acting as an absorbent on the morbid tissue.

Polypi are not unfrequently met with, growing from the inner surface of the uterus, usually from its posterior aspect or fundus. They are generally oval or pyriform, smooth, hard, and insensible, and are attended by repeated hemorrhage; and it is a remarkable fact that in many of the most violent bleeding proceeds from the smallest tumours. In some of the tumours of the uterus are of a soft fibro-cellular, vesicular, or spongy character, attended, like the harder ones, by free hemorrhage.

The *Treatment* of polypi of the uterus is best conducted by ligature of the pedicle. This may usually be readily enough effected by means of a suture or ligature applied by Gooch's double cannula, which has been variously modified, and a good deal improved by different surgeons. The ligature gradually tightens, and usually cuts its way through in from ten to fifteen days; the tumour swells, and decomposes often with a good deal of discharge, which requires to be carefully syringed away by means of chlorinated lotions. It is an useful precaution, not to apply the ligature near the uterine end of the pedicle; as cases have occurred in which, in so doing, the surgeon has given rise to serious and even fatal inflammation of the womb. Any portion of pedicle that is left will gradually be absorbed.

Cauliflower Excrescence from the uterus, attended by copious hemorrhage, is a rare and dangerous affection. The only *Treatment* that is to be of any avail, is to draw down the neck of the uterus by a vulsellum, and then to excise the tumour with the surface of the scalpel. This operation is not attended by any very serious hemorrhage, and succeeds in ridding the patient effectually of her disease.

Malignant Affections of the Uterus usually commence in the form of a scirrhous tubercle or ulceration of the cervix, attended by the usual constitutional symptoms of this affection; there is much offensive discharge, and cancerous cachexy speedily sets in.

The *Treatment* of these cases must be of a purely palliative character, consisting in the administration of opiates and the use of chlorinated lotions, the latter principally relied on. Excision of the diseased cervix has been recommended, and was formerly a good deal practised; but this is a barbarous and contrary to every principle of good surgery, as it is impossible to cure a patient of scirrhous disease by the partial removal of the affected part. Its complete extirpation cannot be thought of. Tumours, however, of a simple character requiring removal are occasionally met with springing from the cervix.

the cervix; they may be excised by putting the patient in the position for lithotomy, drawing the uterus well down with forceps, and removing them with the knife. This has been done during pregnancy, and even during parturition, with good effects.

OVARIAN TUMOURS AND DROPSY.

Ovarian tumours of a cystic character are commonly met with. The cysts may be uni- or multi-locular, and vary greatly in the nature of their contents. These may be either solid or fluid—often a combination of the two. If fluid, the liquid is usually more or less viscid, albuminous, dark and variously coloured. Ovarian tumour invariably ends fatally; in some cases rapidly, in most gradually, occupying many years in its course.

DIAGNOSIS.—It is not my intention to enter into the difficult subject of the diagnosis of ovarian tumours. From pregnancy, ascites, tumours of the uterus and omentum, enlargements of the liver, kidney, spleen, and stomach, hydratids, hysterical tympanitis, fat in the omentum, stercoraceous accumulations, distension of the bladder, spinal curvature, abdominal and pelvic abscesses, the diagnosis has carefully to be made; and that this is a matter of no slight difficulty, is evident from the numerous cases in which errors have happened and are constantly occurring to most experienced practitioners. It is impossible for the surgeon to be too cautious in effecting a diagnosis before he proceeds to open the abdominal cavity in any supposed case of ovarian disease. There is, however, one form of disease that so closely resembles an ovarian cyst, that I may refer to it; it is a *dilated state of the Fallopian tube, containing fluid*—in fact, dropsy of that tube. This condition may generally be recognised by the tumour being of moderate size, wholly fluid, having deep pelvic adhesions, displacing the uterus and bladder, and drawing up the vagina into a pouch. The displacement is often very remarkable and considerable. I have seen the bladder flattened out and drawn up as high as the umbilicus—the top of the vagina above the pubes. In these cases, the abdominal wall is not so much thinned and expanded as in true ovarian disease. The tumour, which cannot of course be extirpated, is never pediculated.

TREATMENT.—The treatment of ovarian tumour may be conducted:—1, by Medical Means; 2, by Tapping; 3, by Tapping, conjoined with Auxiliary Measures; 4, by Injection; 5, by Extirpation.

1. MEDICAL MEANS exercise no influence in curing ovarian tumours, and but little, if any, in retarding their progress. Specific treatment by means of mercury or iodine has always appeared to me to hasten the progress of the malady, by breaking down the constitutional powers of the patient; and attempts at promoting the absorption of the fluid by purgatives, diuretics, &c., are invariably unsuccessful. An ovarian cyst is a parasitic growth, the tissues of which are not influenced to increased power of absorption by the action of deobstruents on the system generally. The utmost that can be done by medical means in such cases is, to attend to the general health and to support the patient's strength by tonics.

2. TAPPING in ovarian dropsy may be done as for ascites, through the linea alba; but not unfrequently the tumour presents more distinctly at some other part of the abdominal wall, and may be emptied through the linea semilunaris; or, if multilocular, it may require the trochar to be inserted at different points into its separate compartments. The paracentesis of ovarian cysts should, unless the disease be very acute, always be deferred as long as is compatible with the comfort of the patient; as it is not only followed by speedy reaccumulation of the fluid, and often by rapid exhaustion, few patients surviving the first operation more than three or four years; but is

attended by certain special danger, exhaustion, or possibly even of the small intestine, which is sometimes ovarian cyst, and may be met with.

3. TAPPING, CONJOINED WITH A CAUTERY, has succeeded in effecting a cure of the various kinds:—firm pressure; incision of its wall, plugging the aperture in the catheter or tube; the establishment of a communication with the interior of the cyst, either through the vagina, have all been adopted. Much these different procedures rest on one principle; viz., that of causing the rupture and the cohesion of its walls—a principle applicable to unilocular cysts, and has been successful in a number of cases, and those the same means can be looked upon as concerned. By means of them the cyst collapses and contract. But secondly, the base, and whose development has been arrested, and absorption of nutrition by the cyst, when this has been reduced in size, the tumour may be substituted for an

4. INJECTION OF TINCTURE OF IODINE, has been employed both in this country and abroad. It has been tapped, from four to six ounces, and through a catheter passed down the vagina. The effect of this injection is the contraction of the cyst, the effusion of plastic matter with the cyst, and disturbance follows; in others, a violent iodism, the urine and saliva become loaded with iodine; in others again, suppuration of the cyst follows. This method of treatment is only applicable to unilocular cysts: and in them it must be looked upon as a temporary measure—the cyst collapsing, and the tumour being removed.

5. OVARIOTOMY.—Ovarian cysts have been removed on account of their large size and the danger to life by them, or from their rapid growth, and the want of a speedy extinction of life. To the merit of having introduced and performed this operation was first proposed by John Bell, and was first performed in Kentucky. The first operation was done by Lizars, in 1823. From that time to the present it has, after various fluctuations in its estimation, as an established surgical operation, been performed by Spencer Wells, and Tyler Smith. Amongst practitioners as to the propriety of the operation has been chiefly condemned on two grounds:—first, that it is not compatible with long life, it is not a safe procedure for its removal; and, secondly, that it is so high as not to justify a surgical

With regard to the first objection, it may be stated that ovarian disease is attended by very great discomfort and inconvenience in all cases; that it prevents a woman from discharging the active duties of life, and, amongst the poorer classes, from obtaining a livelihood; and that, so far from being a comparatively innocuous affection, it wastes and enfeebles the patient, interfering seriously with nutrition, and with the actions of the abdominal or pelvic organs, and is not generally compatible with prolonged existence. Dr. Lee states that about 80 per cent. of the cases that are not operated upon, die within one year and three quarters after the appearance of the disease. When it grows rapidly, or so soon as it attains such a size as to require tapping, death takes place much more quickly. Mr. Safford Lee states that of 46 patients with ovarian disease, who were tapped, 37 died, and only 9 recovered; and that of the 37 who died, more than one-half did so in four months from the first tapping, and 27 out of the 37 within a twelvemonth, and of these 18 were tapped once only. In those who survive, repeated tapplings are required at constantly decreasing intervals.

The second objection can have little weight with any practical surgeon. The mortality after ovariectomy is not so high as that after many operations, which no surgeon would hesitate for a moment in performing. It is true that in some of these cases, as in the ligation of the larger arteries for aneurism, speedy death would be the penalty of non-interference; whereas, in ovarian disease, a miserable existence may be protracted for some months after the tumour has attained so great a bulk as to render surgical aid necessary. But in other surgical diseases in which operations of the gravest character are performed without hesitation, as in the removal of the upper jaw for tumour, or in amputation at the hip-joint for tumours of the femur, the same objection would hold good. The diseases for which these great and dangerous operations are performed, are not incompatible with some months or even years of painful existence; yet the surgeon does not hesitate to give the patient the chance of a doubtful recovery, in order to extricate him from the miseries of prolonged suffering. It is not necessary, in order to justify an operation even of a dangerous character, that the patient be in immediate peril of death. It is sufficient that the death from the disease which it is proposed to remove should ultimately be certain, though it may be delayed by months or years of previous suffering. From this point of view Ovariectomy appears to me to be a perfectly proper and justifiable operation, and it presents the advantage of the cure, if practised, being complete and permanent. In it there is no mean; the death is speedy, or the cure complete.

Mr. John Clay of Birmingham, in the appendix to his translation of Kiwisch's *Chapters on Disease of the Ovaries*, has collected from various sources the particulars of 567 cases. Of these, the operation was completed by the removal of the entire ovarian tumour in 425, or about three-fourths; the mortality being 183, or about 43 per cent. In 24 cases, the tumour was only partially removed; of these 14 died. In 13 cases, extra-ovarian (mostly uterine) tumours were removed; the mortality here amounted to 10. Of 105 cases in which the operation was abandoned, there were adhesions in 83; and in 23 the disease was mostly extra-ovarian, while in a few no tumour was found. Amongst these 105 abandoned cases, 27 died. The results of ovariectomy in the hands of those who have most extensively practised it of late years—as Baker Brown, Tyler Smith, and Spencer Wells—is, however, even more favourable than these.

The mortality after ovariectomy appears to be increased by the existence of adhesions. When these complicated the operation, in those cases in which

the ovarian tumour was completely removed, 49 per cent. of the cases when they did not exist, 32 per cent. were fatal.

When we compare these returns, not only with the mortality which follows operations of immediate urgency—as primary amputation of the limb for injury—but with that which attends great operations for disease which might be palliated and in which existence might be protracted for a little time—as amputation at the hip-joint for tumour, or the division of the innominate and subclavian arteries for aneurism, or even the extraction of vesical calculus of large size by lithotomy in the female, we cannot consider the mortality after ovariectomy so great as to influence the performance of the operation, if other circumstances justify it.

It has further been objected to Ovariectomy, that it has not unfrequently happened that, after the operation has been commenced, it has been impossible to complete it, owing to the existence of adhesions between the tumour and the contents of the abdomen. This objection is certainly well founded; but I believe that, with care in examining the tumour, and ascertaining its mobility during respiration, the existence or absence of such adhesions, the position of the abdominal wall during the respiratory movements, the free connection with the uterus, as determined by finding that organ by the introduction of the uterine sound, and the previous non-existence of peritonitis, this mistake is not now so likely to happen as formerly, and the liability to it was not suspected.

OPERATION.—On the day preceding the operation a dose of castor-oil should be administered, and on the morning of it an enema, so that the bowels may be completely emptied. The room having been warmed to a temperature of at least 70° F., chloroform administered, and the patient emptied by the catheter, the patient must be placed upon a table with blankets, in such a way that the legs hang over the end of the table, and the abdomen is fairly and evenly exposed. The surgeon, taking care between the patient's legs, makes an incision, usually about six inches in length, from the umbilicus downwards, directly in the middle. With a few touches of the knife, the structures, which are usually much adherent, are divided along the linea alba, and the abdominal cavity is opened.

There has been much discussion as to the length to which the abdominal wall should be made; some practitioners recommending that this should be of very limited extent, others that it should reach ensiform cartilage to the pubes. No definite rule can be laid down at this point. The incision must be proportioned in extent to the nature of the tumour, and the existence or absence of adhesions. If the tumour be cystic and unilocular, and not adherent, it may be readily extracted by making an incision only an inch or two in length in the middle, tapping it through this, and then drawing the emptied cyst for the means of a vulsellum. If, on the other hand, the ovarian growth be solid, a larger incision, from four to six inches in extent, will be necessary. Should adhesions exist, it may even be necessary to go beyond the umbilicus. I cannot believe that it is ever necessary to rip up the abdominal wall from the sternum to the pubes, for the removal of any tumour, however adherent. In making this incision, the surgeon must be careful to divide the peritoneum fairly, and not to mistake it for the cyst-wall, and to cut off the abdominal muscles.

The tumour now comes into view; if cystic, it must be tapped with a long trocar, and the fluid evacuated. Especial care should be taken not to allow this viscid ovarian fluid to escape into and flood the abdominal and pelvic cavities. This may often be avoided by conducting

from the patient, by means of a vulcanised India rubber tube attached to the cannula. In this way, the size of the tumour may be so much lessened as to admit of its more ready extraction. If cystic, and emptied, it may now perhaps be drawn out through the incision in the abdominal wall without further difficulty. If it be solid, or if there be any adhesions, the surgeon must introduce his hand, and by sweeping it round the tumour assist in removing the mass. The chief difficulty in the operation will consist in the presence of adhesions. Should none exist, nothing can be simpler than the extraction of the tumour, which has a tendency to protrude forwards into the wound. Should they be slight and confined to its anterior part attaching this to the abdominal wall, they may readily enough be broken through by the hand being swept round the forepart of the tumour. If they be firm, deep, and extensive, then the real difficulty of the operation will have to be encountered. It is, however, important to observe that adhesions of this kind will chiefly be found at the anterior part, between the tumour and the abdominal wall; comparatively seldom posteriorly, or connected with any of the abdominal viscera, except the uterus. If possible, these adhesions should not be cut across, as they often contain vessels that would bleed freely if so divided; but they should rather be torn—no slight force occasionally being required to detach them. Should the tumour be so closely adherent to any viscus that its separation is attended with danger, it might be safer to cut across the cyst-wall, and leave the adherent portion of this, than to run the risk of laceration of the liver or intestine. During the withdrawal or protrusion of the mass from the abdomen, an assistant on each side must press gently upon the sides of the incision with the hands or with soft napkins, so as to prevent the protrusion of the intestines, which, if possible, should not be seen during the operation. The tendency to intestinal protrusion sometimes occasions considerable trouble; especially if the patient have taken chloroform and begun to vomit, when it may be necessary to discontinue the operation for a time.

The separation of the pedicle is the next step, and perhaps the most important one in the operation. In order to do this securely, some surgeons fix the pedicle by means of a clamp, and then cut it across above this instrument. To this there can be no objection, if the pedicle be long and narrow; but if it be short and thick, great inconvenience may result by the clamp either being drawn down into the pelvic cavity, or the pedicle and pelvic organs being drawn upwards to a painful and perhaps dangerous extent. I prefer tying with a whipcord ligature. This may best be done by drawing the tumour well forwards, transfixing the pedicle with a *navus*-needle carrying a strong whipcord ligature, tying this firmly on each side, and then cutting it across above the constricted portion. In doing all this, a few points require attention. Care should be taken that the needle does not transfix any large artery or vein. This may generally be avoided by spreading out or unravelling, as it were, the pedicle, and examining its structure before passing the ligature. After it has been transixed, and before the cord is tied, it is well to dissect off that portion of the peritoneal investment of the pedicle which corresponds to the line that will be constricted by the ligature. In doing this, great care must, however, be taken not to wound the vessels, especially the veins, which are very thin-walled. In this way there will, I think, be less risk of peritonitis, as there is less chance of any slough of the pedicle falling into the peritoneum, and I attribute to the adoption of this precaution much of the success that attended the removal of an ovarian tumour, partly solid and partly cystic, weighing about fifteen pounds, which I extracted from a lady, sixty-five years of age.

After its ligature, the pedicle shows the part tied. If it be cut across near the stump retracting under it, and caused 16 per cent. of the deaths after.

The next point in connection with of the peritoneal cavity, so that always has a tendency to do, and in presence of the ligatures and results look upon this fixing of the pedicle as of the most important steps of the more immediately depends than on a convenient way to fix it is to close the minimal wall by a hare-lip pin passed at an angle, and, drawing the stump of, through this, to retain it there in which it has been tied, in the usual this way it cannot possibly be retracted the slough or ligature falling into the

The incision in the abdomen made from within outwards, or by a series of lip to the other, at intervals of 1/2 inch. Pins should be passed deeply, not only through the integuments and muscles, but also through the sutures are passed round these in the same way to pin. In this way the whole line is supported. The abdominal wall must be covered with long slips of plaster, and a laced napkin.

Should it unfortunately be found that adhesions exist, so close and extensive, the wound in the abdominal wall must be treated as in the successful

The *after-treatment* of the case is very different although it presents nothing of a very serious nature. The management of ordinary abdominal inflammation is headed are from peritonitis, exhaustion, and shock. Peritonitis requires to be more carefully treated: of 150 fatal cases, it caused 100 per cent. The patient should be kept in bed. Nothing but ice and barley- or Seltzer water should be allowed for several days; and opium should be given in sufficient and repeated doses to relieve him by it. The urine must be drawn off by catheter. The bowels should be left unrelieved, and merely opened by an enema. As in the case of the whole of this time, little inconvenience is caused. Should a strangulated hernia be present, the patient must be kept up by the irritable state of the stomach with

After recovery from ovariectomy, the disease, even when colloid, is cured through the medium of the ovary and is accomplished.
